Distally, the interval between the flexor carpi ulnaris and the extensor carpi ulnaris occurs along the subcutaneous border of the ulna.
TECH FIG 9 • Surface anatomy and incision for the ulnar shaft. A, ulnar head and styloid; B, subcutaneous border of ulna.

- Both muscles can be raised volarily and dorsally off the ulna, respectively, in a subperiosteal fashion.
- The ulnar artery and nerve travel deep and radial to the flexor carpi ulnaris. The nerve is protected by careful subperiosteal elevation of the flexor carpi ulnaris.

PEARLS AND PITFALLS

Approach to the interphalangeal joints (proximal and distal)

- Protect the germinal matrix and terminal tendon at the base of the distal phalanx.
- Protect the central slip at the base of the middle phalanx.

Approach to the metacarpophalangeal joints

- If necessary, release the ulnar sagittal band at the joint. Avoid releasing the radial sagittal band.

Approach to the carpal tunnel

- Protect branches of the palmar cutaneous branch of the median and ulnar nerves in the subcutaneous tissue by centering the incision in the interthenar eminence.
- Remain vigilant for a transligamentous recurrent motor branch of the median nerve.

Volar approach to the radius

- Dissection should not drift ulnar to the flexor carpi radialis tendon to protect the median nerve and its cutaneous branches.

Dorsal approach to the radius

- The posterior interosseous nerve ends at the level of the wrist dorsally in line with the fourth metacarpal and is easily approached for denervation for postoperative pain relief.

ORTHOPAEDIC SURGERY MAKES UP A CONSIDERABLE PORTION OF THE 70% OF PROCEDURES DONE ON AN AMBULATORY BASIS IN THE UNITED STATES.9

Several factors have fueled this growth in outpatient orthopaedic surgery, including less invasive surgical approaches, changes in practice patterns, and the introduction of anesthetic agents associated with fewer postoperative side effects.

Percutaneous pain management represents a particular challenge with ambulatory surgery, as 40% of patients experience severe pain despite treatment.5

Regional anesthesia techniques have been used to solve this problem. Anesthetic techniques incorporating peripheral nerve blocks are associated with superior analgesia and a lower incidence of postoperative nausea and vomiting.12,15

Regional anesthetic techniques result in increased patient satisfaction and fewer unanticipated hospital admissions.23

Peripheral nerve blocks administered with a single dose of long-acting local anesthetic (bupivacaine or ropivacaine) have frequently been used to provide postoperative pain control. However, patients and surgeons alike are frustrated when these blocks dissipate in the middle of the night, resulting in the return of severe pain. In these situations, the pain state is longer than the duration of the block.

Despite the selection of long-acting local anesthetics (14 to 24 hours of analgesia), about 20% of patients after orthopaedic surgery have significant pain requiring opioids after 7 days.14

Continuous regional analgesia, using an indwelling nerve catheter and local anesthetic pump, can maintain analgesia until the pain state dissipates.

The frustration with the limited analgesia provided by a single dose of local anesthetic causes some physicians to avoid nerve blocks altogether. They choose instead to use an opioid strategy begun preoperatively with sustained-release analgesics (oxycodone SR).

This approach is associated with increased side effects such as urinary retention, pruritus, ileus, nausea, and vomiting.

If continuous regional analgesia is selected, it may be used for anesthesia and postoperative analgesia.

The continuous peripheral nerve catheter offers prolonged analgesia and minimal side effects and eliminates the problem of block resolution and the return of severe pain. The nerve block is maintained with a continuous infusion of local anesthetic agents.

Pumps have been developed allowing outpatient infusions, and these elastometric pumps are ideal because they are compact, simple to operate, and designed to provide safe infusion rates of local anesthetic in the uncontrolled home environment.

Regional anesthetic techniques result in increased patient satisfaction and fewer unanticipated hospital admissions.23

whether the intubation is performed with the patient awake or asleep.

- General anesthesia is frequently used for orthopaedic trauma. Factors that influence this decision include surgery on more than one extremity, unknown duration of procedure, the need to assess postoperative neurologic function, and surgeon or patient preference.
- Nerve blocks with concentrated local anesthesia (bupivacaine or ropivacaine 0.5% or higher) can mask symptoms of compartment syndrome and should be avoided in patients at risk.
- Advantages of regional anesthesia for upper extremity trauma surgery include:
  - Increased blood flow in anesthetized area
  - Lower incidence of deep venous thrombosis with neuraxial blocks
  - Decreased blood loss
  - Decreased postoperative nausea and vomiting
  - Avoidance of difficult endotracheal intubation
  - Decreased phantom limb pain following amputation by preventing pain centralization

### Pediatrics

- General anesthesia is often used in pediatric surgery because children lack the emotional and intellectual maturity to be conscious during the procedure (FIG 1).
- Regional anesthesia may be performed in a child during general anesthesia, but the loss of patient feedback regarding pain and paresthesia increases the risk of neural injury.
- Regional anesthesia decreases anesthetic and opioid requirements, resulting in shorter wake-up times with general anesthesia.
- Caudal and spinal blocks have been the most commonly used regional techniques due to the anesthesiologist familiarity and their relative safety when performed in the anesthetized patient.
- Nerve blocks may provide preemptive analgesia by blocking painful stimuli and lead to lower stress hormone levels and less overall pain.
- Nerve blocks done while the patient is under anesthesia have caused severe injury in adults, but these injuries are much less common in children.
- Ultrasound-guided nerve blocks during general anesthesia may reduce the risk of nerve injury, allowing direct visualization of neural targets.
- Pediatric regional techniques require smaller needles, which have only recently become available, but continuous blocks are done with adult equipment, a less-than-optimal situation.
- Pediatric patients require cautious local anesthetic selection and administration to avoid toxicity.
- Epinephrine is typically added to enable the diagnosis of an intravascular injection of local anesthetic and to decrease its systemic absorption.
- Fasting guidelines for children up to 3 years old are given in Table 2.
- Pediatric doses of local anesthetics are summarized in Table 3.
- Continuous peripheral nerve catheters offer the same advantages in pediatric patients as in adults.
- Recommended infusion rates begin at 0.15 mL/kg per hour of bupivacaine 0.25%.
- Continuous peripheral nerve catheters may be dosed with dilute local anesthetics (bupivacaine or ropivacaine 0.1%) because of incomplete myelinization of neural fibers, permitting greater local anesthetic penetration. This will decrease the risks of local anesthetic toxicity.

ANESTHESIA SELECTION FOR UPPER EXTREMITY PROCEDURES

- Anesthesia for arm and hand surgery may be general, regional, or a combination of techniques.
- The potential benefits of an upper extremity nerve block are less nausea, a shorter recovery, and faster discharge from the hospital, in part due to improved postoperative analgesia, requiring fewer narcotics for pain.8
- The anesthetic plan may also be based on factors unrelated to evidence-based medicine, such as anxiety, extended case duration, or the need for immediate neurologic examination after surgery.

General Anesthesia
- Easier to apply and no anesthetic failures
- Provides unconsciousness for the long procedure or uncomfortable position
- Pediatric and mentally retarded patients are easier to manage.
- Cadaveric conditions when the surgery requires no movement
- Procedure and graft harvest can be in different anatomic locations.
- Nerve function can be immediately assessed.
- Efficient anesthesia recovery with anesthetics such as propofol, sevoflurane, or desflurane

Regional Anesthesia
- Increases operating room efficiency: nerve blocks are done before entering the operating room, eliminating the time needed for induction and emergence from anesthesia
- Simplified perioperative management with conditions such as malignant hyperthermia, cardiomyopathy, and obstructive or restrictive lung conditions
- Continuous nerve blocks may provide anesthesia and be used for postoperative pain control.
- Propofol may be administered with regional blocks for light or heavy sedation.
- Less postoperative nausea and vomiting
- Faster recovery from anesthesia and earlier discharge
- Less postoperative cognitive dysfunction than from general anesthesia due to superior pain control, fewer sleep disturbances, and fewer unplanned admissions to the hospital
- By avoiding unplanned admissions to the hospital, the incidence of postoperative cognitive dysfunction is lowered from 9.8% to 3.5%.9
- American Society of Regional Anesthesia and Pain Medicine guidelines on anticoagulation are given in Table 4.

REGIONAL ANESTHESIA FOR UPPER EXTREMITY SURGERY

- Nerve blocks for upper extremity surgery are summarized in Table 5.
- Shoulder Surgery
  - Because of the intense perioperative pain, particularly with arthroplasty or open rotator cuff operations, general anesthesia is rarely the sole technique for shoulder surgery.
  - Performing regional anesthesia for shoulder surgery requires knowledge of the anatomy and the surgical approach.
- The shoulder is innervated primarily by the brachial plexus, with minor contributions of sensory innervation from the superficial cervical plexus (FIG 2).

- No contraindication
- Carpel tunnel syndrome
- Multiple sclerosis (spinal anesthesia contraindicated)
- Stroke
- Diabetes mellitus

**Contraindications**
- Absolute
  - Acute or resolving nerve injury in the regional block distribution
  - Progressive peripheral neuropathy
  - Infection at the puncture site for the block
  - Patient refusal
  - Bleeding disorder: full anticoagulation, thrombolytic therapy, and hemophilia
- Relative
  - Stable nerve impairment
  - Interscalene blocks with severe chronic obstructive pulmonary disease
  - Fever, bacteremia
The interscalene block is done at the level of the trunks and blocks the superior and middle trunks along with the superficial cervical plexus.

Identification of superficial landmarks and the needle puncture site is done by palpating the space created by the trunks between the anterior and middle scalene muscles at the level of the cricoid cartilage (FIG 3A).

The nerves can be localized using paresthesia, nerve stimulator, or ultrasound (FIG 3B).

Once the needle is in approximation to the brachial plexus trunks, local anesthetic is incrementally injected, resulting in anesthesia of the shoulder and proximal arm.

Interscalene blocks with bupivacaine or ropivacaine provide perioperative analgesia.

Interscalene blocks cause a sympathectomy and resultant redistribution of blood away from the surgical site, decreasing intraoperative blood loss.

Incisions and port holes are occasionally outside the block’s anesthetic distribution, requiring local anesthetic to be injected by the surgical team into the affected area.

Intra-articular local anesthetic and narcotic infusions may be helpful but must be combined with interscalene blocks for maximum postoperative analgesia.

The semisitting position is often selected for the surgery, and the table must be equipped with a head piece securing the patient’s head with a padded strap at the forehead.

The semisitting and lateral decubitus positions place the operative site above the heart, rarely resulting in air embolism.

Head and neck positioning is crucial to avoid spinal cord compression and neurologic deficits. However, the anesthesiologist may be hampered by this position because the proximity of the surgical incision allows little access to the head.

It may be very difficult to convert to general anesthesia without disrupting the sterile surgical field when a patient with a regional anesthetic must be put to sleep in the middle of the procedure. General anesthesia can be administered without endotracheal intubation either by holding a mask on the face or by inserting a laryngeal mask airway while the patient remains in the semisitting position.

Although this does not provide protection from stomach content aspiration, it offers some control of the airway without putting the patient supine and taking down the drapes for endotracheal intubation.

Because of this potential problem, many anesthesiologists and surgeons alike prefer to use general anesthesia with an endotracheal tube in combination with an interscalene block.

This combined anesthetic would also be chosen with complicated reoperations or where induced hypotension is needed.

Continuous interscalene blocks may be done to provide analgesia for a prolonged period.

Typically 48 hours of postoperative pain is adequate, and catheters are then removed.

Prolonged interscalene analgesia may be required in acute surgical shoulder pain in the chronic pain patient or in a patient with a frozen shoulder requiring mobilization therapy.

Continuous interscalene blocks have been associated with enhanced physical rehabilitation after shoulder surgery due to superior pain control.

Interscalene block side effects include phrenic nerve, recurrent laryngeal nerve, and stellate ganglion blockade.

These may result in transient loss of ipsilateral diaphragm function, weak voice, miosis, ptosis, and anhidrosis (Horner syndrome).

Elbow Surgery

Surgical procedures at the elbow, whether for arthroplasty or the reattachment of a biceps brachii tendon, frequently require general anesthesia despite the advantages of regional anesthesia.
The proximity of nerves to the surgical incision is concerning to surgeons who may wish to examine neurologic function in the immediate postoperative period, which is not possible with a nerve block.
- Regional techniques are often performed in the recovery area after nerve function is assessed.
- Functional outcomes after elbow surgery often depend on early rehabilitation using continuous passive motion devices.
- This therapy can be facilitated with continuous brachial plexus analgesia. The infraclavicular and the axillary approaches to the brachial plexus are options for catheter placement.
- The infraclavicular block is performed by placing the needle 1 inch distal to the midclavicle, with the needle advanced toward the axillary pulsation until twitch or paresthesia is obtained (FIG 4).
- Continuous infraclavicular blocks are ideal as they cover the brachial plexus, including the musculocutaneous nerves, providing anesthesia of the entire arm.
- Continuous axillary nerve blocks cover the brachial plexus, with the exception of the musculocutaneous nerve. This may result in pain during continuous passive motion and it may need to be separately blocked.
- Surgery with brachial plexus blocks may require supplementation at the musculocutaneous and intercostobrachial nerves.

Hand Surgery
- Hand procedures are frequently done with nerve blocks because of the ideal operating conditions and early discharge times postoperatively.
  - General anesthesia is reserved for extremely long cases and is combined with brachial plexus analgesia.
  - Carpel tunnel release surgery is one of the most common hand procedures and may be done with an intravenous regional block (Bier block).
  - Bier blocks are impractical for the efficient outpatient practice. Local infiltration by the surgeon combined with intravenous sedation is a more common and efficient anesthetic approach.
- The axillary approach to the brachial plexus is ideal for more extensive hand procedures (FIG 5A).
  - The block may be placed easily, sets up quickly, covers all of the nerves of the hand, and is associated with low complication rates.
  - The nerves in the axilla have a predictable anatomic relationship to the axillary artery.
  - The block may be done with paresthesia, nerve stimulation, or transarterial approaches.
  - Ultrasound guidance more recently has been used to provide real-time visualization of both the needle and the neural targets (FIG 5B,C).
  - The success of the block can be predicted by confirming circumferential spread of local anesthetic around the nerves.
  - Continuous peripheral nerve catheters may be placed if the procedure is prolonged, a sympathectomy is needed, or significant pain is expected.
  - Brachial plexus anesthesia with an intercostobrachial nerve block will prevent tourniquet pain, unlike general anesthesia.

Supplementing Nerve Blocks
- It is preferable to place blocks outside the operating room so that block efficacy can be evaluated.
  - Often a “failed” block is simply the result of inadequate time for local anesthetic distribution to nerve targets.
  - Insufficient blocks can be supplemented, and again ultrasound offers a safe option for this.
  - Propofol infusions will allow control of anxiety and can turn an incomplete block into an intraoperative success.
Continuous Nerve Blocks

- Postoperative pain control after a single injection of local anesthesia is limited to 16 hours, and this limits its usefulness for postoperative pain management.
  - In a procedure associated with moderate to severe postoperative pain, patients experience significant pain when the block resolves.
  - Undertreated pain may result in more refractory pain states, such as chronic pain or complex regional pain syndromes.
- Because of the anatomic relationships of the upper extremity, a single catheter may provide continuous analgesia in the distribution of surgical pain.
  - The catheter is placed and local anesthetic administered preoperatively and combined with other analgesic interventions.
  - The surgical pain is not amplified at the tissue level or centrally in the spinal cord, so the pain is less intense and of shorter duration.20
- Continuous blocks may be maintained in the hospital as well as at home using disposable infusion pumps. To ensure success with home-going regional anesthesia, instructions and teaching must begin in the preoperative period.
  - Patients must be counseled about the danger of injury in the absence of normal pain responses. They are instructed to avoid working with extreme heat or cold and to avoid driving.
  - Patients are educated about symptoms of local anesthetic toxicity, and phone numbers are provided with instructions to call in the event of problems.
  - When continuous peripheral nerve catheters are part of a multimodal pain therapy consisting of nonsteroidal anti-inflammatory medications, acetaminophen, cryotherapy, and weak opioids, greater analgesia and patient satisfaction may be achieved.

- The efficacy of continuous interscalene blocks was demonstrated in patients treated with ropivacaine 0.2% after open rotator cuff surgery; they achieved pain scores averaging 1 out of 10 compared to placebo.13
  - Similar results were achieved with outpatient shoulder patients sent home with continuous interscalene blocks.11
  - The efficacy of continuous infraclavicular blocks was demonstrated when ropivacaine 0.2% was administered to outpatients with moderately painful orthopaedic procedures; they achieved pain scores of 2 versus 6 in the placebo control group. The blocks were associated with less pain, resulting in fewer sleep disturbances, less opioid consumption, and fewer side effects.10
  - Infusion pumps maintain the block by infusing dilute local anesthetic (bupivacaine 0.1% and ropivacaine 0.2%) at 10 cc/hr.
  - Local anesthetic toxicity resulting from the continuous infusion is very rare. Local anesthetic toxicity is most likely during the initial injection (bolus with 30 to 40 cc of bupivacaine or ropivacaine 0.5%).

Local Anesthetics and Additives

- Local anesthetics produce anesthesia by inhibiting excitation of nerve endings and blocking conduction in peripheral nerves due to the binding and inactivation of both sodium and potassium channels. This prevents the sodium influx through these channels that is necessary for the depolarization of nerve cell membranes and propagation of impulses along the course of the nerve.
- There are two classes of local anesthetics, named for their linkage between the carbon chain and aromatic chain.
  - The amino amides have an amide link between the chain and the aromatic end, and amino esters have an ester link between the chain and the aromatic end.
  - The amino esters are metabolized in the plasma via pseudocholinesterases, and amino amides are metabolized in the liver.
Amino esters are eliminated rapidly compared with amides, decreasing the possibility of toxicity.

Amino esters are much more likely than amino amides to cause true allergic reactions due to metabolites like para-aminobenzoic acid.

Varying the concentration of local anesthetics will produce a differential block. Higher concentrations produce an intense motor and sensory block. More dilute locals result in a sensory block with little motor blockade.

Toxicity from local anesthesia occurs when a peak plasma level is reached, typically from inadvertent intravascular administration of anesthetic.

Toxicity from rapid absorption is also possible, especially in vascular areas (intercostal, epidural, or interscalene), and epinephrine is added to the local anesthetic to signal intravascular injection and decrease the vascular absorption of the local anesthetic.

The inadvertent intravascular injection of bupivacaine or ropivacaine may result in cardiovascular collapse (ventricular tachycardia or fibrillation).

Because of their potent binding to the heart, these arrests can be difficult to treat.

Cardiotoxicity from bupivacaine has been successfully treated with 2 mL/kg of 20% lipid emulsion in a case report. The mechanism of the lipid emulsion is the binding of bupivacaine in the plasma and tissues. In other cases patients have required cardiopulmonary bypass until the conduction blockade resolved.

Recommended doses of local anesthetics are given in Table 6.

The use of additives with local anesthetics has increased as regional analgesia has become a standard method for managing postoperative pain.

Some additives prolong the duration of the block and therefore the postoperative pain control (Table 7).

### EQUIPMENT

#### Airway Management

- For 30 minutes after a nerve block, patients must be closely monitored for signs of systemic toxicity.
- Medications to treat seizures and to establish general anesthesia must be immediately available.
- Induction drugs such as propofol and succinylcholine and airway equipment, including oxygen, an Ambu-bag with mask for positive-pressure ventilation, and a laryngoscope with assorted endotracheal tubes, should be nearby.

#### Monitoring

- The rare occurrence of local anesthetic toxicity mandates full monitoring in the operating room and in areas where blocks may be done before surgery.
- Pulse oximetry measures blood oxygen saturation in response to sedatives and analgesics, and the electrocardiogram is required to diagnose rhythm changes in the unlikely event of cardiac toxicity.
- Observation of the patient for early signs of central nervous system excitation is perhaps the best monitoring practice.

#### Regional Equipment

- The practice of regional anesthesia requires special equipment designed for peripheral nerve blockade.
- The nerve stimulator allows confirmation of the needle position adjacent to the nerve when a motor response is seen with low current output (0.5 mA; FIG 6).
- In today’s clinical practice, continuous nerve blocks for pain control are commonly placed using nerve stimulation.
- A newer technique uses ultrasound to visualize the nerve to be blocked.
- With ultrasound, it is possible to visualize, in real time, images of the nerve, the needle approaching the nerve, and

**PAIN MANAGEMENT**

**Preemptive Analgesia**
- Preemptive analgesia is implemented before a painful stimulus, which limits the sensitization of the nervous system to the pain. This should result in less intense pain of shorter duration.
- A dense, sustained nerve block inhibits the transmission of noxious afferent stimuli from the operative site to the spinal cord and brain.
- Multimodal pain control uses multiple analgesics affecting multiple pathways to maximize analgesia (Table 8).
- These interventions complement each other and often allow smaller individual drug doses to be used, thereby minimizing side effects.

</table>
The primary goal is to avoid hyperalgesia, allodynia, and increased pain.

Acetaminophen is a weak analgesic, but it should be given preoperatively and postoperatively (1 g every 8 hours) unless contraindicated.

The drug acts on prostaglandin synthesis centrally, so there are no concerns with hyper- or hypo-coagulation side effects perioperatively.

Celecoxib is currently the only available cyclooxygenase inhibitor available for clinical use.

It is an ideal nonsteroidal anti-inflammatory as it has no platelet and few gastrointestinal effects.

Caution should be exercised with chronic administration: strokes and myocardial infarctions have been reported after 18 months of regular use.

Gabapentin has been shown to reduce pain and analgesic requirements when given preoperatively.

The drug is an N-methyl-D-aspartic acid antagonist, and it reduces hyperexcitability of dorsal horn neurons induced by tissue trauma.

Gabapentin is active only where there is tissue trauma and sensitization of nociceptive pathways, which distinguishes it from other analgesics.

Mild side effects include slight dizziness and somnolence.

Multimodal Analgesia Perioperative Pain Control

Table 9 covers equianalgesic dosages of opioids.

Table 10 summarizes multimodal postoperative pain control methods.

**Chronic Pain**

- Patients with chronic pain can be expected to have higher analgesic requirements after surgery.
- These patients are tolerant to the effects of opioids and tend to have very low thresholds for pain.
- Plans for pain management, in consultation between the surgeon, anesthesiologist, and patient, should be made preoperatively to optimally manage this acute-on-chronic pain state.
- The patient’s chronic narcotic therapy should be continued and increased 30% to 40%, depending on the expected severity of the postoperative pain.
- Multimodal analgesia should be implemented before the procedure.
- Continuous peripheral nerve blocks are critical in the treatment of this population of patients.
- Reasonable expectations for analgesia should be discussed by the care team with the patient, and the goal for pain control should be to reach his or her average pain score.

The concept of pain as the “fifth vital sign” (postoperative pain score of 3 or less out of 10) will not apply to these patients.

**INFORMED CONSENT**

- The anesthesiologist must separately articulate both the risks and benefits of regional and general anesthetic options.
- Patients are most often accepting of a regional technique once it has been explained properly and they understand the benefits of superior pain management and the avoidance of postoperative nausea and vomiting.
- The patient may make the final decision, but it is important for the surgical and anesthesia staff to recommend techniques associated with positive outcomes.
- The clinical impression is that regional anesthesia is safer than general anesthesia.
- Numerous studies have examined the complication rate for general and regional anesthesia.
- These studies have compared long-term outcomes between both techniques and have found no difference between regional and general anesthesia in terms of nonfatal myocardial infarction, unstable angina, or 6-month mortality.
- This is reassuring, but there are other outcomes important when choosing an anesthetic plan.

COMPLICATIONS

General Anesthesia

- The perceived efficiencies of general anesthesia may not be evident in the postoperative period where more complications must be managed, and the level of postoperative care with general anesthesia will be dictated by these complications.

Postoperative Nausea and Vomiting

- Avoiding postoperative nausea and vomiting (PONV) is a high priority because of the expense resulting from treatments and subsequent delays.
  - PONV may not respond to treatment, leading to an unplanned hospital admission.
  - Patient satisfaction surveys have determined that patients often find PONV more unpleasant than postoperative pain.
- Postoperative nausea and vomiting risk is related to age.
  - There is a low risk in children less than 2 years old, but the risk increases until puberty and then drops as aging occurs.
- Patients with prior PONV or who have motion sickness have a higher risk of PONV with general anesthesia.
  - Women have a higher incidence of PONV.
  - Nonsmokers have a higher risk of PONV.
- The risk of PONV varies with the type of surgery.
  - Ear, nose, and throat and dental procedures have a high incidence of PONV, followed by orthopaedic and plastic surgery.
  - Procedures such as strabismus, peritoneal, testicular, and middle ear surgeries are associated with PONV.
- The risk of PONV is higher with general anesthesia than regional anesthesia.
  - General anesthetics such as the inhalational gasses (nitrous oxide, sevoflurane, and desflurane) increase the incidence of PONV compared to propofol.
  - Droperidol (0.625 mg) has been a PONV treatment mainstay because of its efficacy and low cost.
  - However, as a result of isolated cardiac events with large doses of droperidol (1.25 to 2.5 mg) in the presence of prolonged Q-T syndrome, the U.S. Food and Drug Administration has issued a black box warning for its clinical use.
- Table 11 summarizes factors related to patient and surgery and lists treatment guidelines.

Urine Retention

- Vomiting difficulty is common after spinal anesthesia and in patients with prostatic hypertrophy as well as in urology, inguinal hernia, and genital procedures.
- The use of parenteral opioids to control significant pain will increase the incidence of urine retention.
- For procedures associated with a low risk of urine retention, patients may be discharged without demonstration of voiding.
- Patients must be instructed to return for evaluation if they have not voided in a specified time frame.

Postanesthetic Injuries

- Corneal abrasion
  - Corneal abrasion may occur due to drying of the cornea or incidental trauma during mask ventilation or intubation or as a result of the patient rubbing the eyes after the procedure.
- Nerve injuries
  - Nerve injuries may occur due to improper positioning and padding during the procedure.
  - Injury may occur from compression or stretch of the neural tissue.

The symptoms of corneal abrasion include redness, tearing, photophobia, decreased visual acuity, and pain.
- They are usually self-limited, resolving in 24 to 48 hours, and artificial tears and an eye patch are standard treatments.
- Severe abrasions may warrant ophthalmologic consultation as they may lead to cataract formation.

Pharyngeal injuries

- Endotracheal intubation may cause a sore throat in 20% to 50% of patients, depending on the amount of trauma during laryngoscopy or oropharyngeal suctioning.
- Local anesthetic ointments during anesthesia, once thought to prevent sore throats, may also result in airway irritation. This may present as pain or an unquenchable thirst.
- Mucosal trauma may also be the result of the laryngeal mask airway, despite the impression that they are less invasive and traumatic than endotracheal tubes.
- Dental damage may occur during the induction or emergence from anesthesia.
  - Any dental damage should be carefully documented, and dental consultation may be needed depending on the extent of the injury.
  - Lip, gum, or tongue damage may be treated with ice to manage the pain and inflammation.

Nerve injury is usually thought to be associated with regional anesthesia, but the incidence of nerve injury is higher with general anesthesia (ulnar nerve).

Regional Anesthesia

Nerve Injury

The incidence of nerve injury was evaluated in a large retrospective European study involving over 150,000 regional anesthetics.1

The anesthetics were administered over a 10-month period; over 50,000 were peripheral nerve blocks. The incidence of peripheral nerve injury was 0.04% (4/10,000). Peripheral nerve injury occurred in 12 patients, and the symptoms were present after 6 months in 7 patients.

Much has been written about the risks of nerve injury after peripheral nerve blocks, but it is only recently that the positive merits of these techniques have been discussed.

Peripheral nerve injury with regional anesthesia may be the result of direct needle or catheter trauma, local anesthetic toxicity, or vasoconstrictors added to the local solution.

Severe injuries occurred, in adult patients under general anesthesia, when local anesthetic was inadvertently injected into the spinal cord. This resulted in irreversible paralysis.2

Short-beveled needles do not result in fewer cases of nerve injury compared with long-beveled needles, as had previously been believed.

The neural repair appears more rapid after injury from a long-beveled needle according to animal data, although there are no clinical data to support this.

Patient factors increasing the risk of nerve injury include diabetes mellitus, pre-existing nerve injury, male sex, and older age.

Surgical factors associated with a higher rate of nerve injury include trauma, stretch, positioning, tourniquet ischemia, and cast compression.

Neurologic changes should be evaluated urgently so that treatable causes such as hematoma, constrictive dressings, and abscess formation may be diagnosed and treated, limiting the extent of injury.

If significant nerve injury is suspected, documentation of neurologic status and neurology consultation with early and late electromyography are advisable.

Infectious Complications

Infection may result after a nerve block from the contamination of the needle or local anesthetics as well as from bacteremia.

This would be less likely with a single injection block because the local anesthetics used in regional anesthesia are bactericidal (bupivacaine at a concentration of at least 0.25%).

Infection is more likely with a continuous block as the catheter is a track for bacteria and dilute local anesthetics are less bactericidal.

Local infection at the site of the block is a clear contraindication to a regional anesthetic, especially catheter placement.

Bacterial colonization of continuous nerve blocks was examined by Capdevila et al.4

In the 969 catheters that were cultured, bacterial colonization was found to be present in 28.7% (278), but only 3% of the patients had signs of local inflammation at the site.

The bacteria most often identified were coagulase-negative staphylococci (Staphylococcus epidermidis; 61%), gram-negative bacillus (21.6%), and Staphylococcus aureus (17.6%).

Localized inflammation or infection at the site is associated with factors such as catheter duration greater than 48 hours, male sex, absence of antibiotic prophylaxis, and postoperative monitoring in the intensive care unit.4

It is our practice to limit the peripheral nerve catheter and infusion to 48 hours.

Catheters are tunneled under the skin for prolonged analgesia, preventing bacteria from migrating to deeper tissue planes.

Hemorrhagic Complications

The risk of bleeding during regional anesthesia, although rare, is always present because of the anatomic relationships of nerves and vascular structures.

Hematoma formation has been reported with almost every nerve block approach, and superficial bruising is very common.

A high index of suspicion will allow early diagnosis and treatment, avoiding permanent injury.

Patients at particularly high risk for hemorrhagic complications are those receiving low-molecular-weight heparins, antiplatelet drugs such as clopidogrel (Plavix), therapeutic Coumadin levels, and antithrombotic drugs.

Hematomas should be considered in the setting of an evolving neural deficit and obviously if vascular injury occurred during the technique.

Acute hematoma formation may be handled conservatively by holding pressure for at least 5 minutes and continued observation.

A large hematoma that continues to expand or is causing acute neural deficits will require surgical drainage to preserve nerve function.

Imaging such as ultrasound or CT scanning may confirm the diagnosis before surgery if there is doubt.

Local Anesthetic Toxicity

Local anesthetics in the proper concentration and dosage are safe. When local anesthesia is inadvertently injected intravascularly, seizures may occur.

Seizures result due to high concentration of local anesthesia in the plasma despite binding by albumin and alpha-1 acid glycoprotein.

The seizures tend to be short with the prompt administration of benzodiazepines and positive-pressure ventilation.

When a significant portion of a bupivacaine dose becomes intravascular, death has occurred as a result of the cardiac conduction being blocked, which resulted in cardiovascular collapse.

Factors affecting toxicity of local anesthetics

Location of block (intercostal, epidural, or interscalene)

Patient characteristics (extremes of age, parturients, hypoalbuminemia)

Pharmacologic factors

Toxicity: bupivacaine> ropivacaine >> mepivacaine>> lidocaine

Perioperative Considerations

The proper selection of anesthetic techniques for orthopaedic surgery begins with the consideration of surgical and patient factors. Additionally, factors such as safety, cost-effectiveness, and efficiency are considered.
A well-organized surgical and anesthetic practice allows patients to receive nerve blocks before going to the operating room.

Peripheral nerve blocks need not delay surgery or fail if proper utilization of the induction room occurs.

Operating room efficiency and turnover are increased in this manner. The patient will be sedated and have monitors, intravenous access, and a functional regional block in place when he or she enters the operating room.

The regional patient will also bypass the postanesthesia care unit and may move to the outpatient or regular nursing area without delay.

The upper extremity is uniquely suited for regional anesthesia because the brachial plexus may be anesthetized with one injection, and continuous blocks may be maintained postoperatively, providing extended analgesia.

Whether general, regional, or a combination is selected for anesthesia, patients' perioperative experiences are improving.

In the past, regional anesthesia was selected for safety reasons, and now regional anesthesia is being administered for its superior pain control.

In the future, anesthetics may be selected based on the patient's genotype, and the patient may have surgery and postoperative pain control without needles, catheters, or even a general anesthesia. Until then, regional techniques, in conjunction with multimodal analgesic protocols, will continue to be the care standard after orthopaedic surgery.

REFERENCES

BACKGROUND

- Since its inception, wrist arthroscopy has continued to evolve. The initial emphasis on viewing the wrist from the dorsal aspect arose from the relative lack of neurovascular structures as well as the familiarity of most surgeons with dorsal approaches to the radiocarpal joint.
- Anatomic studies provided a better understanding of both the interosseous ligaments as well as carpal kinematics, which led to the development of midcarpal arthroscopy.
- Innovative surgeons continue to push the envelope through the development of techniques for treating intracarpal pathology, which in turn has culminated in a plethora of new accessory portals.

ANATOMY

- The standard portals for wrist arthroscopy are dorsal (FIG 1A–C). This is in part due to the relative lack of neurovascular structures on the dorsum of the wrist as well as the initial emphasis on assessing the volar wrist ligaments. The dorsal portals that allow access to the radiocarpal joint are so named in relation to the tendons of the dorsal extensor compartments.
- The 1–2 portal lies between the first extensor compartment tendons, which include the extensor pollicis brevis and the abductor pollicis longus, and the second extensor compartment, which contains the extensor carpi radialis brevis and longus (FIG 1D).
- The 3–4 portal is named for the interval between the third dorsal extensor compartment, which contains the extensor pollicis longus tendon, and the fourth extensor compartment, which contains the extensor digitorum communis (EDC) tendons.
- The 4–5 portal is located between the EDC and the extensor digiti minimi (EDM).
- The 6R portal is located on the radial side of the extensor carpi ulnaris (ECU) tendon; the 6U portal is located on the ulnar side.
- The midcarpal joint is assessed through two portals, which allows triangulation of the arthroscope and the instrumentation.
- The midcarpal radial portal is located 1 cm distal to the 3–4 portal and is bounded radially by the extensor carpi radialis brevis and ulnarly by the EDC.
- The midcarpal ulnar portal is similarly located 1 to 2 cm distal to the 4–5 portal and is bounded by the EDC and the EDM.
- The triquetrohamate portal enters the midcarpal joint at the level of the triquetrohamate joint ulnar to the ECU tendon. The entry site is both ulnar and distal to the midcarpal ulnar portal. Branches of the dorsal cutaneous branch of the ulnar nerve are most at risk (FIG 2A).
- The dorsal radioulnar joint portal lies between the ECU and the EDM tendons. Transverse branches of the dorsal cutaneous branch of the ulnar nerve are the only sensory

nerves in proximity to the dorsal radioulnar portal, at a mean of 17.5 mm distally (range 10–20 mm) (FIG 2B,C).

- There are two volar portals that can be used to access the radiocarpal joint.
  - The volar radial portal is accessed through the floor of the flexor carpi radialis tendon sheath at the level of the proximal wrist crease.5,7,9
  - Anatomic studies revealed that there is a safe zone free of any neurovascular structures, equal to the width of the flexor carpi radialis tendon plus at least 3 mm in all directions.
  - The volar aspect of the midcarpal joint can be accessed through the volar radial midcarpal portal. The same skin incision is used but the capsular entry point is about 1 cm distal.
  - The volar ulnar portal is located underneath the ulnar border of the flexor tendons at the level of the proximal wrist crease.6

- The volar aspect of the distal radioulnar joint (DRUJ) can be accessed through the volar distal radioulnar portal using the same skin incision, but the capsular entry point for the volar distal radioulnar portal lies 5 mm to 1 cm proximal to the ulnocarpal entry point (FIG 2D,E).

**AUTHOR’S EXPERIENCE**

- The volar radial portal has been used in 111 patients since 1998.4
  - Additional pathology was evident in 61 of the patients that was not visible from any standard dorsal portals. This included 1 case of hypertrophic synovitis of the dorsal capsule (FIG 3A), 1 patient with an avulsion of the radioscapopholunate ligament that exposed the volar scapholunate cleft (FIG 3B), 2 patients with tears restricted to the palmar region of the scapholunate interosseous ligament (SLIL), and 57 patients with tears of the dorsal radiocarpal ligament (DRCL). In 16 patients an isolated DRCL tear alone was responsible for chronic dorsal wrist pain (FIG 3C,D).
- The midcarpal joint was accessed from the volar radial portal in three cases. In one patient with Preiser disease, the use of the volar radial midcarpal portal allowed a more complete assessment of the distal articular surface of the

---

**FIG 3**

scaphoid. Another patient had unrecognized chondromalacia of the palmar capitate following a perilunate dislocation (FIG 3E). The volar radial midcarpal portal admirably demonstrated the intact dorsal portion of the SLIL in the patient with the palmar tear (FIG 3F).

- The volar ulnar portal has been used in 61 patients since 1998.8

- The ulnar-sided pathology included 21 tears of the lunotriquetral interosseous ligament (LTIL) (FIG 4A), 19 triangular fibrocartilage complex (TFCC) tears, and 2 ulnolunate ligament tears. In one patient a TFCC tear was found to extend into the dorsoulnar ligament (FIG 4B,C). The volar ulnar portal facilitated débridement of the palmar region of the LTIL ligament through the 6R or 6U portals. In three of these

patients unrecognized chondromalacia of the palmar aspect of the lunate was identified (FIG 4D), and one patient had chondromalacia of the palmar triquetrum. One patient was found to have a loose body in the ulnocarpal joint (FIG 4E).

The volar aspect of the DRUJ was accessed in eight of these patients to rule out a peripheral TFCC tear. The DRUJ was well visualized, demonstrating an intact articular disc in four and a full-thickness tear with undersurface fibrillation in one (FIG 4F). The foveal attachment of the TFCC was seen to be intact in each case (FIG 4G,H).

NONOPERATIVE MANAGEMENT

- In general, wrist arthroscopy is indicated as a diagnostic technique in any patient with persistent wrist pain that has not responded to an appropriate trial of conservative measures:
  - Nonsteroidal anti-inflammatory and activity modification
  - Cortisone injection
  - Wrist arthroscopy is used as an adjuvant procedure for the treatment of acute fractures of the distal radius or scaphoid, or for staging degenerative disorders involving the carpus.

Indications

- The indications for the use of the standard dorsal portals are intertwined with the indications for wrist arthroscopy and depend largely on the condition that is being treated.
  - A typical arthroscopic examination of the wrist will include variable combinations of the 3–4 portal, the 4-5 portal, and the 6R and 6U portals.
Arthroscopic Wrist Procedures

- The 3–4 and 4–5 portals are the main viewing portals for the radial aspect of the radiocarpal joint and for instrumentation.
- The 4–5 and 6R portals are used to access the ulnocarpal joint.
- The 6U portal is typically used for outflow.
- The volar radial portal is indicated for the evaluation of the DRL and the palmar portion of the SLIL. The volar radial portal also facilitates arthroscopic reduction of intra-articular fractures of the distal radius fractures by providing a clear view of the dorsal rim fragments.
- The volar ulnar portal is indicated for visualizing and débriding palmar tears of the lunotriquetral ligament. It also aids in the repair or débridement of dorsally located TFCC tears since the proximity of the 4–5 and 6R portals makes triangulation of the instruments difficult.
- Midcarpal arthroscopy through the dorsal midcarpal portals is essential in making the diagnoses of scapholunate and lunotriquetral instability.
- The grading scale reported by Geissler and colleagues provides a means for staging the degree of instability and provides an algorithm for treatment.
- Midcarpal arthroscopy is likewise employed for the assessment and treatment of chondral lesions of the proximal hamate.
- The triquetrohamate joint can also be accessed through another special-use midcarpal portal.
- The volar radial midcarpal portal is occasionally used as an accessory portal for visualizing the palmar aspects of the capitohamate joint.
- This portal facilitates visualization of the palmar aspect of the capitohamate interosseous ligament, which is important in minimizing translational motion and has an essential role in providing stability to the transverse carpal arch.
- The volar distal radioulnar portal is useful for assessing the deep foveal attachment of the TFCC, which would normally require an open capsulotomy.
- It may be employed if the suspicion of a peripheral TFCC detachment remains despite the absence of any visible TFCC tears through the standard ulnocarpal portals.
- The dorsal DRUJ portals may be used in concert with the volar distal radioulnar portal to more completely assess the status of the articular cartilage of the ulnar head and sigmoid notch as well as for instrumentation.
- The number of conditions amenable to arthroscopic treatment continues to grow. Many arthroscopic procedures are now common, while others await clinical validation. Table 1 provides a list of the more standard procedures.

**Contraindications**
- Contraindications to the use of dorsal or volar portals would include marked swelling, which distorts the topographic anatomy; large capsular tears, which might lead to extravasation of irrigation fluid; neurovascular compromise; bleeding disorders; or infection.
- Unfamiliarity with the regional anatomy is a relative contraindication.

**SURGICAL MANAGEMENT**
- It is useful to have a systematic approach to viewing the wrist.
- The structures that should be visualized as a part of a standard examination include the radius articular surface; the proximal scaphoid, lunate, and triquetrum; the SLIL and LTIL, both palmar and dorsal; the radioscaphocapitate ligament; the long radiolunate ligament; the radioscapholunate ligament; the ulnolunate ligament; the lunotriquetral ligament; and the radial and peripheral TFCC attachments.
- It is my practice to establish the dorsal portals first but then to start the arthroscopic examination with the volar radial portal to visualize the palmar SLIL and the DRCL ligament to minimize any error from iatrogenic trauma to the dorsal capsular structures.
- In patients with ulnar-sided wrist pain, the volar ulnar portal is used to assess the palmar LTIL and dorsal radioulnar ligament, the region of the extensor carpi ulnaris subsheath, and the radial TFCC attachment.
- The scope is then inserted in the 3–4 portal followed by various combinations of the 4–5 portal and 6R portal. The 6U portal is mostly used for outflow, but it may be used for instrumentation when débriding palmar LTIL tears.
- Midcarpal arthroscopy is then performed to probe the SLIL and LTIL joint spaces for instability, the capitohamate interosseous ligament, and to look for chondral lesions on the proximal capitohamate ligament and loose bodies (FIG 5).
- The special-use portals such as the dorsal and volar DRUJ portals and the 1–2 portal are used as needed.

**Preoperative Planning**
- A 2.7-mm, 30-degree-angled scope along with a camera attachment is used.
- Table 2 describes the typical field of view as seen through a 2.7-mm arthroscope under ideal conditions.
- A 1.9-mm scope is sometimes beneficial, especially for evaluation of the DRUJ.
- A fiberoptic light source, video monitor, and printer have become the standard of care.
- Digital systems allow direct writing to a CD and superior video quality as compared to analog cameras.
- A 3-mm hook probe is needed for palpation of intracarpal structures.

Ligament repairs can also be facilitated by use of a Tuohy needle, which is generally found in any anesthesia cart.

Positioning
- The patient is positioned supine on the operating table with the involved arm abducted on an arm table.
- A tourniquet is placed as far proximal on the arm as feasible.
- Traction is useful:
  - A shoulder holder along with 5- to 10-lb sand bags attached to an arm sling
  - A commercially available traction tower such as the Linvatec tower (Conmed–Linvatec Corporation, Utica, NY) or the ARC traction tower (Arc Surgical LLC, Hillsboro, OR)
- For the dorsal portals the surgeon faces the dorsum of the wrist and is seated by the patient’s head. For the volar portals the surgeon faces the palm and is seated in the patient’s axillary region.

Approach
- Portals are established by palpating and identifying anatomic landmarks and then inserting a 22-gauge needle into the joint space. The joint is then injected with 5 cc of saline.
  - The ability to draw the saline back into the syringe serves as evidence that the needle is in the joint.

A motorized shaver or diathermy unit such as the Oratec probe (Smith & Nephew, NY) is useful for débridement.
- Ancillary equipment is largely procedure-dependent.
- A motorized 2.9-mm burr is needed for bony resection.
- There are a variety of commercially available suture repair kits, including the TFCC repair kit by Linvatec (Conmed–Linvatec Corporation, Largo, FL).

CHIL, capitohamate ligament; DRCL, dorsal radiocarpal ligament; DRUL, dorsal radioulnar ligament; LRL, long radiolunate ligament; LTIL, lunotriquetral interosseous ligament; PRUL, palmar radioulnar ligament; PSR, prestyloid recess; PTO, piso-tiquetal orifice; RSC, radioscaphocapitate ligament; RSL, radioscapholunate ligament; SLIL, scapholunate interosseous ligament; SRL, short radiolunate ligament; TFCC, triangular fibrocartilage complex; ULL, ulnolunate ligament; ULT, ulnotriquetral ligament.

Shallow incisions avoid injury to sensory nerve branches and tendons. Soft tissues are dissected using a blunt mosquito clamp or a pair of small curved scissors. The dorsal capsule is pierced with these same instruments, providing access to the joint.

- A blunt trocar is used to introduce the scope cannula, which will house the scope and the inflow.

Routinely, an 18-gauge needle is placed in the 6U portal for outflow.

- Synovitis, fractures, ligament tears, and a tight wrist joint may limit the field of view and necessitate the use of more portals to adequately assess the entire wrist.

3–4 PORTAL

- The concavity overlying the lunate between the extensor pollicis longus and the EDC is located just distal to the tubercle of Lister, in line with the second web space.

- The radiocarpal joint is identified with a 22-gauge needle that is inserted 10 degrees palmar to account for the volar inclination of the radius.

- The vascular tuft of the radioscapholunate ligament is directly in line with this portal. Superior to the radioscapholunate ligament is the membranous portion of the SLIL.

- Routinely, an 18-gauge needle is placed in the 6U portal for outflow.

4–5 PORTAL

- The 6R portal is identified on the radial side of the ECU tendon, just distal to the ulnar head.

- The scope should be angled 10 degrees proximally to avoid hitting the triquetrum. The TFCC is immediately below the entry site.

- The LTIL is located radially and superiorly, whereas the ulnar capsule is immediately adjacent to the scope.

- By rotating the scope dorsally while looking in an ulnar direction, the insertion of the dorsal capsule onto the dorsal aspect of the SLIL can often be visualized. This is a common origin for the stalk of a dorsal ganglion.

- The radioscapholunate ligament and the long radiolunate ligament are radial to the portal and can be probed with a hook in the 4–5 portal.

- The LTIL, TFCC, and ulnolunate ligament are ulnar to the portal.

6R AND 6U PORTALS

- The 6R portal is identified on the radial side of the ECU tendon, just distal to the ulnar head.

- The scope should be angled 10 degrees proximally to avoid hitting the triquetrum. The TFCC is immediately below the entry site.

- The LTIL is located radially and superiorly, whereas the ulnar capsule is immediately adjacent to the scope.

- The 6U portal is found on the ulnar side of the ECU tendon. Angling the needle distally and ulnar deviation of the wrist helps avoid running into the triquetrum.

- This portal can be used to view the dorsal rim of the TFCC or for instrumentation when débriding the palmar LTIL.
1–2 PORTAL

- The relevant landmarks in the snuff box are palpated and outlined, including the distal edge of the radial styloid, the abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus tendons, and the radial artery in the snuff box.
- To minimize the risk of injury to branches of the superficial radial nerve and the radial artery, the 1–2 portal should be no more than 4.5 mm dorsal to the first extensor compartment and within 4.5 mm of the radial styloid (TECH FIG 1).
- A blunt trocar and cannula are inserted with the wrist in ulnar deviation to minimize damage to the proximal scaphoid.

![TECH FIG 1](image1)

1. Cadaver dissection demonstrating the placement of the 1–2 portal. SR, superficial radial nerve branches; EPL, extensor pollicis longus; EPB, extensor pollicis brevis; APL, abductor pollicis longus.

MIDCARPAL RADIAL PORTAL

- The midcarpal radial portal is found 1 cm distal to the 3–4 portal.
- Flexing the wrist and firm thumb pressure helps identify the soft spot between the distal pole of the scaphoid and the proximal capitate.
- The scaphotrapezial trapezoidal joint lies radially and can be seen by rotating the scope dorsally.
- The scapholunate articulation can be seen proximally and ulnarly; it can be probed for instability or step-off.
- Further ulnarly, the lunotriquetral articulation is visualized.
- Moving the scope superiorly yields oblique views of the proximal surface capitate and hamate as well as the capitohamate interosseous ligament.
- The continuation of the radioscapohamate ligament, which forms the radial arm of the arcuate ligament (ie, the scaphocapitate ligament) can occasionally be seen across the midcarpal space.
MIDCARPAL ULNAR PORTAL

- The midcarpal ulnar port is found 1 cm distal to the 4–5 portal and 1.5 cm ulnar and slightly proximal to the midcarpal radial portal, in line with the ring metacarpal axis.
- This entry site is at the intersection of the lunate, triquetrum, hamate, and capitate with a type I lunate facet and directly over the lunotriquetral joint with a type II lunate facet. This portal provides preferential views of the lunotriquetral articulation.
- Directly anteriorly, the ulnar limb of the arcuate ligament (ie, the triquetro-hamate-capitate ligament) can be seen as it crosses obliquely from the triquetrum, across the proximal corner of the hamate to the palmar neck of the capitate.
- This is especially important in midcarpal instability.
- Normally there is very little step-off between the distal articular surfaces of the scaphoid and lunate.
- Direct pressure from the scope combined with traction may force the carpal joints out of alignment.
- The traction should be released and the scapholunate joint should be viewed with the scope in the midcarpal ulnar portal, whereas the lunotriquetral joint should be viewed with the scope in the midcarpal radial portal.

VOLAR RADIAL PORTAL

- A 2-cm transverse or longitudinal incision is made in the proximal wrist crease overlying the flexor carpi radialis tendon. The portal is established in the usual manner (TECH FIG 2).
- It is not necessary to specifically identify the adjacent neurovascular structures, provided that the anatomic landmarks are adhered to.

**VOLAR RADIAL MIDCARPAL PORTAL**

- The volar aspect of the midcarpal joint can be accessed through the same skin incision as the volar radial portal.
- The capsular entry site through the volar radial midcarpal portal is entered by angling the trocar 1 cm distally and about 5 degrees ulnarward to the radiocarpal site.
- A hook probe can be inserted dorsally in the midcarpal radial portal for palpation.
- With tears of the palmar SLIL one can see the intact dorsal fibers and the volar surface of the capitate.

**VOLAR ULNAR PORTAL**

- The volar ulnar portal is established via a 2-cm longitudinal incision centered over the proximal wrist crease along the ulnar edge of the finger flexor tendons (TECH FIG 3).
- The tendons are retracted to the radial side and the radiocarpal joint space is identified with a 22-gauge needle.
- Care is taken to situate the portal underneath the ulnar edge of the flexor tendons and to apply retraction in a radial direction alone to avoid injury to the ulnar nerve and artery.
- The median nerve is protected by the interposed flexor tendons.
- The palmar region of the LTIL can usually be seen slightly distal and radial to the portal.
- A hook probe is inserted through the 6R or 6U portal.

**TECH FIG 3** • Technique for volar ulnar portal. **A.** Skin incision for volar ulnar portal. **FCR,** flexor carpi radialis tendon; **FDS,** flexor digitorum sublimis. **B.** FDS retracted, saline injection of radiocarpal joint. **C.** Insertion of cannula through capsule deep to FDS tendons. (From Slutsky DJ. The use of a volar ulnar portal in wrist arthroscopy. Arthroscopy 2004;20:158–163.)
**VOLAR DRUJ PORTAL**

- The volar DRUJ portal is accessed through the volar ulnar skin incision.
  - The joint is entered by angling the 22-gauge needle 45 degrees proximally.
    - It is useful to leave a needle or cannula in the ulnocarpal joint for reference.
  - Alternatively, a probe can be placed in the distal DRUJ portal and advanced through the palmar incision to act as a switching stick over which the cannula can be threaded.

- Initially, the space appears quite limited, but over the course of 3 to 5 minutes the fluid irrigation expands the joint space, which improves visibility.

- A 3-mm hook probe is inserted through the dorsal distal DRUJ portal for palpation.
  - A burr or thermal probe can be substituted as necessary.

- Direct visualization of the foveal attachment prevents accidental injury to this structure.
- The articular disc is seen superiorly.
- Proximal surface tears of the TFCC, which are usually caused by severe axial load, may be detected through this portal.
- The dome of the ulnar head lies inferiorly.
- The TFCC attachment to the sigmoid notch can be palpated with a hook probe in the distal dorsal DRUJ portal as it penetrates the dorsal DRUJ capsule.
- The deep attachments of the dorsal radioulnar ligament can be seen as it inserts into the fovea.

**DORSAL DRUJ PORTALS**

- The dorsal aspect of the DRUJ can be accessed through proximal and distal portals.
  - The proximal DRUJ portal is located in the axilla of the joint, just proximal to the sigmoid notch and the flare of the ulnar metaphysis.
    - This portal is easier to penetrate and should be used initially to prevent chondral injury from insertion of the trocar.
    - The forearm is held in supination to relax the dorsal capsule, to move the ulnar head volarly, and to lift the central disc distally from the head of the ulna.
    - Reducing the traction to 1 to 2 pounds permits better views between the ulna and the sigmoid notch by reducing the compressive force caused by axial traction.
    - The joint space is entered by inserting a 22-gauge needle horizontally at the neck of the distal ulna.
      - Fluoroscopy facilitates needle placement.

- The distal dorsal DRUJ portal is identified 6 to 8 mm distally with the 22-gauge needle, and just proximal to the 6R portal.
  - This portal can be used for outflow drainage or for instrumentation.
  - It lies on top of the ulnar head but underneath the TFCC and so is difficult to use in the presence of positive ulnar variance.
  - The TFCC has the least tension in neutral rotation of the forearm, which is the optimal position for visualizing the articular dome of the ulnar head, the undersurface of the TFCC, and the proximal radioulnar ligament from its attachment to the sigmoid notch to its insertion into the fovea of the ulna.
  - Because of the dorsal entry of the arthroscope, the course of the dorsal radioulnar ligament is not visible until its attachment into the fovea is encountered.
  - Entry into this portal provides views of the proximal sigmoid notch cartilage and the articular surface of the neck of the ulna.

**PEARLS AND PITFALLS**

- Use shallow skin incisions.
- Use the wound spread technique to protect surrounding sensory nerves.
- If the trocar does not insert easily, reposition to avoid chondral injury.
- Wrist traction often diminishes during the procedure and should be readjusted as needed to avoid scraping the articular surface.
- Use of a standard methodologic approach ensures a complete and thorough examination.

**POSTOPERATIVE CARE**

- The postoperative rehabilitation depends on the specific procedure that is performed.
  - After diagnostic arthroscopy, with or without débridement, the patient is splinted for comfort for a brief period of 4 to 7 days.

- Active wrist motion is encouraged after this period and patients are allowed activities of daily living, followed by gradual strengthening.
  - If a ligament repair or TFCC repair has been performed or if there is interosseous pinning, the protocol is adjusted as necessary and typically involves an initial period of immobilization before instituting wrist motion.
COMPLICATIONS

- Most of the complications related to use of the dorsal portals are related to injury to the sensory branches of the superficial radial nerve and the dorsal cutaneous branch of the ulnar nerve.
  - The palmar cutaneous branch of the ulnar nerve is at risk with the volar radial portal, although the interposed flexor carpi radialis tendon mitigates this risk.
  - There is no true internervous plane when using the volar ulnar portal; hence, sensory branches of the palmar cutaneous branches of the ulnar nerve or nerve of Henle are always at risk. Thus, proper wound spread technique is paramount.
  - The ulnar neurovascular bundle is also potentially at risk with overzealous retraction or poor portal placement.
  - Venous bleeding, loss of wrist motion (especially forearm supination), complications related to fluid extravasation, and infection are general risks attendant to any arthroscopic procedure.
  - These can be minimized by fastidious surgical technique, aggressive rehabilitation as necessary, and diligent follow-up in the early postoperative period.

REFERENCES

DEFINITION

- Motion in the human forearm is a complex interaction between the radius and ulna produced by the combination of multiple muscles working coherently and hinged at the proximal and distal radioulnar joints.
- Surgical reconstruction of diaphyseal forearm fractures requires precise realignment of both radius and ulna to minimize complications and maximize function.
- Ingenious surgical approaches have been described that allow the surgeon to follow defined internervous planes to the bones for internal fixation. The design of the forearm allows near 180-degree rotation combining with considerable elbow flexion-extension and wrist circumduction. To achieve this, the ulna is enlarged proximally, making it a principal bone of the elbow, and is smaller distally, while the reverse is true for the radius, with the enlarged radius being the primary articulation with the carpus. The result for the diaphysis of each bone is that the proximal ulna is metaphyseal for about 25% to 30% of its length but distally less than 10%, with the reverse holding true for the radius. Implant design has taken these differences into account, with many whole systems available for metaphyseal distal radius and proximal ulna fractures.
- The importance of maintaining the radial and ulnar heads has only recently been understood. New developments are taking place, therefore, for the management of distal ulna and proximal radius fractures.
- This chapter discusses ulna fractures distal to the junction of the proximal and middle thirds to the distal margin of the pronator quadratus (PQ) and radius fractures distal to the biceps tuberosity down to the distal flare of the radius.
- Pediatric fractures, distal radius and ulna fractures, olecranon and radial head fractures are not covered.
- Diaphyseal forearm fractures usually are classified according to the AO classification.

ANATOMY

- The surgical approaches to the forearm bones for fracture osteosynthesis involve five steps:
  - Finding an interval between longitudinally oriented superficial muscles
  - Finding and preserving vessels and nerves
  - Understanding the anatomy of deeper muscles that cross the forearm obliquely or transversely
  - Knowing where to lift these muscles to expose the bone
  - Understanding the shape of the bones themselves and their relation to one another

Radius and Ulna

- Motion of the forearm involves a complex interaction between the radius and ulna.
  - The radius rotates around a longitudinal axis that passes through the center of the radial head at the proximal radioulnar joint and through the center of the ulnar head distally.
  - With rotation, the radius rotates around the ulna, and the ulna moves in a varus–valgus direction about 9 degrees at the elbow. This allows the ulnar head to move out of the way of the rotating radius distally.
  - At the distal radioulnar joint (DRUJ), motion between 50 degrees pronation and 50 degrees supination is almost pure rotation, but at the extremes the radius translates in a dorsal direction during pronation and a palmar direction during supination.
  - Movement at the proximal radioulnar joint (PRUJ) is primarily rotation.
  - The radius and ulna have two bows that assist in getting out of the other’s way. Schemitsch and Richards quantified the importance of the distal of the two bows in the radius. Restoration of this bow is the single most important step in reconstruction of the forearm after diaphyseal fracture.
  - To determine whether the bow has been restored after osteosynthesis, draw a line from the biceps tuberosity to the sigmoid notch. A perpendicular line from the apex can then be measured (FIG 1). The normal range of bow is 15.3 ± 0.3 mm at a point at 60% of the radius measured between the bicipital tuberosity and the distal radius at the sigmoid notch.
  - At the apex of this bow on the convex side is the insertion of the pronator teres. This provides a biomechanical advantage for pronation.
  - The biceps insertion is at the apex of a smaller proximal bow. As a result, the biceps needs to be much larger to overcome the disadvantage of insertion into a small bow for balanced supination.
  - The arrangement in the ulna is the converse of the radius: a longer shallower proximal bow (the anconeus inserts into the apex for valgus of the elbow), and a small distal bow for the insertion of the PQ.
  - The radius and ulna are bound together essentially throughout their length, with the annular ligament at the PRUJ, the interosseous ligament through the middle 75%, and the ligaments of the triangular fibrocartilage complex.
Muscles and Ligaments

- The forearm is criss-crossed with longitudinal, oblique, and transversely directed musculotendinous units. These muscles are in layers, with longitudinal muscles more superficial and crossing muscles deeper.

- Most activities performed by the forearm, wrist, and hand occur from the midpronation position, with the wrist moving into extension and radial deviation, then in an arc accelerating past neutral again, to flexion and ulnar deviation (FUD, end of deceleration) before returning to wrist neutral. The forearm is designed to maximize the ability to perform this motion. This wrist motion is commonly known as the “dart thrower’s motion” or primary wrist motion.

- The extensor carpi radialis longus (ECRL), the cocking or lifting muscle of primary wrist motion, originates proximal to the lateral epicondyle on the supracondylar ridge, is positioned “above” the forearm, and inserts into the radial and dorsal aspect of the index metacarpal.

- On either side of the ECRL is the brachioradialis (BR), which originates high on the lateral supracondylar ridge, inserting on the radial styloid deep to the first dorsal compartment, and the extensor carpi radialis brevis (ECRB), which originates more distally just above the lateral epicondyle and inserts into the long finger metacarpal. ECRL and ECRB share the second dorsal compartment at the wrist.

- Together the BR, ECRL, and ECRB form a mobile wad above the forearm (in the functional position). They are innervated directly by the radial nerve and are best palpated just distal to the elbow.

- In a posterior approach to the radius, which is performed in pronation, after incising the deep fascia, the dissection interval is between the ECRB and the extensor digitorum communis (EDC) muscle. The EDC originates from the lateral epicondyle (where it shares a common origin with the extensor digiti minimi) and passes essentially in a straight line down the forearm, then through the fourth dorsal compartment at the wrist, just ulnar to Lister’s tubercle.

- In an anterior approach, which is performed in supination, the deep fascia is incised along the medial border of the BR. The BR is then mobilized radially and the interval between it and flexor carpi radialis is developed. The FCR, like the EDC, has a straight course in the forearm from the medial epicondyle to the scaphoid tubercle (where it passes en route to the index metacarpal).

- The muscle of utmost importance in approaches to the ulna is the flexor carpi ulnaris (FCU). It is the primary accelerator of the wrist, and thus has a large tendon (equal to the mechanical strength of the ECRL and ECRB combined), which originates from two heads, one from the medial epicondyle and one from the ulna. It proceeds straight down the forearm along the ulna border and inserts into the pisiform. From the distal tip of the lateral epicondyle originates the extensor carpi ulnaris, which runs down the forearm on the extensor side of the subcutaneous border of the ulna, sharing a septum with the FCU.

- The ulna is approached along this septum. The anterior surface and posterior aspects of the ulna can be approached this way. The true anterior approach to the ulna is along the radial edge of the FCU, mobilizing the ulna neurovascular bundle and going between the FCU and the flexor digitorum profundus (FDP). The FDP occupies the floor of most of the flexor compartment of the forearm.

- Crossing the forearm in its deepest parts are a series of obliquely oriented muscles. The supinator plays a role in both the anterior and posterior approaches to the radius. It has two heads of origin and probably can be thought of as two muscles, because the fibers of each head traverse in different directions.

- The ulnar head attaches to the supinator crest on the radial side of the ulna. Its fibers are transverse (like those of the PQ distally) and attach to the most proximal part of the radius, deep to the posterior interosseous nerve (PIN).

- The humeral head attaches to the lateral epicondyle, deep to the ECU and anconeus. Its fibers slope down the forearm more longitudinally, and wrap over the deep or ulnar head to attach to the radius distal to the ulnar head of the supinator and proximal to the insertion of the pronator teres.

- In an anterior approach to the radius, the forearm is supinated, protecting the PIN, and the humeral head of the supinator is lifted from its most ulnar attachment.

- The pronator teres originates mainly from the medial supracondylar ridge, arches obliquely across the ulnar artery and median nerve, and inserts into the apex of the larger bow of the radius. Distally, it is superficial, but distally, where it must be lifted from the radius, it is deep to the BR muscle (FIG 2). It must be lifted from the most radial aspect of the radius in the anterior approach.

- Distally in the floor of the anterior compartment the PQ muscle comes into play in anterior approaches to the radius and ulna. It must be lifted from the radial border in an approach to the radius and the ulna border in an approach to the ulna.

- In a posterior approach to the radius, the abductor pollicis longus muscle drapes across the radius just distal to its midpoint. It can be lifted to allow plate fixation to this part of the radius. Its ulnar origin is always left intact.

- Cross-shaped muscles are especially the flexor digitorum superficialis and flexor digitorum profundus, the superficialis being crossed over the deepis.
Nerves
- The forearm is traversed longitudinally with three major nerves plus an additional three sensory nerves, only one of which is of surgical importance. Once the interval between muscles is breached, care is taken to find these nerves. Each nerve enters the forearm from a predictable place, and each gives off key branches that must be protected.
- Although the radial nerve supplies all the extensor muscles of the arm and forearm, it is an anterior structure after it pierces the lateral intermuscular septum 10 cm above the elbow.
- At the elbow the radial nerve lies between the BR and the brachialis and gives off the PIN.
- The radial sensory nerve continues deep to the BR muscle, on its undersurface. Here, the nerve generally lies close to the radial artery. The anterior approach to the radius is through the interval between the nerve and artery.
- The posterior interosseous branch leaves the main nerve just distal to the elbow and passes through the supinator muscle, between its two heads, to enter the dorsal or extensor compartment of the forearm.
- As it leaves the supinator, it fans into multiple variable branches to supply the EDC, EDM, and ECU, with the majority of the nerve continuing distally deep to the interval between EDC and ECRB.
- The course of the ulnar nerve is represented by a line drawn from the medial epicondyle to the pisiform. Throughout the forearm the nerve is deep to the FCU muscle and lies deep and slightly radial to the tendon of this muscle at the wrist. Throughout most of the forearm the nerve is between the FCU and the FDP.
- The median nerve enters the forearm between the brachial artery and the tendon of the biceps brachii. It lies deep to the pronator teres, then passes deep to the fibrous arch of the FDS. The nerve is closely associated with the undersurface of the FDS as it travels distally.

Blood Supply
- The vascular anatomy is of critical importance in the flexor compartment.
- The brachial artery enters the forearm deep to the lacer-tus fibrosus, next to the median nerve. It almost immediately branches into radial and ulnar arteries.
- The ulnar artery passes deep to the arch of origin of the FDS to lie next to the ulnar nerve throughout the distal two thirds of the forearm.
- The radial artery is pushed more superficial by the bulk of the FDS and the pronator teres lying just deep to the fascia along the medial border of the BR muscle.

PATHOGENESIS
- The degree of injury and specifics of the fracture are directly related to the magnitude, direction, and duration of energy.
- Both-bone forearm fractures are common in motor vehicle trauma.
- Industrial trauma often is associated with a high level of soft tissue injury.
- Forearm fractures occur relatively commonly in some sports, eg, rugby in all its forms and wrestling.
- The most common mechanism of injury is a direct blow to the mid-forearm. If this blow is directed primarily at the ulna, an isolated ulna shaft fracture results ("nightstick" fracture).
- An isolated radius fracture often is associated with a fall onto an outstretched hand.

NATURAL HISTORY
- Normal function of the human forearm requires the radius to rotate around the ulna.
- Matthews showed in a cadaveric study that 10 degrees of angulation of one or both bones of the forearm results in a loss of 20 degrees of pronation and supination. Thus, the natural history is highly dependent on the position of healing of the two forearm bones.
- It is reasonable to consider nonoperative treatment of an isolated ulna fracture with less than 10 degrees angulation, but nonoperative treatment of both-bone forearm fractures has a poor outcome.

PATIENT HISTORY AND PHYSICAL FINDINGS
- In most cases, the initial presentation of a radius or ulna diaphyseal fracture makes the diagnosis obvious. Most fractures are displaced due to the high-energy nature of the traumatic event and, therefore, deformity is common. Patients with nondisplaced fractures usually have considerable pain and swelling in the forearm.
- Despite the ease of initial diagnosis, the treating physician must be on guard for significant associated injuries and complications, not only of the bone and joint but also of soft tissue.
- A systems approach to these associated injuries is as follows:
  - Skin: Look at the skin for any evidence of laceration or abrasion. A laceration may communicate with the fracture site; therefore, a contaminated abrasion at the site of surgical incision should be allowed to heal before surgery.
  - Fascia: Tense tissues to palpation over the flexor or extensor compartments and pain with passive finger extension are evidence of compartment syndrome, and compartment release must be considered.
  - Vascular: Radial and ulnar pulses distal to the site of injury must be palpated and compared to the uninjured side. These pulses can be difficult to palpate due to the proximity of the fractures, so checking capillary refill in the digits is the next step. In the multiply injured patient, the peripheries are shut down, making capillary refill and pulses difficult to perform. In such a situation, a needle stick to the digit should reveal bright red blood.
  - Nerve: Assessment of nerve injury is summarized later in this chapter.
  - Bone: The joints above and below the fracture must be palpated for associated joint disruption.
- For any upper extremity injury, a history of the causative event is essential to understand the degree of energy that the limb has had to absorb. Given the common association with high energy, the patient must be assessed according to an appropriate trauma checklist protocol.
- The patient must be questioned specifically regarding elbow or wrist pain, and neurologic symptoms of numbness, tingling, or unusual sensation in the hand. Severe pain should suggest the possibility of compartment syndrome or vascular injury.
- Palpation of the mid-forearm should be gentle, step by step feeling along the radius and ulna. A tense forearm may indicate a compartment syndrome.
Palpation should then proceed over the DRUJ and ulnar head plus PRUJ and radial head. Palpation should be performed of the medial and lateral epicondyles, of the scaphoid in the snuff box, and over carpal bones and the carpometacarpal joints.

A systematic examination of the median, ulnar, and radial nerves involves examination of sensory and motor aspects (Table 1).

- The sensory examination involves static two-point discrimination of the digital nerves and light touch over the autogenous zones of each nerve.
- Motor examination is graded by Medical Research Council (MRC) grading and is done by stressing the appropriate joint and palpating the affected muscle.

### IMAGING AND OTHER DIAGNOSTIC STUDIES

- High-quality plain radiographs of the forearm, wrist, and elbow are the mainstay of diagnosis of diaphyseal radius and ulna fractures.
- Mino16 described a technique to interpret the lateral wrist radiograph whereby the radial styloid is aligned with the center of the lunate, and an assessment of the overlap of the radius and ulna is made. The head of the ulna should be completely obscured by the radius. If only part of the ulnar head is obscured by the radius, then there is subluxation of the head; if the ulnar head is clearly seen, there is dislocation. Any shift in the ulnar head is a subluxation and, when combined with a radius fracture, represents a Galeazzi fracture-dislocation.9
- A CT scan in neutral, pronation, and supination is useful in interpreting the degree of DRUJ congruity. This is rarely used in the acute setting.

### DIFFERENTIAL DIAGNOsis

- Pathologic fracture may result from a number of causes.
- **Metabolic causes:** osteoporosis, estrogen deficiency, renal transplantation, vitamin D deficiency, parathyroid disease, Cushing disease, hyperthyroidism, hypogonadism, hypophosphatasia
- **Primary tumors:** osteosarcoma, Ewing sarcoma and primitive neuroectodermal tumors, chondrosarcoma, myeloma, fibrous histiocytoma, desmoplastic fibroma, hemangioma, intraosseous lipoma, acute myeloid leukemia, Langerhans’ cell histiocytosis, fibrous dysplasia, chondroblastoma
- **Metastatic tumors:** breast, thyroid, lung, prostate, melanoma
- **Infection:** osteomyelitis, tuberculosis
- **Congenital disorders:** Turner syndrome, neurofibromatosis, pseudoarthrosis, osteogenesis imperfecta
- **Iatrogenic fracture:** post–plate/screw removal; post–osteocutaneous radial forearm flap; post–elbow, forearm, and wrist manipulation
- **Stress fracture**

### NONOPERATIVE MANAGEMENT

- Slight deviations in the spatial orientation of the radius and ulna will significantly decrease the forearm’s ability to rotate, impairing hand function.

MRC, Medical Research Council system.
Fractures of the radius and ulna can be regarded as articular fractures in the sense that functional restoration requires anatomic reduction.

The only indication for nonoperative treatment is a nondisplaced fracture of the ulna,14,21 or if the patient’s general condition makes operative treatment ill advised.

In the case of a displaced fracture, closed reduction and cast immobilization sometimes is possible but is unreliable. Loss of initial satisfactory reduction is common.3,8,12,13

The treatment of choice for adult diaphyseal forearm fractures is open reduction and internal fixation.1,7,20

SURGICAL MANAGEMENT

The most common scenario is fractures of the radius and ulna in the middle third of both bones. The most common questions confronting the surgeon are considered here.

Which approach should be used?

- The anterior surface of the radius and ulna is the best location for a plate. This surface is broad and flat on both bones, and a plate on this surface is covered with muscle, resulting in less plate irritation for the patient.
- Consequently, I prefer the anterior approach to both the radius and the ulna. In addition, the patient is positioned supine for these approaches, reducing the need to reposition the patient during the procedure.
- Should one or two incisions be used?
  - Use of two incisions markedly decreases the risk of synostosis, decreases the length of the incision, and reduces tension on the skin and soft tissue by retractors.
  - Which bone should be stabilized first?
    - The fracture with the least comminution should be approached first and stabilized. This allows for length to be restored in the forearm, allowing easier judgment of length in the more comminuted bone.

Where there is equal comminution or no comminution, the radius is generally approached first.

Should fixation be completed on one bone before approaching the other?

- I recommend not completing fixation but stabilizing one bone before proceeding to the next. This allows reduction of the second bone.
- In a stable, non-comminuted fracture, “temporary stability” may mean a plate and one screw through two cortices on each side of the fracture. In a comminuted fracture, it may mean four cortices and two screws on each side.
- Completion of fixation should occur after the second bone is reduced and stabilized.
- What implant and what length of implant should be used?
  - The plate must span the fracture complex and provide six cortices of fixation in stable bone, both proximally and distally.
  - Non-comminuted transverse fractures require at least a six-hole small fragment limited contact–dynamic compression (LC-DC) or locking plate.
  - Oblique fractures and comminuted fractures require a longer plate. Oblique fractures are treated with an interfragmentary screw or screws at right angles to the fracture line and a seven-hole plate.
  - A unicortical locked screw can be considered “bicortical,” but practically speaking, this rule is used only for the screw hole furthest from the fracture. In almost all situations there must be three screw holes in the plate over stable bone away from the fracture complex.
  - In distal metaphyseal, diaphyseal fractures of the ulna, it often is impossible to get six cortices of fixation. In this situation, two mini fragment plates (with 2.7-mm screws) applied at a 90-degree angle to each other provides excellent fixation.

Anterior and posterior approaches can be used to treat fractures along the entire length of each bone. The anterior approach to the radius is preferred when possible.

- This location allows for excellent soft tissue coverage, reducing the need for plate removal.
- Most diaphyseal forearm fractures are best stabilized by plates and screws, but other implants sometimes are indicated.
- External fixation may be used in the following settings:
  - Open fractures with severe soft tissue damage, as a temporizing measure until reconstruction can safely be undertaken
  - Maintenance of length in fractures with severe bone loss (this usually occurs in open fractures)
  - Patients with multiple injuries (“damage control” surgery)
  - The Ilizarov technique is useful in segmental fractures, especially when the fractures are very close to the wrist and elbow joints.
  - Intermedullary nailing is used in the following settings:
    - Young women who desire a better cosmetic result
    - Segmental fractures
    - Re-fracture at the bone plate interface in a contact athlete or following plate removal

Preoperative Planning

- The surgeon must develop a strategy to achieve satisfactory alignment of the radius and ulna with congruency of the PRUJ and DRUJ.

FIG 3 • The Bado classification of Monteggia lesions lists four types, depending on the direction of the radial head. In type I lesions the head is anterior to the distal humerus. In type II lesions it is posterior, and in type III lesions it is lateral. Type IV fracture-dislocations involve a dislocation of the radial head associated with a fracture of both the radius and the ulna.
Factors that must be considered include the following:
- Operating room time and availability (ideally within 7 days of the injury)
- Implant and equipment availability (eg, a distraction device)
- Patient factors and patient support factors (in outpatient surgery a supportive family or friend is needed in the early postoperative period)
- Regional versus general anesthesia
- Standard AO planning18 consists of drawing the fragments on transparent paper; superimposing the transparent sheets to align the bones; adding a chosen implant template; and drawing the final outcome corresponding to the expected postoperative radiograph. With experience in fracture management, these steps are intuitive.
- AO principles of internal fixation using plates and screws should be reviewed by the surgeon before attempting internal fixation.

Positioning
- Generally, the patient is positioned supine and the hand table is attached to the main table so the midpoint of the hand table is directly opposite the patient’s shoulder. The shoulder is directly over the adjoining point of the hand and main tables. The arm is abducted to 90 degrees at the shoulder, so the entire arm lies across the midpoint of the hand table.
- In the case of a posterior approach to the proximal ulna, the patient is positioned supine and a pillow is placed across his or her chest and secured with broad paper tape to the operating table. A hand table is used to rest the instruments rather than support the upper extremity. If other forearm fractures are present, however, the arm table may then be available.
- A non-sterile tourniquet is applied to the upper arm before prepping and draping the patient.
- The surgeon usually is seated on the side of the hand table closest to the bone being reduced and stabilized.
- For the anterior approach to the radius, the surgeon is on the side of the table closest to the patient’s head. The forearm is supinated and the elbow extended. For a posterior approach to the radius, the forearm is pronated and the elbow extended.
- For a posterior or subcutaneous approach to the ulna, the elbow is flexed, and the forearm is in a neutral position.

Approach
- The anterior approach to the radius is the standard approach for a radius fracture, but the posterior approach is useful when soft tissue lesions are posterior or the anterior approach is compromised in some way.
- The posterior or subcutaneous approach to the ulna is the common approach. I prefer an anterior approach, however, because the anterior border of the ulna is flat, and, therefore, the plate fits better and is buried deep to the FCU and FDP muscles, reducing plate irritation.
- In general, the incision is 2 cm longer than the implant to be utilized.

ANTERIOR APPROACH TO THE RADIUS
- The anterior approach to the radius, first described by Henry,17 is one of the classic approaches in orthopaedic surgery.
- A straight metallic instrument is placed on the forearm skin, and a C-arm image is taken to judge the position of the fracture. The skin is marked (TECH FIG 1A).
- The biceps tendon and radial styloid are found and marked. The diathermy cord is extended between these points (TECH FIG 1B), and the skin incision is marked centered on the fracture site (TECH FIG 1C).
- The skin is incised, and the superficial tissues are carefully dissected, looking for the lateral antebrachial cutaneous nerve (lateral cutaneous nerve of the forearm) (TECH FIG 1D).
- At the level of the deep fascia, a Raytech (Raytech Industries, Middletown, CT) is used to sweep the soft tissues so that the ulnar edge of the BR can be seen (TECH FIG 1E).
- The deep fascia is incised along the ulnar edge of the BR, and the BR is mobilized and lifted (TECH FIG 1F). The radial nerve and radial artery are found deep to the BR.
- The interval between the radial artery and nerve is opened (TECH FIG 1G,H), exposing the radius.
- The radial aspect of the pronator teres insertion is dissected off the radial shaft, in this case exposing the distal fragment (TECH FIG 1I).
- For more proximal exposure, follow the radial sensory nerve proximally to the place where it and the posterior interosseous nerve bifurcate (TECH FIG 1J).
- The supinator is dissected off the ulnar aspect of the radius to protect the PIN, thus exposing the proximal fragment (TECH FIG 1K).
- The fracture is then reduced and held following AO principles. I prefer six cortices of screw fixation on either side of the fracture and currently use the Synthes Small Fragment Locking Compression Plates as fixation.
TECH FIG 1 • (continued) B. The estimated level of the fracture is marked. The radial styloid and biceps tuberosity are marked, and the diathermy cord is placed between these two points to align the incision. C. The incision is centered on the fracture. The length of the incision depends on fracture comminution, the primary determinant of implant length. The most common implant used is a seven-hole 3.5-mm small fragment plate, and the incision is 2 cm longer than the implant. D. The incision is made and the lateral cutaneous nerve of the forearm is isolated in the superficial fat and preserved. E. The incision is continued to the deep fascia, and the fascia is swept with a Raytech sponge (Raytech Industries, Middletown, CT). The fascia is incised at the ulnar edge of the brachioradialis. F. The brachioradialis muscle and tendon are mobilized. G. The radial artery and radial nerve are located, and the dissection is continued through the fascia between these structures. H. The radius is exposed over the length of the incision. I. The pronator teres insertion is dissected off the radial shaft from the radial aspect of the bone, in this case exposing the distal fragment. J. In this image, the elbow is at the top. For proximal exposure of the radius, the superficial radial nerve is traced proximally to the posterior interosseous branch. K. The elbow is to the right in this image. The supinator is dissected from the ulnar aspect of the radius to protect the posterior interosseous branch of the radial nerve, exposing the proximal fracture fragment.
POSTERIOR APPROACH TO THE RADIUS

- The posterior approach to the radius also is known as the dorsolateral approach or Thompson’s approach.24
- Lister’s tubercle is palpated at the dorsal aspect of the distal radius and marked. The lateral epicondyle of the humerus is palpated and marked.
- The diathermy cord is extended between these bony prominences, and the skin incision is centered on the fracture site.
- A straight metal instrument is placed transverse to the forearm, and fluoroscopy is used to find the level of the fracture site, which is marked with a transverse line.
- The approach uses the theoretical internervous plane between the ECRB (radial nerve) and the extensor digitorum (PIN; TECH FIG 2A).
- The ECRB is part of the mobile wad of Henry,10 which also includes the BR and the ECRL. This usually can be palpated and can help guide placement of the skin incision.
- After the skin incision and superficial dissection are performed, the interval between the ECRB and EDC is opened distally where the abductor pollicis longus transversely spans the forearm (TECH FIG 2B).
- Extending the interval proximally reveals the PIN as it leaves the supinator. Here, it is always accompanied by a leash of vessels, the posterior interosseous artery, and its venae communicantes.
- The surgeon must be cautious at this stage, because as it leaves the supinator, the PIN quickly gives off small branches to the EDC and ECU. The main nerve at

TECH FIG 2 • Posterior approach to the radius. A. After incising the deep fascia, the interval between the extensor carpi radialis brevis and the extensor digitorum communis muscles is identified. B. The interval between the extensor carpi radialis brevis and extensor digitorum is developed. C. Further dissection of the interval proximally with splitting of the aponeurotic origin of the extensors reveals the supinator and the posterior interosseous nerve as it leaves the arcade of Frohse. D. Development of the interval between extensor carpi radialis brevis and extensor pollicis longus reveals the radius distal to the extensor pollicis brevis. Proximally, the nerve can be mobilized where it exits the supinator if required. The posterior interosseous nerve should be identified and protected throughout the whole procedure.
this stage can become relatively small, taking on the appearance of a branch.
- Branches to the long muscles to the thumb also can come off relatively high, giving a fan-like appearance to the nerves and branches (TECH FIG 2C).
- The PIN must be mobilized from the deep head of supinator. The deep head is then split to reach the radius proximally. Fibers of the pronator teres encroach into the field over the middle radius, and distally the abductor pollicis longus must be carefully lifted from the radius to provide room for the plate (TECH FIG 2D).
- The fracture is then reduced and held with a plate and screws. I prefer a locked small fragment plate (Synthes) with six cortices on either side of the fracture.
- The deep fascia is closed, followed by the skin.

**ANTERIOR APPROACH TO THE ULNA**

- The anterior approach is my preferred approach for fixation of the distal two thirds of the ulna, because the plate is buried deep to the FCU and FDP muscles and the anterior surface of the ulna is flat, much like the anterior surface of the radius. This allows for minimal contouring of the plate and minimal overhang of the plate over the borders of the bone.
- The bony landmarks for the incision are the medial epicondyle of the humerus and the ulnar aspect of the pisiform at the wrist.
- As with the radius approach, the diathermy cord can be extended between these two points, a straight metal instrument can be placed on the patient transverse to the long axis of the forearm, and a C-arm image taken to confirm that the incision is centered on the fracture site (TECH FIG 3A).
- The skin incision should be through skin and dermis only.
- If the fracture is relatively distal, care should be taken to avoid injuring the dorsal branch of the ulnar nerve, which exits between the FCU and the ulna about 4 cm proximal to the ulnar head.
- The dissection continues directly deep down to the fascia overlying the FCU muscle. The epimysium and fascia are incised in the line of the incision (TECH FIG 3B), and the

**TECH FIG 3 • Anterior approach to the ulna. A.** The radial incision has been temporarily closed with staples. The medial epicondyle and ulnar aspect of the pisiform are marked. Using a similar technique to that described in Tech Fig 1A, with C-arm fluoroscopy and diathermy lead, the incision is centered on the fracture. **B.** The deep fascia and epimysium of the flexor carpi ulnaris are opened. The fascia is mobilized off the FCU and followed around the ulnar border of the muscle. **C.** The interval between the flexor carpi ulnaris and extensor carpi ulnaris is incised, and the ulna exposed subperiosteally at the level of the fracture site. A Hohmann retractor lifts the FCU. **D.** The flexor digitorum profundus and distally the pronator quadratus are lifted, the fracture is reduced, and a locked small fragment plate applied. (The elbow is to the left and the wrist to the right.)
dissection continues superficial to the FCU muscle ulnarly around onto the ulna (TECH FIG 3C).

- Dissection is continued proximally and distally in the interval between the FCU and ECU, and the fracture is reduced and held with a locked small fragment plate (Synthes; TECH FIG 3D).

- I prefer to use six cortices of fixation on either side of the fracture, but this is not possible within 3 cm of the ulnar head. In this situation, two 2.7-mm mini-fragment plates are placed at right angles to each other.

- The fascia and epimysium are closed together, and skin closure follows.

### POSTERIOR APPROACH TO THE ULNA

- The posterior approach is preferred for fractures of the proximal third of the ulna diaphysis but can be used to expose the entire ulna.
- Distally, the dorsal branch of the ulna nerve is at risk where it exits between the FCU and the ulna, but it usually passes distal to the head of the ulna where it crosses the ECU tendon sheath and the extensor retinaculum.
- The interval for the approach is between the ECU and FCU, which share a short fascial septum along most of the length of the ulna.
- The olecranon and ulnar head can be palpated on all patients, and marked. In slim individuals, the fracture and the entire subcutaneous border of the ulna can be palpated.
- The incision is centered on the fracture, over the subcutaneous border or in line with the olecranon and ulnar head.
- The incision is deepened down to the fascia, and in most cases the epimysium over the ECU is opened. The ulna is exposed in the interval between the ECU and FCU distally and between the FCU and anconeus proximally.
- The fracture is reduced and held following AO principles with a locked small fragment plate. The plate usually is placed on the lateral surface of the ulna.

### FRACTURE REDUCTION AND FIXATION

- Once the bone is reached by an anterior or posterior approach, reduction and fixation are performed.
- Bone-holding clamps allow delivery of the fracture ends into the wound (TECH FIG 4A).
  - For an oblique fracture, a lobster claw bone reduction clamp is placed on either side of the fracture site and angled about 30 degrees to the longitudinal axis of the bone. This allows control of both fracture fragments.
- The fracture fragments are completely cleaned of all soft tissue debris (TECH FIG 4B).
- The fracture fragments are reduced using longitudinal traction and rotation (TECH FIG 4C).
- Once this is accomplished provisional stability is obtained using a bone clamp across the fracture site (TECH FIG 4D).

- The clamp is then lifted and the plate slid beneath and the clamp replaced (TECH FIG 4E).
  - The two screw holes closest to the fracture are filled first, followed by placement of an interfragmentary screw (TECH FIG 4F).
- In both-bone fractures, the second bone is now approached and stabilized in a similar manner before final fixation of the first fracture.
- Locking (TECH FIG 4G) or non-locking screws are placed in the remaining open screw holes, and fixation is complete (TECH FIG 4H).
Chapter 4  ORIF OF DIAPHYSEAL FOREARM FRACTURES

**TECH FIG 4 (continued)**

C. Fracture reduction is obtained using longitudinal traction, and rotation applied through the lobster clamps. D. The lobster-claw bone clamp temporarily secures the fracture site. E. The clamp is lifted and the plate slid beneath. F. One screw on each side of the fracture and closest to the fracture is placed first, followed by an interfragmentary screw. G. Locking guides attached to the proximal two holes allow placement of the locking screws in this Synthes plate. H. Fixation is complete.

**PEARLS AND PITFALLS**

</tbody>
</table>
POSTOPERATIVE CARE

- The key points in immediate postoperative care are splinting, pain relief, elevation of the extremity, and watching for signs of complications.
- The patient usually receives axillary block anesthesia, which allows him or her to return home pain-free.
- A sugartong splint is placed at the time of surgery and is worn for 2 weeks, at which time the patient returns to the office for a removal of splint and sutures.
- Narcotic pain relief usually is ceased at 2 weeks.
- Radiographs of the wrist, elbow, and forearm are ordered at the 2-week visit.
- At the 2-week visit the patient is referred for physical therapy and rehabilitation to work on ROM of the elbow, forearm, and wrist using active and gentle active assisted exercises.
- From 2 to 6 weeks, the patient is given a 5-pound weight lifting restriction and is placed on restricted work duty, including no repetitive forearm twisting, until union occurs.
- At 6 weeks, simple two-part fractures usually are united and all lifting and twisting restrictions are removed. If there is no evidence of union, the patient is placed on a 20-pound weight restriction until union has occurred.

OUTCOMES

- In two-part fracture of the radius and ulna, patients can expect over 95% problem-free consolidation before 6 months. In a study by Hertel,11 out of 132 patients there were two delayed unions and two non-unions that required reoperation. Plates were removed from 70 patients (53%) at a mean of 33.1 months (range 8–122 months) after the first operation. In this group, there were three refractures (4.3%) occurring at a mean of 8.7 months (range 0–14) after plate removal. In another study by Chapman,9 98% of the fractures united, and 92% of the patients achieved an excellent or satisfactory functional result.
- Nonunion rates are much higher in comminuted fractures, approximately 12%, but it has been shown that bone grafting primarily does not lead to improved outcomes.19

COMPLICATIONS

- Complications of forearm fractures include compartment syndrome,6 malunion,23 nonunion,5 and radioulnar synostosis.4 The rate of infection is about 2%.7
- In a study by Stern23 of 64 adult patients with 87 diaphyseal forearm fractures treated by plating, 18 patients (28%) had a major complication. There was a nonunion rate four times higher for bones plated with four screws than six screws, and screws loosened in three fractures, all involving the ulna. Radioulnar synostosis occurred in seven forearms, and in five of these the forearm injuries were associated with multiple-system trauma involving head injury. Two patients had osteomyelitis.
- The surgeon must be aware of the DRUJ and PRUJ dislocation associated with either an isolated or both-bone forearm fracture.
- With attention to detail, using the appropriate anatomic approach, accurate reduction, and the use of hardware that provides adequate bone stability, outcomes from diaphyseal fractures of the forearm are as good as any in orthopaedic surgery.

REFERENCES

DEFINITION
- In 1934 Galeazzi described a fracture of the junction of the middle and distal thirds of the radius and called attention to the associated dislocation or subluxation of the distal radioulnar joint (DRUJ).
- Garcia-Elias and Dobyns divided DRUJ dislocations into three types:
  - Type I: Pure soft tissue dislocations
  - Type II: Intra-articular fracture dislocations where there is a fracture involving the joint surface of the sigmoid notch of the radius
  - Type III: Extra-articular DRUJ fracture dislocations for subdivided
- Type III fracture-dislocations can be subdivided as follows:
  - IIIa: abnormal joint surface orientation; usually involve fractures of the distal two thirds of the radius without complete longitudinal disruption of the forearm
  - IIIb: radioulnar length discrepancy; fractures of the distal two thirds of the radius with complete longitudinal disruption of the forearm; also known as Essex-Lopresti injuries
- In this chapter, the term Galeazzi fracture-dislocation refers to a type IIIa (extra-articular) fracture of the distal two thirds of the radius with any disruption at all of the congruency of the DRUJ due to soft tissue injury.
- Management of the fractured radius is discussed elsewhere (see Chaps. HA-8 to HA-13). A fracture of the ulna styloid commonly is associated with a distal radius fracture. Reduction and fixation of this fracture is covered in Chapter HA-14.

ANATOMY
- During forearm rotation a complex interaction occurs between the radius and the ulna.
- From about 50 degrees pronation to 50 degrees supination there is a nearly pure rotation of the radius around the ulna, with the center of rotation through the middle of the ulna head. The ulna head moves out of the way of the radius by virtue of a 9-degree varus-valgus motion that occurs at the elbow.
- At 50 degrees supination or pronation, a translational slide of the radius occurs on the ulna at the DRUJ.
- In full pronation the radius slides volar, making the ulna head prominent dorsally. The opposite takes place in full supination.
- The head of the ulna is the keystone of the DRUJ. It is flattened distally adjacent to the triangular fibrocartilage disc and rounded radially articulating with the sigmoid notch of the radius. The sigmoid notch of the radius is only mildly concave but is functionally deepened by a horseshoe-shaped labrum. A flimsy, somewhat loose capsule attached to this labrum allows the nearly 180 degrees of rotation required of the forearm.
- The capsule is relevant only when it is thickened, causing a contracture and limitation in forearm motion.
- Considerable incongruity exists between the curvature of the sigmoid notch and the radius. The sigmoid notch of the radius is only mildly concave but is functionally deepened by a horseshoe-shaped labrum. A flimsy, somewhat loose capsule attached to this labrum allows the nearly 180 degrees of rotation required of the forearm.
- The triangular fibrocartilage is a specialized structure, part meniscus (to allow compression accommodating the relative shortening of the radius in pronation) and part ligament. It has palmar and dorsal fibrous thickenings known as the palmar and dorsal radioulnar ligaments. These attach to the distal palmar and dorsal rims of the sigmoid notch as separate bundles, and have superficial fibers that attach to the ulna styloid and deep fibers that criss-cross to form a weave as they attach to the foveal fossa of the distal ulna adjacent to the head. These ligaments, along with the distal aspect of the interosseous membrane, are the most important primary stabilizers of the DRUJ.
- During rotation, the deep interdigitating fibers create a screw home mechanism, similar to the cruciate ligaments of the knee.
- In pronation the deep fibers of the dorsal radioulnar ligament are taut and the superficial fibers are lax, whereas the superficial fibers of the palmar radioulnar ligament are taut and the deep fibers are lax.
- The opposite is true in supination. Avulsion of the foveal attachment is common in Galeazzi injuries.

PATHOGENESIS
- The most common mechanism of injury is an axial load in pronation, associated with wrist hyperextension.
- Acute dislocations of the DRUJ also can occur in supination. This usually happens after a fall with a rotating body on an outstretched hand, but also can occur in the workplace when the forearm is twisted by rotating machinery.
- The direction of force is radial to ulnar and proximal to distal, through the radius fracture down the interosseous membrane, and through the DRUJ.
- The DRUJ zone of injury includes the capsule, avulsion of the foveal attachment of the palmar and dorsal radioulnar ligament, and tear of the extensor carpi ulnaris (ECU) subsheath.

NATURAL HISTORY
- Hughston, in 1957, brought attention to the poor outcome of these fracture-dislocations without surgical intervention. The criteria used for a perfect result were very strict, leading to a judgment of poor results in 92% of cases. This injury complex has been termed “the fracture of necessity,” meaning open reduction and internal fixation of the radius is necessary for a good result.
- Milic drew attention to the significance of the DRUJ injury. He advocated reduction and percutaneous K-wire fixation, noting poor results otherwise.
Experiments have shown that with an artificial osteotomy of the radius, up to 5 mm of radial shortening occurs. Shortening of more than 10 mm does not occur unless both the interosseous ligament and the triangular ligament are sectioned. Alexander and Lichtman added another subcategory of Galeazzi injury, those in which closed reduction cannot be achieved. The natural history of injuries in this subcategory depends on the recognition and appropriate management of neurologic and vascular complications, in addition to the adequacy of reduction and the degree of DRUJ instability. The DRUJ component of Galeazzi fracture dislocations, after anatomic reduction and fixation of the radius, can be considered simple (ie, able to be reduced closed) or complex (ie, requiring open reduction). Once reduced, the DRUJ is re-examined and judged stable or unstable.

PATIENT HISTORY AND PHYSICAL FINDINGS

Lister stated “nothing influences the eventual recovery of hand function more than the mechanism and the force of the injury.” This is certainly true for forearm injuries. Accurate anatomic bone anatomy is required for perfect functioning of the forearm during rotation. Patients with a Galeazzi fracture-dislocation usually present acutely to an emergency department due to the severity of the pain. Three common mechanisms lead to Galeazzi injuries: falls, industrial accidents, and motor vehicle trauma.

It is important to elicit information regarding the degree of energy associated with the injury. A fall off a ladder from a height or from a roof is associated with much greater energy than a ground-level fall. In industrial accidents, the worker will tend to use technical jargon in referring to machinery, but the examiner must obtain a layman’s description of the machinery and get an accurate idea of the force the machinery will generate. Any motor vehicle accident is associated with high energy. Any crushing component to the injury must be elicited. Initially, the fracture pain may overwhelm both the patient and the examiner. Reassessment of the patient following a radiograph showing a radius fracture in the presence of an intact ulna should direct the examiner to the DRUJ as a site of pathology. The patient must be asked about neurologic symptoms in the hand, in particular numbness and tingling in the median nerve distribution. Acute carpal tunnel syndrome and forearm and hand compartment syndromes must be ruled out in the Emergency Department. Forearm swelling and tenderness with dorsal prominence of the distal ulna (ie, caput ulna deformity) will be observed. The entire carpus and the elbow should be palpated to rule out any longitudinal forearm injury (ie, Essex Lopresti injury). Forearm, wrist, and digital motion often are extremely limited due to pain.

FIG 1 • Intraoperative distal radioulnar joint (DRUJ) shuck test. The head of the ulna is held with a chuck pinch grip, and the wrist and distal radius are held with a span grasp with the thumb extended across the wrist joint. The radius is held firmly and the ulna is moved back and forth in a palmar-dorsal direction. The test is done first in neutral (A), then in supination (B) and in pronation (C).
A sensory examination using static two-point testing is the most reliable Emergency Department examination for sensation. Vascularity is best assessed by examination of radial and ulnar pulses together with capillary refill in the fingers.

- Often the fingers are pale in this situation. A needle stick to the digital pulp should cause bright red bleeding.
- The fingers must be passively extended to rule out a forearm compartment syndrome. Inability to extend the fingers combined with tense forearm swelling are the best indicators of a compartment syndrome, which if present, necessitates urgent surgery.
- Patients presenting late, in the office, usually complain of ulnar-sided wrist pain, pain with activities requiring pronopronation, and DRUJ instability. In these situations the radius often is malunited or there is unrecognized bowing of the ulna.
- The DRUJ is examined initially by direct observation, looking for a caput ulna deformity. Palpation begins at the radial head, along the intersosseous membrane to the ulnar head. Tenderness at the DRUJ proper is elicited by palpating the head of the ulna with the examiner’s thumb and sliding the thumb off the head in a radial direction. Tenderness just distal to the head dorsally is associated with a dorsal tear of the triangular fibrocartilage complex (TFCC). A volar tear of the TFCC is tender on palpation of the ulnar head between the FCU and ECU and when the examiner slides his or her thumb distally over the head.
- The fingers must be passively extended to rule out a forearm compartment syndrome. Inability to extend the fingers combined with tense forearm swelling are the best indicators of a compartment syndrome, which if present, necessitates urgent surgery.
- Patients presenting late, in the office, usually complain of ulnar-sided wrist pain, pain with activities requiring pronopronation, and DRUJ instability. In these situations the radius often is malunited or there is unrecognized bowing of the ulna.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Imaging of the patient with a suspected Galeazzi injury consists of plain radiographs of the elbow, forearm, and wrist.
- The forearm views help in preoperative planning for fixation of the radius fracture.
- The wrist views help to determine the degree of disruption to the DRUJ. On a posteroanterior (PA) view of the wrist, the degree of ulna shortening has been shown to differ depending on which structures are torn at the DRUJ. Less than 5 mm of positive variance of the ulna indicates that TFCC disruption is unlikely; more than 1 cm indicates intersosseous membrane disruption.
- Mino et al described a technique for interpreting the lateral wrist radiograph whereby the radial styloid is aligned with the center of the lunate and an assessment of the overlap of the radius and ulna is made. The head of the ulna should be completely obscured by the radius. If only part of the ulna head is obscured by the radius, then there is subluxation of the head, and if the ulnar head is clearly seen, then the joint is dislocated. In the operating room a C-arm image in neutral forearm rotation is obtained with the radial styloid in the mid-lunate position to interpret DRUJ subluxation.
- A CT scan is very useful in measuring the degree of subluxation or dislocation of the DRUJ. A CT scan in the acute situation can be useful in interpreting the degree of DRUJ congruity, but the test is more often performed in the setting of a chronic injury.
- This is most reliably interpreted by the radioulnar ratio (FIG 2), calculated as follows:
  - The center of the ulnar head is found using concentric circles.
  - A line similar to that used in the epicenter method is drawn from the dorsal and volar margins of the sigmoid notch (line A-B).
  - A line perpendicular to this line is drawn to the center of the ulnar head (line C).
  - The AD:AB ratio is the radioulnar ratio. The normal ratios are 0.5 to 0.71 for pronation, 0.42 to 0.58 for neutral, and 0.19 to 0.55 for supination.

DRUJ, distal radioulnar joint; DRUL, distal radioulnar ligament; PRUL, proximal radioulnar ligament.
The DRUJ is unstable:

- The following information is considered in deciding whether fixation of the radius are discussed later in this chapter.
- Options for nonoperative management of the DRUJ after fixation of the radius are discussed later in this chapter.

NONOPERATIVE MANAGEMENT

- The only time the radius is not internally fixed is when other patient factors make such surgery unsafe.
- In the Emergency Department, the longitudinal injury to the forearm should be reduced and held in a splint.
- The reduction maneuver is performed under conscious sedation with the thumb and index fingers placed in finger traps and 10 pounds of traction applied.
- A sugar tong or long-arm splint with an interosseous mold is applied.
- Radiographs must be obtained to confirm reduction.
- If the DRUJ is reduced, then surgery can be delayed for up to 2 weeks. If the DRUJ remains dislocated, surgery should be performed within 72 hours.
- This interval allows an MRI or CT scan to be ordered and interpreted to plan for the operative procedure.
- Options for nonoperative management of the DRUJ after fixation of the radius are discussed later in this chapter.

SURGICAL MANAGEMENT

- The key to the management of a Galeazzi fracture is determination of the degree of injury to the DRUJ. It can be classified
- Triangular fibrocartilage complex injury. Any of the following structures may be injured: fibrocartilage disc, palmar and dorsal radioulnar ligaments, ulnotriquetral ligament, ulnolunate ligament, ECU subsheath.
- Lunotriquetral ligament: isolated and as part of either a perilunate dislocation or a longitudinal wrist
- Essex-Lopresti injury
- Monteggia fracture-dislocation
- Elbow fracture-dislocation
- Stress and pathologic fractures of the radius

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of ulnar wrist pain in the presence of a radius fracture includes:
- Fracture of the ulna: shaft, metaphysis, head, styloid
- Triangular fibrocartilage complex injury. Any of the following structures may be injured: fibrocartilage disc, palmar and dorsal radioulnar ligaments, ulnotriquetral ligament, ulnolunate ligament, ECU subsheath.
- Lunotriquetral ligament: isolated and as part of either a perilunate dislocation or a longitudinal wrist
- Carpal fractures: triquetrum, hamate, lunate
- Essex-Lopresti injury
- Monteggia fracture-dislocation
- Elbow fracture-dislocation
- Stress and pathologic fractures of the radius

NONOPERATIVE MANAGEMENT

- The only time the radius is not internally fixed is when other patient factors make such surgery unsafe.
- If the DRUJ is reduced, then surgery can be delayed for up to 2 weeks. If the DRUJ remains dislocated, surgery should be performed within 72 hours.
- This interval allows an MRI or CT scan to be ordered and interpreted to plan for the operative procedure.
- Options for nonoperative management of the DRUJ after fixation of the radius are discussed later in this chapter.

SURGICAL MANAGEMENT

- The key to the management of a Galeazzi fracture is determination of the degree of injury to the DRUJ. It can be classified
- As stable, unstable but reducible, or unstable and irreducible.
- The following information is considered in deciding whether the DRUJ is unstable:
- If, on the initial pre-reduction PA radiograph, the ulna variance is more than 5 mm positive
- If frank dislocation remains after evaluation of the post-reduction lateral radiograph using the Mino technique (discussed under Imaging And Other Diagnostic Studies)
- In the Emergency Department, the longitudinal injury to the forearm should be reduced and held in a splint.
- The reduction maneuver is performed under conscious sedation with the thumb and index fingers placed in finger traps and 10 pounds of traction applied.
- A sugar tong or long-arm splint with an interosseous mold is applied.
- Radiographs must be obtained to confirm reduction.
- If the DRUJ is reduced, then surgery can be delayed for up to 2 weeks. If the DRUJ remains dislocated, surgery should be performed within 72 hours.
- This interval allows an MRI or CT scan to be ordered and interpreted to plan for the operative procedure.
- Options for nonoperative management of the DRUJ after fixation of the radius are discussed later in this chapter.

SURGICAL MANAGEMENT

- The key to the management of a Galeazzi fracture is determination of the degree of injury to the DRUJ. It can be classified
- As stable, unstable but reducible, or unstable and irreducible.
- The following information is considered in deciding whether the DRUJ is unstable:
- If, on the initial pre-reduction PA radiograph, the ulna variance is more than 5 mm positive
- If frank dislocation remains after evaluation of the post-reduction lateral radiograph using the Mino technique (discussed under Imaging And Other Diagnostic Studies)
- A foveal avulsion of the TFCC is noted on the preoperative MRI scan.
- Intraoperative fluoroscopic examination of the DRUJ after fracture fixation
- Intra-operative C-arm assessment includes PA and lateral views in neutral rotation. In most cases the DRUJ should be reduced following fixation.
- If increased ulna variance, joint diastasis, or subluxation of the ulna head is seen, the first possibility to consider is a malreduction of the radius fracture.
- Most importantly, instability is determined by intraoperative physical examination after fracture fixation.
- Grade I: less than 0.5 cm motion at extremes, with a firm endpoint. Probable intrasubstance tearing of either the proximal radioulnar ligament or the DRUJ. Management is in a cast in neutral rotation.
- Grade II: more than 0.5 cm motion at extremes, with a soft endpoint but no dislocation. This injury usually is associated with foveal avulsion of the TFCC, which can be confirmed by arthroscopy of the DRUJ and repaired. The distal interosseous membrane is not ruptured. Cast in mid-supination.
- Grade III: reduced joint prior to stress with dislocation of the DRUJ at extremes. Requires rupture of the distal aspect of the interosseous membrane. Repair the foveal avulsion as in grade II and pin the DRUJ in mid-supination.
- Grade IV: dislocated joint. “Mushy” feeling with stressing joint. This joint may be reducible with rotation; consider malposition of radius fragments if easily dislocatable. If truly mushy throughout forearm rotation, then there is interposition of soft tissue, and open treatment is required.

POSITIONING

- The patient is positioned supine on the operating table with a hand table, and the affected extremity is abducted at the shoulder and extended across the table.
- The hand table is positioned so that it adjoins the main table at the level of the shoulder. When the extremity is abducted 90 degrees, it lies in the mid portion of the table.
- A tourniquet is applied at the mid-humerus level, and a layer of towels is placed between the humerus and the arm. A layer of padding is placed on the upper arm just proximal to the elbow, and the arm is taped firmly to the hand table. This allows traction to be applied along the axis of the forearm for arthroscopy.
- Following fixation of the radius, finger traps are applied to the long and index fingers, and 10 to 12 lb of traction is applied.

APPROACH

- The DRUJ can be approached using arthroscopy, a mini-open technique, or an open dorsal approach.

ARTHROSCOPICALLY ASSISTED REPAIR OF FOVEAL TFCC AVULSIONS

Arthroscopy of the Distal Radioulnar Joint

- A 1.9-mm scope and 2.0-mm shaver are the working instruments for DRUJ arthroscopy.
- Two principal portals are used.
- The dorsal-proximal DRUJ (PD-DRUJ) portal is located in the axilla of the joint, just proximal to the sigmoid notch of the radius and the flare of the metaphysis of the ulna. It is easily palpated with the wrist supinated, which relaxes the dorsal capsule and facilitates introduction of the trocar and scope sheath.
- The joint is insufflated with about 3 mL of saline (which helps as a direction guide), the skin is incised with a no. 15 blade, and a hemostat pierces the deep fascia and capsule, followed by scope sheath insertion.
After initial joint penetration, the scope is withdrawn slightly until the sigmoid notch and neck of the ulna are brought into view.

Systematically, the steps of a diagnostic arthroscopy are as follows:
- Evaluate the sigmoid notch while in supination.
- Look down into the axilla of the joint (loose bodies sometimes hide here).

The scope is then swept distally over the head of the ulna and pushed anteriorly between the disc of the TFCC and the seat of the head while relaxing the rotation of the forearm to neutral.

Rotate into pronation and visualize the anterior compartment of the DRUJ.

Then slightly withdraw the scope and visualize the foveal region.

The distal DRUJ (DDRUJ) portal is located just distal to the seat of the ulna between the fifth and sixth dorsal compartments. It is about 5 mm proximal to the 6R portal.
- The DDRUJ portal allows entry of the scope between the disc of the TFCC and the head of the ulna.
- A 21-gauge hypodermic needle is inserted as a direction finder with the scope in the PDRUJ portal.
- A probe can be inserted to stress the undersurface of the TFCC disc and ligament insertion into the fovea.
- A shaver and other instruments also can be introduced through the DDRUJ portal.

**Repair of Foveal TFCC Avulsion**
- Diagnostic arthroscopy of the radiocarpal joint may reveal a peripheral tear in the TFCC.
- Mid-carpal arthroscopy is performed primarily to evaluate the integrity of the lunotriquetral ligament.
- DRUJ arthroscopy shows the status of the proximal surface of the TFCC and confirms a foveal tear of the TFCC (TECH FIG 1A).
- A shaver is introduced through the DDRUJ portal to débride this area (TECH FIG 1B), and the mini C-arm is brought in to confirm position over the fovea.
- A curette is used to freshen the ulna at the foveal insertion.
- Using a C-arm and arthroscopic guidance, a 1.8-mm drill hole is made (TECH FIG 1C–E).
- The DDRUJ portal is then enlarged to about 1 cm in size with the drill bit in place (TECH FIG 1F).
- The deep fascia and capsule are opened in line with the incision. A Mitek Mini QuickAnchor (Mitek Products, Norwood, MA) is inserted into the drill hole (TECH FIG 1G).
- Each suture end is placed through the TFCC, and the needle is brought out the 6R window made in the radiocarpal capsule.
- The suture is then tied, pulling the TFCC back to its anatomic position.
- A DRUJ shuck test is performed to ensure restoration of stability, the wounds are closed, and a long-arm splint is added in mid-supination.

**TECH FIG 1** • Diagnostic arthroscopy and distal radioulnar joint (DRUJ) arthroscopy-assisted repair of the triangular fibrocartilage complex (TFCC). A. Foveal avulsion tear. B. Hand placement and portal position using 1.9-mm scope and 2.0-mm shaver. C. Hand placement for drilling before Mitek anchor insertion. D. Position of the mini–C-arm, which is brought in to confirm placement of the drill bit in the fovea for insertion of the Mitek anchor. E. C-arm image confirming placement of the drill bit at the foveal insertion of the TFCC. F. The distal DRUJ portal is opened to about 1 cm, and dissection is carried down through the deep fascia in line with the incision. Care is taken to avoid the dorsal branch of the ulnar nerve. (continued)
ARTHROSCOPICALLY ASSISTED REPAIR OF FOVEAL TFCC AVULSION WITH RADIOCARPAL ARTHROSCOPY AND OPEN TECHNIQUES

Mini-Open Approach

- In the mini-open approach, a diagnostic arthroscopy of the radiocarpal joint is carried out.
- The 6R portal should be made in a longitudinal orientation. This is a guide for creation of a longitudinal 2- to 3-cm incision incorporating the 6R portal.
  - The incision usually is about 5 mm distal to the 6R portal and 2 cm proximal.
  - The dorsal branch of the ulnar nerve is found in the soft tissues at the distal end of the incision and is preserved.
- The deep fascia is incised in line with the incision.
- A 21-gauge needle is inserted through the capsule of the DRUJ into the interval between the head and the proximal edge of the TFCC.
- The joint capsule is incised from just proximal to the TFCC disc to the metaphysis of the ulna.
- A 21-gauge needle is then inserted just distal to the TFCC disc into the radiocarpal joint.
- The radiocarpal joint capsule is incised transversely about 6 or 7 mm (not quite to the lunate).

- The 6R portal also can be enlarged to see the distal aspect of the TFCC disc. This gives the surgeon good visualization of both surfaces of the TFCC disc and associated ligaments.

Repair of Foveal TFCC Avulsion

- The avulsed TFCC is identified and débrided.
- The ulnar fovea is roughened with a curette and drilled with a 1.8-mm bit, after which a single Mitek Mini QuickAnchor (Mitek Products, Norwood, MA) is inserted into the drill hole.
- The torn ulnar border of the TFCC is then advanced and sutured down to the ulnar fovea (TECH FIG 2). The suture on the Mitek Quick Anchor is double ended. Each needle is passed from a proximal to distal direction about 5 mm apart, and then the needles are cut off and the sutures tied within the radiocarpal joint. I use a one-handed suture-tying technique. No additional suturing is necessary.
- The capsule, retinaculum, and skin are closed, and a sterile dressing and long-arm splint are applied.

TECH FIG 1 (continued) G. C-arm image confirming placement of the Mitek anchor.

TECH FIG 2 • Sotereanos triangular fibrocartilage complex repair. The technique involves a 3-cm incision centered on the distal aspect of the head of the ulna. Small windows are created in the capsule of the DRUJ and the radiocarpal joint, and the foveal tear of the TFCC is identified. (continued)
**TECH FIG 2** (continued) C. The TFCC is lifted and the fovea cleared of soft tissue debris. A bone anchor (usually a 2-0 suture mini-Mitek) is placed in the head of the ulna at the fovea. D. The sutures are passed through the TFCC. E. The sutures are tied, repairing the TFCC back to its foveal insertion.

---

**OPEN DRUJ ARTHROTOMY AND TFCC REPAIR**

**Two-Window Exposure of the DRUJ**

- The forearm is pronated and extended at the elbow.
- A dorsal incision is made beginning 3 cm distal to the ulnar styloid.
  - The incision is carried proximally at 45 degrees to the long axis of the forearm in a radial direction until it reaches the dorsal aspect of the radius at the sigmoid notch.
  - At this point it is continued proximally, longitudinally down the forearm for about 7 cm ([TECH FIG 3A](#)).
- The soft tissues are spread, taking care to preserve the dorsal sensory branch of the ulnar nerve, which passes onto the dorsum of the hand about 1 to 2 cm distal to the ulna styloid.

- At the level of the deep fascia the soft tissues are swept off the fascia in the region of the ulna head ([TECH FIG 3B](#)).
- The distal aspect of the antebrachial fascia and the proximal 50% of the extensor retinaculum are incised longitudinally between the EDM and ECU tendons, and an ulnarly based flap is created ([TECH FIG 3C](#)).
- A 21-gauge needle can be inserted to assess the proximal and distal margins of the TFCC disc.

**TECH FIG 3** Open dorsal DRUJ approach.

A. Marker of initial incision. The incision is made 3 cm distal to the ulnar styloid at a 45-degree angle toward the sigmoid notch, then continued parallel to the interosseous interval proximally up the forearm. B. The dissection is taken down to the deep fascia. On the fascia, the fifth compartment is clearly visualized. C. The deep fascia is opened with an L shape along the border of the fifth compartment and the proximal edge of the extensor retinaculum. (continued)
The capsule of the DRUJ is incised proximal to the TFCC disc to the point where it blends with the periosteum over the metaphysis of the ulna (TECH FIG 3D).

The ulnocarpal joint capsule is opened to the lunotriquetrum.

Both capsular incisions are in line with retinaculum–fascial incision.

The TFCC disc and associated ligaments, the DRUJ, and ulnar aspect of the radiocarpal joint can be inspected.

A second, more ulnar window to the distal ulna can be made by sharp dissection to the ulna styloid and carried proximally parallel with the ECU sheath (TECH FIG 3E).

Care is taken to avoid opening the EDM and ECU sheaths.

TFCC Repair

The peripheral foveal avulsion is débrided, and the fovea freshened with a curette.

Two drill holes are made with 0.045-inch K-wires at a 45-degree angle about 1 cm from the articular surface of the head of the ulna, directed from the medial cortex of the ulna and exiting at the ulnar fovea.

The holes are parallel, beginning 1 cm apart, and converge toward the fovea.

A transverse arthrotomy is made in the radiocarpal capsule at the distal edge of the TFCC disc.

Three separate loops of a 3-0 braided nylon suture are passed through one hole, through the peripheral TFCC, and back out the other hole, and tied individually over the medial ulna.

The capsulotomy incisions are closed first, then the retinaculum is closed, and finally the skin is closed.

Two 0.062-inch K-wires are placed through the ulna and into the radius in neutral position (TECH FIG 4).

The capsule, retinaculum–fascia, and skin are closed in layers.

Open DRUJ Arthrotomy and TFCC Reconstruction Using a Palmaris Graft

Rarely, the TFCC can be completely shredded in a high-energy injury. In this instance the TFCC is excised and reconstructed using a palmaris graft.
PEARLS AND PITFALLS

Assessment of DRUJ instability
- The initial PA view of the wrist will show more than 5 mm of ulna shortening. The initial lateral radiograph will show dorsal subluxation of the ulna. A preoperative MRI scan will show increased signal (white) in the TFCC and an avulsion of the TFCC at the fovea. A positive shuck test will be present intraoperatively (this is the most important test). A subluxed ulna will be seen in the lateral intraoperative C-arm view.

Irreducible DRUJ after radial fixation
- Consider lack of anatomic reduction of the radius. Radial bow will not have been fully restored. This is especially prevalent in the segmental or comminuted radius. If convinced the radius is anatomic, then explore the DRUJ with open technique. The ECU and the extensor digitis minimi of the ulnar styloid are commonly in the joint.

Difficulty interpreting DRUJ shuck test
- Ensure forearm is in full supination or pronation. There should be no motion at the DRUJ between the radius and the ulna. If there is any motion then there is likely to be instability, and at the very least, a long-arm cast in mid-supination should be applied.

Difficulty in getting into the joint for DRUJ arthroscopy
- Reduce traction to about 5 lb. Use a 1.9-mm scope, and use a 21-gauge needle and saline to insufflate the joint. Place the forearm in supination. Push the trocar into the neck of the ulna (ie, between the radius and ulna).

POSTOPERATIVE CARE
- All of the following protocols assume that rigid and stable fixation of the radius fracture has been obtained.
  - Stable DRUJ
    - The patient is placed in a sugar-tong splint for 2 weeks, and is given a Carter block arm pillow for strict elevation and encouragement of finger and thumb motion.
    - At 2 weeks, the patient returns to the office for suture and splint removal.
    - The patient is referred to a hand therapist for active, passive, and gentle resisted motion up to 10 lbs resistance.
    - Motion of all joints from the elbow distally is encouraged.
    - Further resistance and weight bearing depend on union of the radius.
    - Usually, union occurs by 6 weeks and restrictions are lifted.
    - Return to work status depends on the level of repetition and lifting required by the patient’s job.
  - Rehabilitation following bone anchor fixation of a foveal avulsion of the TFCC and full palmaris graft reconstruction
    - Long-arm splint, elbow at 90 degrees, forearm in mid-supination, wrist neutral; fingers not included.
    - At 2 weeks the patient returns to the office for suture removal and the arm is placed in a cast in the same position.
    - Four weeks later (ie, 6 weeks postoperatively), the cast is removed and active gentle passive motion is begun to all joints from the elbow distally.
    - At 12 weeks postoperatively, graduated lifting activity is begun, and continues for 6 more weeks.
    - At week 18 all restrictions are removed.
    - Open foveal repair and K-wire
      - At 6 weeks, K-wires are removed.
      - Begin protocol as for bone anchor fixation.

OUTCOMES
- The key to a successful outcome of acute Galeazzi fracture dislocations is accurate reduction and rigid fixation of the radius along with recognition and appropriate repair or reconstruction of the disrupted DRUJ. Conservative management seems to be successful only in children.
  - In a classic article by Mikic, conservative management in adults resulted in failure in 80% of cases. The results of operative treatment were much better, and the conclusion was that rigid internal fixation is necessary for the dislocation as well as the fracture.
  - So-called “isolated” fractures of the radial diaphysis, where there is less than 5 mm of positive ulna variance, are more common than true Galeazzi fractures. Fractures without identifiable radioulnar disruption can be treated without specific treatment of the DRUJ and with immediate mobilization. In this situation, patients with anatomic fracture reduction have minimal sequelae and better or equal functional results than patients with imperfect reduction.
  - In a series of 50 Galeazzi fracture dislocations treated by early open reduction and internal fixation, Mohan et al found, at 1 year, 40 good, 8 fair, and 2 poor results. Their conclusion was that early open reduction and rigid internal fixation re-establishes the normal relation of the fractured fragments and the DRUJ without repair of the ligaments. Thus, in many situations, ligament repair is unnecessary. (However, in Mohan et al’s series, 1 in 5 had a less than good result.)
  - Rettig and Raskin, in a more recent series, found that the more distal the fracture the greater the likelihood of DRUJ disruption. In this series, 12 out of 22 fractures within 7.5 cm of the midarticular surface of the distal radius had intraoperative DRUJ instability, whereas only one of 18 more proximally were unstable. Their conclusion was that a high index of suspicion, early recognition, and acute treatment of DRUJ instability will avoid chronic problems in this complex injury.
  - This high index of suspicion will lead to the recognition that dislocations of the DRUJ associated with fractures of the forearm often are irreducible. These have been termed “complex” DRUJ dislocations: dislocations characterized by obvious irreducibility, recurrent subluxation, or “ mushy” reduction caused by soft tissue or bone interposition.
  - With the advent of internal fixation of the radius, most Galeazzi fractures are predictably reduced. It is mandatory that the DRUJ be evaluated and managed according to the degree of instability to the joint. A high index of suspicion means the outcome is associated more with the degree of energy involved in the injury than with any inability on the part of the surgeon to care for the DRUJ appropriately.

COMPLICATIONS
- The most common complication of a Galeazzi fracture is malunion of the radius and residual DRUJ instability, due to
malrotation and residual angulation of the radial shaft. In most cases a DRUJ-stabilizing tenodesis cannot restore the joint, and a corrective osteotomy is required.

- A preoperative three-dimensional CT reconstruction of the bones of the entire forearm is very helpful in this situation.
- Management of a missed dislocation depends on the timing of presentation.
  - If less than 10 weeks after the injury, open reduction and repair usually is possible.
  - After 10 weeks, reconstruction with ligament grafting is required.
- The incidence of radius nonunion is directly related to the number of screws used: the rate is four times higher for bones plated with four screws compared to those plated with five or more screws.
- Radioulnar synostosis may be seen, particularly in patients with multiple system trauma involving head injury.
- Osteomyelitis may develop in open and crush injuries.
- Nerve palsies, including the anterior interosseous and ulna nerves, have been associated with Galeazzi fractures, and acute carpal tunnel syndrome is a common complication, particularly in crush and high-energy injuries.
- Compartment syndrome of the forearm also is a known complication.
- Osteoarthritis of the DRUJ is a long-term complication and can be managed by arthroscopy, interposition arthroplasty, ulna shortening, ulna head replacement, or total joint arthroplasty, depending on severity of the injury and age of the patient.
- Complications in Galeazzi fracture-dislocations can be minimized with attention to detail, in particular accurate anatomic reduction of the radius fracture, thorough assessment and repair of instability of the DRUJ, and appropriate postoperative rehabilitation.

DEFINITION
- Malunion of the radial or ulnar shaft can lead to pain, loss of motion, loss of strength, and instability at the level of the wrist or elbow.
- Malrotation, angulation (with narrowing of the interosseous space between the radius and ulna), shortening, and loss of the radial bow have been shown in various studies to lead to decreased functional outcomes.4,5,9,10,12
- Arthritis has been reported at the level of the proximal radioulnar joint (PRUJ) with longstanding malunions, although the distal radioulnar joint (DRUJ) is most commonly affected by forearm malunions.11

ANATOMY
- The forearm can be thought of as a ring, connected at the PRUJ, the interosseous membrane, and the DRUJ (FIG 1).
- Force transmission occurs through the interosseous membrane from the radius distally to the ulna proximally.
- Radius
  - The radius lies parallel to the ulna in supination. With pronation, it rotates around the ulna while the ulna maintains its position throughout forearm rotation.
  - The radius shaft is triangular in cross section, with the apex toward the attachment of the interosseous membrane.
  - It contains three surfaces: anterior, lateral, and posterior.
- The shaft possesses a gentle bow, with the volar surface concave and the dorsal and lateral surfaces convex.1
- Schemitsch and Richards5 devised a formula that locates the apex and defines the magnitude of the radial bow for each individual (FIG 2).
- Ulna1
  - The ulna is a long bone that has a triangular cross section in the proximal two thirds and a circular cross section distally.
  - It possesses three surfaces: anterior, posterior, and medial.
  - The proximal half of the shaft is slightly concave volarly. The distal half is relatively straight.
- The PRUJ consists of the radial head, the radial notch, the annular ligament, and the quadrate ligament.
- The DRUJ consists of the sigmoid notch, the ulnar head, the dorsal and volar radioulnar ligaments, the extensor carpi ulnaris (ECU) subsheath, and the triangular fibrocartilage complex (TFCC).

PATHOGENESIS
- Both-bone forearm fractures occur through a variety of mechanisms, including indirect trauma (such as falls on an outstretched arm or motor vehicle accidents) and direct trauma (such as blows to the forearm).

FIG 1 • Lateral projection of the radius and ulna. Relationship of the interosseous membrane to the radius and ulna during forearm rotation. The fibers of the interosseous membrane are longest with the forearm in neutral position and shorten in both pronation and supination.

FIG 2 • Measurement of the location and magnitude of the radial bow. The distance y represents the length of the radius as measured from the bicipital tuberosity to the ulnar aspect of the radius. Line a, drawn perpendicular to y from the point of greatest curvature of the radius, represents the magnitude of the radial bow (expressed in millimeters). The distance x represents the length of the radius from the bicipital tuberosity to the point where a intersects y. The location of the radial bow is calculated by \( \frac{x \times y}{100} \). (Adapted from Schemitsch EH, Richards RR. The effect of malunion on functional outcome after plate fixation of fractures of both bones of the forearm in adults. J Bone Joint Surg Am 1992;74A:1068–1078.)
Acute fractures treated closed or with intramedullary nailing techniques are more likely to heal malunited.\(^7,^8\)
Radius malunions have a greater effect on forearm rotation than ulna malunions.\(^10,^12\)
A torsional deformity of greater than 30 degrees in the radius leads to significant loss of forearm motion.\(^4\)
Changes in the length–tension curve of the interosseous membrane may also account for loss of rotation.\(^12\)

**NATURAL HISTORY**
Fifty degrees of supination and 50 degrees of pronation are needed for activities of daily living.\(^6\)
Patients with untreated forearm malunions may experience loss of forearm rotation, PRUJ or DRUJ instability, wrist pain, loss of strength, and arthritis at the PRUJ.\(^11\)
The severity of the symptoms depends on the degree of malunion and the corresponding alteration in degree and location of the bow of the radius.

- Malunions of 10 degrees or less lead to less than a 20-degree loss of forearm rotation and hence are clinically insignificant.\(^7\)
- Angular malalignment of more than 20 degrees in the radius or ulna results in clinically significant loss of motion. Greater than 15 degrees of malalignment leads to inability to perform activities of daily living.\(^5,^7,^10\)
- Patients with greater than 15 degrees of malalignment or loss of the radial bow will have clinically significant loss of motion and strength if left untreated.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
The preoperative evaluation for patients with forearm malunions includes a detailed assessment of the patient’s functional limitations as well as documentation of elbow and wrist range of motion, the supination–pronation arc of the forearm, and the stability of the PRUJ and DRUJ.

**Physical examination**
- The skin is inspected for scarring or previous incision sites.
- Muscle bulk and tone are examined.
- The wrist, elbow, and malunion site are palpated for tenderness.

**Range of motion**
- The flexion–extension arc of the elbow is measured with the shoulder at 30 degrees of forward flexion.
- Rotation of the forearm is ascertained with the humerus stabilized against the chest wall and the elbow at 90 degrees of flexion.
- Wrist flexion and extension are determined with the forearm in neutral rotation.
- Joint loss of motion may indicate location of pathology.
- A high degree of motion loss will lead to functional deficits.

**PRUJ and DRUJ**
- Stability of the PRUJ is assessed by palpation during passive pronation and supination.
- The DRUJ is evaluated by stressing the ulna volarly and dorsally while stabilizing the radius.
- Subluxation of the ulnar head or the ECU is evaluated during passive range of motion (ECU subluxation test).
- The piano key test can also be used to assess for an unstable DRUJ. Patients with a positive piano key sign will have an ulnar head that shifts volarly with a minimal volarily directed force and then rebounds dorsally once that force is removed, much like a key in a piano.
- Pain with compression of the radius and ulna at the level of the DRUJ may also be indicative of DRUJ instability or arthritis (DRUJ compression test).
- Neurovascular examination
  - The examiner should check for anterior interosseous nerve (OK sign), posterior interosseous nerve (thumb extension), and ulnar nerve (abduction–adduction of fingers) function.
  - Inability to perform tasks identifies nerve injury.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- AP and lateral radiographs of both forearms should be obtained (FIG 3A,B).
- Both the bicipital tuberosity and the radial styloid should be visualized for the film to be adequate.
- The degree of angulation and comminution can be calculated from these films.
- Contralateral forearm films provide a comparison for the amount of shortening as well as for the location and angle of the radial bow.\(^9\)

**FIG 3 • A,B.** AP and lateral radiographs demonstrate a segmental radius shaft fracture resulting in a malunion both proximally and distally despite open reduction and internal fixation. Note the loss of radial bow in both direction and magnitude, narrowing of the interosseous space between the radius and ulna, dorsal positioning of the distal ulna, and nonunion of the basilar ulnar styloid fracture. The patient was unable to supinate to neutral and demonstrated instability at the distal radioulnar joint. C. CT scan demonstrates narrowing of the interosseous space with heterotopic bone formation.
A CT (Fig 3C) scan or MRI can also be obtained to assess for malrotation.2

DIFFERENTIAL DIAGNOSIS
- DRUJ injury or instability
- PRUJ injury or instability
- Injury to the interosseous membrane
- Synostosis
- Nonunion

NONOPERATIVE MANAGEMENT
- Nonoperative treatment of malunions depends on the patient’s symptoms and includes occupational therapy for strengthening and range of motion, removable off-the-shelf braces, non-narcotic medications, and custom molded DRUJ orthoses.

SURGICAL MANAGEMENT
- Operative intervention for forearm malunions depends on the functional limitations of the patient, not the degree of deformity apparent on radiographs.
- Indications for surgery include loss of forearm rotation that leads to a functional deficit (rotational arc less than 100 degrees), DRUJ instability, unacceptable cosmetic, and painful nonunion.
- Risks to the patient include vascular injury, nerve injury or paresthesias (specifically the superficial radial nerve), infection, nonunion, delayed union, need for iliac crest bone graft, synostosis, loss of motion, and DRUJ instability.
- Patients treated within 1 year of the initial injury may be more likely to improve functionally and have a lower surgical complication rate.11
- Malunions of the radius and ulna are generally treated with an open approach, corrective osteotomy of one or both bones, compression plating, and bone grafting as necessary.
  - Generally, the more deformed bone is corrected first. If after correction of the first bone forearm rotation is still lacking, an osteotomy is performed on the second bone.
  - If both bones are equally deformed, the ulna is osteotomized and provisionally plated first to provide a working length for the radius.
- Restoration of the radial bow in large part determines functional outcome.
  - Patients whose radial bow is restored within 1.5 mm of magnitude and located within 4.3% of the contralateral forearm regain 80% of normal motion.
  - Eighty percent of grip strength is regained if the radial bow is located within 5% of the contralateral side.9
  - Anatomic realignment of the radius and ulna will not improve functional deficits if a synostosis or significant scarring and contracture involving the soft tissues has occurred.
  - Occult injury to or contracture of the DRUJ and PRUJ must be identified and treated at the time of surgery.

Preoperative Planning
- Radiographs of the affected and contralateral extremity should be reviewed.
  - A CT scan is helpful to assess for rotational deformity.
  - A corrective three-dimensional osteotomy is planned using standard AO technique (Fig 4).
  - The need for corticocancellous iliac crest bone graft should be determined by the degree of shortening.
  - The surgeon should be familiar with techniques for reconstruction or stabilization of the DRUJ should it remain unstable after correction of the malunion.

Positioning
- The patient is positioned supine on the operating table. A radiolucent hand board is attached to the table, centered on the patient’s axilla. The affected extremity is then extended and can be positioned for either a volar or dorsal approach to the radius by rotating through the shoulder.
- The subcutaneous border of the ulna can be visualized by flexing the arm at the elbow or by placing the arm across the chest.
- A nonsterile tourniquet may be used on the arm.

Approach
- Radius shaft malunions may be approached either volarly or dorsally.
  - The volar (Henry) approach is best suited for midshaft and distal radius shaft malunions.
  - The proximal radius shaft can be approached volarly in this manner; however, injury to the posterior interosseous nerve (PIN) can occur when dissecting the supinator muscle off the radius.
  - The approach is extensile and can be used to expose not only the entire length of the radius but also the wrist joint.3
  - The dorsal (Thompson) approach to the radius is used most commonly for proximal malunions.
  - It provides access to the PIN, allowing the surgeon to isolate the nerve and retract it out of harm’s way for the remainder of the procedure.
  - This approach may be of value for midshaft exposure of the radius, especially in the case of a midshaft segmental malunion (see Fig 3A,B).
  - The entire dorsal surface of the radius can be exposed through this approach.3
  - The ulna is approached along its subcutaneous border.
  - The entire length of the ulna can easily be exposed through this approach.

FIG 4 Preoperative planning using AO technique for correction of the malunion of the case in Figure 3. A. The malunion is first sketched out from the preoperative radiographs. B. Each fragment is then drawn out separately. C. The osteotomy sites are noted on both the AP and lateral views. The radius is then realigned through the planned osteotomy sites and bone graft (yellow) is inserted to restore the normal magnitude and location of the radial bow.
**VOLAR APPROACH TO THE RADIUS**

- **Landmarks:** biceps tendon, brachioradialis (BR), radial styloid
- **Center the skin incision over the malunion site and follow a line that begins lateral to the biceps tendon, continues over the medial edge of the BR, and ends distally at the level of the radial styloid.**
  - The length of the incision depends on the amount of exposure needed to take down the malunion and plate the osteotomy.
- **To expose the midshaft, dissect between the BR and the pronator teres (PT) proximally (TECH FIG 1).**
  - The superficial radial nerve lies on the undersurface of the BR and must be protected.
- **Ligate the recurrent radial artery to retract the BR laterally.**
- **Pronate the forearm and release the PT insertion.**
- **Dissect the PT muscle subperiosteally from a lateral to medial direction to expose the volar surface of the radius.**
- **To expose the distal radius, the surgical interval lies between the flexor carpi radialis (FCR) and the radial artery.**
- **Retract the FCR medially and the radial artery laterally to expose the flexor pollicis longus (FPL) and the pronator quadratus (PQ).**
- **Retract the FPL medially.**
- **Release the PQ from its radial insertion and dissect the muscle belly from the volar distal radius.**

**DORSAL APPROACH TO THE RADIUS**

- **Landmarks:** lateral epicondyle, tubercle of Lister
- **The skin incision is centered over the malunion and follows a gently curved line starting just anterior to the lateral epicondyle and ending just distal and ulnar to the tubercle of Lister at the wrist (TECH FIG 2A).**
- **Incise the fascia in line with the skin incision.**
- **Dissect between the extensor digitorum communis (EDC) and the extensor carpi radialis brevis (ECRB) proximally.**
- **Pronate the forearm.**
- **Identify the PIN as it emerges from the supinator 1 cm proximal to the distal edge of the muscle (TECH FIG 2B).**
- **Follow the nerve in a distal to proximal direction through the supinator, carefully preserving its motor branches.**
- **Once the nerve is fully mobilized and protected, supinate the arm and release the supinator from the anterior surface of the radius in a medial to lateral direction.**
- **To expose the midshaft of the radius dorsally, the abductor pollicis longus (APL) and the extensor pollicis brevis (EPB) must be mobilized as they cross radially over the dorsal shaft of the radius.**
- **Incise the fascia along the inferior and superior borders of the two muscles and lift them off the radius.**
- **Retract them distally or proximally as needed for exposure of the malunion.**
Chapter 6  CORRECTIVE OSTEOTOMY FOR RADIUS AND ULNA DIAPHYSEAL MALUNIONS

**TECHNIQUES**

**Exposure of the radius through the dorsal approach.** This approach is best for proximal shaft malunions.

A. Skin incision on dorsal surface, running from tip of lateral epicondyle toward radial styloid. B. The posterior interosseous nerve is followed through the supinator, with its branches preserved.

**TECH FIG 2**

**APPROACH TO THE ULNA**

- Landmark: subcutaneous border of the ulna
- Make a longitudinal incision along the subcutaneous border of the ulna (TECH FIG 3A).
- Incise the fascia in line with the skin incision.
- Dissect between the extensor carpi ulnaris (ECU) dorsally and the flexor carpi radialis (FCU) volarly (TECH FIG 3B).
  - Take care to avoid disrupting the ECU subsheath distally over the ulna head.

**TECH FIG 3**

**REDUCTION, PLATING, AND BONE GRAFTING**

- Based on the preoperative scheme, perform the planned osteotomy at the site of malunion using a combination of a water-cooled saw and osteotomies.
- Bring the radius out to length and insert bone graft as necessary (TECH FIG 4A).
- Make a template for plate contouring so as to match the radial bow (TECH FIG 4B, C).
- Plate the malunion using a 3.5-mm compression plate and AO compression plating techniques (TECH FIG 4D–G).
  - Obtain a minimum of six cortices of fixation proximal and distal to the malunion.
  - In smaller patients, a 2.7 DC plate may be used instead.

**TECH FIG 4**

A. Reduction after osteotomy of the midshaft segmental radius malunion through a volar exposure in the patient in Figures 3 and 4. Because of the segmental nature of this malunion, fixation was accomplished by plating both volarly and dorsally. B. A metal template is placed on the volar surface of the corrected radius. C. The template is used to precisely contour the plate so that when applied, the normal curvature of the radius is restored. (continued)
After fixation, take the forearm through a full supination–pronation arc.
- Blocks to motion result from an uncorrected ulnar malunion, DRUJ incongruency or instability, failure to restore the radial bow, synostosis, and soft tissue or interosseous membrane scarring and contracture.
- If an ulna osteotomy is required, the plate can be placed on the volar surface of the ulna or on its subcutaneous border in the manner detailed above.
- If the DRUJ is unstable, consider palmar capsular reefing, reconstruction with tendon graft, fixation of an ulnar styloid base nonunion, or pinning of the joint in full supination.

If the joint is incongruent or arthritic, consider ulna shortening, matched resection arthroplasty, Darrach resection, or the Sauve-Kapandji procedure.
- Reapproximate tendon insertions. For example, in the case of a volar exposure to the distal radius, repair the PQ to its radial insertion using absorbable suture.
- Close the subcutaneous tissues and skin.
- To minimize the risk of compartment syndrome, do not close the fascia.
- Apply a volar splint.
- In patients with concomitant DRUJ instability, a sugar-tong splint with the forearm in full supination is placed.

PEARLS AND PITFALLS

Indications
- Assess DRUJ stability.
- Determine that lack of motion is not due to soft tissue contracture, synostosis, or interosseous membrane scarring, for which realignment of the malunion would not improve motion.

Osteotomy
- Obtain contralateral forearm films to determine location and magnitude of radial bow.
- Obtain CT or MRI if concerned for rotational malunion.
- Perform detailed preoperative drawings to determine the ideal location for the osteotomy, the degree and direction of correction required, and the need for bone graft.
- Obtain consent for bone graft.

Approach
- If a volar approach to the proximal radius is chosen, avoid injury to the PIN by careful subperiosteal stripping of the supinator from the radius and gentle retraction of the supinator laterally to prevent a traction neurapraxia. Avoid placing a retractor around radial neck as this can compress the PIN (or cause a traction injury of the nerve). Gently retract the superficial radial nerve and radial artery.
- Protect the PIN during dissection when approaching the proximal radius dorsally. The nerve lies directly on bone dorsally, opposite of the bicipital tuberosity in 25% of patients. Avoid trapping the nerve between the plate and bone when placing a plate proximally.

DRUJ
- Determine the cause of instability of the DRUJ once malalignment is restored.
- Perform a procedure that addresses the precise cause of the DRUJ instability.
POSTOPERATIVE CARE
- In a compliant patient with secure fixation, the splint may be removed 5 to 7 days after surgery and range-of-motion exercises initiated.
- A removable orthosis is worn for the next 4 to 5 weeks.
- Strengthening exercises are begun 6 weeks after surgery.
- Resistive strength training is delayed until radiographic evidence of healing is present (usually 8 to 12 weeks postoperatively).
- Normal activities are resumed when a solid union is present.
- Plates are generally not removed in adults.
- If concomitant DRUJ instability is present:
  - A Munster cast is applied at the first postoperative visit. The forearm is held in full supination for 6 weeks.
  - Finger range-of-motion and elbow flexion–extension exercises are begun at the first postoperative visit.
  - At 6 weeks, any pins in the DRUJ are removed, and supination–pronation exercises are initiated.

OUTCOMES
- Trousdale and Linscheid retrospectively reviewed 27 patients with corrective osteotomies for forearm malunions. Indications for surgery included loss of rotation (20 patients), unstable DRUJ (6 patients), and cosmesis (1 patient).11
  - Of the six patients with DRUJ instability, five had stable wrist joints at follow-up. Three patients were stabilized with correction of the deformity alone, and three required reefing of the palmar capsule and temporary pinning of the DRUJ with Kirschner wires (K-wires).
  - The patient who underwent the procedure for cosmesis lost 10 degrees of rotation but was happy with the overall appearance and function.
  - The age of the patient at the time of injury, location of the malunion, and involvement of one or both bones were not associated with the final outcome.
  - Shorter time from injury to corrective surgery (less than 12 months) was associated with improved forearm rotation and a lower complication rate.

COMPLICATIONS
- A 48% complication rate was noted in Trousdale and Linscheid’s study.11
  - Infection
  - Wrist pain
  - Loss of motion
  - Heterotopic ossification
  - DRUJ instability
  - Delayed union or nonunion
  - Superficial radial nerve paresthesias

REFERENCES
DEFINITION
- A diaphyseal forearm fracture is generally considered to be a nonunion if healing has not taken place within 6 months.
- Nonunions are generally classified as hypertrophic or atrophic, an important distinction in treatment selection.
  - Hypertrophic nonunions have abundant callus and a rich blood supply and result from inadequate stability of fracture fixation. This type of nonunion is rare in the forearm and constitutes less than 10% of nonunion cases.9
  - Atrophic nonunions are characterized by poor blood supply and little or no callus formation.
- Nonunion of the forearm diaphysis is rare because of the success of current techniques of plate and screw fixation. Nonunion rates of only 2% in the radius and 4% in the ulna are reported.2

ANATOMY
- The forearm consists of the radius and ulna, joined at either end by the proximal and distal radioulnar joints (PRUJ and DRUJ, respectively) (FIG 1).
- The ulna is straight, while the radius has both an apex radial and apex dorsal curvature.
- It can help to think of the forearm as a joint rather than a pair of long bones.
  - Pronation and supination are achieved by rotation of the curved radius about the straight ulna.
- Both the curvature of the radius and the integrity of the interosseous space and interosseous membrane (IOM) must be maintained for the forearm “joint” to function optimally.
- The diaphyseal portions of the radius and ulna are surrounded by complex anatomy, including neural and vascular structures, that must be considered during any surgical approach. Both radius and ulna are covered by muscle proximally, while the ulna emerges distally to be subcutaneous.

PATHOGENESIS
- Nonunions of the diaphysis of the forearm are rare and result most commonly from incorrect or inadequate treatment.
  - Inadequate fixation, generally less than six cortices of screw fixation proximal and distal to the fracture, will increase the rate of nonunion.
  - Lack of attention to critical surgical principles such as creating compression across the fracture site (either with the use of an interfragmentary screw or a compression plate) also leads to nonunion.
- Nonoperative treatment results in markedly increased rates of nonunion and other complications.2 With the exception of isolated, minimally displaced ulnar shaft fractures, all adult diaphyseal forearm fractures require operative management.
  - Comminution increases the risk of nonunion, with 12% of comminuted, diaphyseal fractures going on to develop nonunion after treatment with dynamic compression plates.11
  - Fracture characteristics that increase the risk of nonunion include extensive devascularization and periosteal stripping, bone loss, and infection.
    - Open, comminuted fractures with bone loss have the highest rate of nonunion.7
  - Patient comorbidities known to increase rates of nonunion include diabetes mellitus, steroid use, malnutrition, and renal dysfunction.

NATURAL HISTORY
- Once a nonunion of the forearm is established, it will not go on to heal spontaneously.
  - If significant shortening of either the radius or ulna occurs, the intricate anatomy of the entire forearm “joint” can be disrupted. Malalignment of the DRUJ secondary to such shortening can cause pain and lead to loss of motion at the wrist.
  - Loss of motion secondary to pain, particularly pronation and supination, can lead to shortening and fibrosis of the IOM. This can lead to permanent loss of rotational motion in the forearm.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with nonunion of the diaphysis of the radius or ulna most commonly present with pain.
  - This pain frequently worsens with attempts to use the extremity for lifting or pushing, but may also occur at rest.
Resisted rotational movements are frequently painful, such as turning a key in a lock.

It is important to explore whether infection could be the cause of the nonunion. Important history includes whether or not the original fracture was open, whether postoperative complications or drainage developed, and whether the patient has received antibiotics.

During the physical examination, the examiner should do the following:

- Palpate the nonunion site for pain.
- Grasp the bone on either side of the nonunion and attempt to flex and extend the nonunion to assess fracture stability and healing. Palpable motion and increased pain indicate lack of union.
- Loss of flexion–extension in the elbow may result from pain. Loss of pronation and supination indicates deranged forearm anatomy or pain.
- Loss of flexion or extension at the wrist may indicate pain or scarring of muscle and tendons around the nonunion. Loss of radioulnar deviation may indicate DRUJ abnormality secondary to shortening at the nonunion site.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs are essential for diagnosis. This should include AP and lateral views of the forearm, elbow, and wrist.
- Comparative views of the contralateral forearm, elbow, and wrist are also essential for preoperative planning.
- Plain radiographs will allow the surgeon to determine if the nonunion is hypertrophic (FIG 2A) or atrophic (FIG 2B).
- CT is helpful in identifying synostosis, assessing rotational deformity, and evaluating the size of the gap between bone ends at the nonunion site. CT also allows assessment of the DRUJ and PRUJ.
- The metal suppression CT technique minimizes the bright scatter created by retained hardware.

**DIFFERENTIAL DIAGNOSIS**

- Malunion
- Infection
- IOM injury
- Painful hardware

**NONOPERATIVE MANAGEMENT**

- The goal of treatment is to alleviate pain and restore function to the forearm. This can rarely be accomplished without surgical intervention.
- In rare circumstances (if the patient is a high risk for surgery due to comorbidities, for example), an external bone stimulator can be used.
- A minority of patients develop a stable, fibrous nonunion that is painless and allows good function. Nonoperative management can be considered in such patients.

**SURGICAL MANAGEMENT**

- In all nonunions of the forearm, the first considerations are the patient’s level of pain and function.
- The surgeon should not elect to operate based on radiographic findings alone.
- All patients with nonunions should undergo a workup to determine if the cause of the nonunion is infection, particularly after open fractures.
- The workup should include careful history of open fracture, drainage, or postoperative complications after initial surgery.
- Blood should be obtained for a complete blood count, erythrocyte sedimentation rate, and C-reactive protein.
- Nuclear medicine imaging should be performed if the suspicion of infection is high.

**Preoperative Planning**

- All imaging studies should be reviewed and pathoanatomy recognized.
- Plain radiographs should be reviewed for presence or absence of callus in order to categorize the nonunion as hypertrophic or atrophic.
- If a nonunion of the forearm is hypertrophic (which is rare), it may be treated by simple revision of hardware, creating compression across the fracture site with either a compression screw or a compression plate. This is the same technique that should be used for initial management of radius or ulna fractures (see Chap. HA-4).
- If any possibility of infection at the nonunion site exists, plans must be made to search for infection when the nonunion site is opened, and to have an alternative treatment plan if infection is encountered.
- Preoperative antibiotics may be held until cultures are obtained from the nonunion site (ensuring the tourniquet is not inflated if antibiotics are administered later in the case).

**FIG 2** A. Radiograph showing an infected, hypertrophic nonunion. The abundant callus formation indicates a biologically active nonunion. B. Radiograph showing an atrophic nonunion. There is complete absence of callus at the fracture site. The problem in an atrophic nonunion is lack of biologic activity. (Courtesy of Thomas R. Hunt III, MD.)
Intraoperative culture swabs and tissue for aerobic, anaerobic, and fungal cultures should be obtained from sites within the nonunion.

Patients should be made aware that if severe infection is encountered, the planned procedure may need to be altered. For example, if frank purulence is encountered, the nonunion repair may be abandoned in favor of débridement and irrigation with possible antibiotic bead placement and even external fixation if stability is compromised.

Template the radiographs to ensure selection of proper plate size and length.

DCP, LCDCP, and combination locking plates are all appropriate.

A minimum of six cortices of screw purchase proximal and distal to the nonunion is critical. This may require plates longer than those available in a standard plating set.

In osteoporotic bone, the use of locking plates should be considered.

If bone graft will be required, the type of graft should be determined preoperatively. While autograft is still considered the gold standard, a vast array of bone graft substitutes are now available. The surgeon’s preference and familiarity with various bone graft substitutes may guide this choice. It is important to determine if a structural graft will be required, as this may necessitate the use of autograft.

Patients should be counseled regarding the possible need for (and risks associated with) various types of autograft, including the possible need for a tricortical iliac crest or fibula graft if significant bone loss is encountered.

A vascularized fibula graft may be used to fill large defects, especially those associated with infection.

A complete examination of range of motion of the elbow and wrist, including pronation and supination, should be performed under anesthesia.

**Positioning**
- The patient should be positioned supine with the operative arm extended on a radiolucent arm table.
- A nonsterile or sterile tourniquet may be applied, but full access to the elbow is necessary.
- Because restoration of the radial bow is a critical component in restoring forearm motion, intraoperative radiographs showing the entire radius are essential. For this reason, use of the mini C-arm should be avoided in favor of regular fluoroscopy, with its much larger field of view.
- The selected site for harvest of autograft should also be prepared and draped.

**Approach**
- The approach to either the radius or ulna should generally be through the original surgical incisions.
- Approach to the radius is most commonly volar through the standard Henry approach. Proximal nonunions of the radius may be more easily accessed via a dorsal Thompson approach, particularly in muscular individuals.
- Care should be taken to identify and protect the posterior interosseous nerve during this approach.
- The ulna is accessed along the subcutaneous border in the interval between the flexor carpi ulnaris and the extensor carpi ulnaris.
- Care should be taken to identify and protect the dorsal cutaneous branch of the ulnar nerve distally.
- In all cases, preservation of blood supply is key to healing of a nonunion. Therefore, periosteal stripping should be kept to a minimum and the use of cautery should be restricted to vessel coagulation.

**Techniques**

**PLATE FIXATION FOR TREATMENT OF FOREARM NONUNIONS**

**Preparation of the Nonunion**
- Determine the correct length of the radius or ulna by measuring the corresponding contralateral bone.
- Expose the nonunion site and search for evidence of infection. If found, send specimens for Gram stain and culture and abort the planned procedure. Perform a two-stage reconstruction.
  - Thoroughly débride all necrotic and infected bone and soft tissue. Remove all hardware.
  - Place antibiotic-loaded PMMA beads in the gap.
  - Begin a multiweek course of antibiotics before proceeding with definitive nonunion repair.
- If infection is considered unlikely, after removal of all hardware, thoroughly débride the nonunion site of all necrotic and inflammatory tissue, synovial membranes, and sclerotic or avascular bone.
  - Tools such as curved curettes, small rongeurs, and a small high-speed burr (with copious irrigation to prevent thermal injury to the bone) are helpful.
  - Flatten the bone ends to allow for excellent fragment-to-fragment contact with compression.
- Open the sclerotic bone ends using sequentially larger diameter drills.
  - Pass these drills proximally and distally as far as possible to open the medullary canals (TECH FIG 1B).
  - Restrict elevation of muscle and periosteum to only what is needed to thoroughly débride the nonunion and to realign the bone.
  - Realign the bone and restore length by manipulating fragments with bone-holding forceps.
  - Use of a small skeletal distractor, small external fixator, or lamina spreader aids in restoration of length.
  - Measure the length of the residual bone defect directly and, taking into consideration the preoperative plan, determine the appropriate bone graft to use.

**Compression Plating Without Bone Graft**
- In rare cases with minimal or no bone loss at the nonunion site, the bone may be plated in situ without causing shortening. Because the bone remains at normal
Chapter 7  OPERATIVE TREATMENT OF RADIUS AND ULNA DIAPHYSEAL NONUNIONS

TECHNIQUES

length, the relationship of the radius and ulna at both the DRUJ and the PRUJ is not disrupted and rotation will be preserved.

- This technique may also be used if there is nonunion of both the radius and the ulna. Both bones may then be shortened a symmetrical distance.

- After bone preparation as detailed above, anatomically align the bone ends and precisely apply a compression plate using the same technique employed for acute forearm fractures.

- Ensure that compression of the bone ends is achieved.

- If a small bone gap exists after compression, the other forearm bone may then be shortened to restore the length relationship.

- Because this approach involves surgery on a normal bone, this strategy should be used with caution.

Cancellous Bone Grafting

- Cancellous bone grafting is generally used for small defects up to 3 cm that can be effectively stabilized with a plate.

- Gaps of up to 6 cm have been successfully treated using cancellous bone for grafting.9

- Firmly pack the cancellous autograft into the residual nonunion defect after the plate is applied.

- Ensure the graft does not escape from the nonunion site and come to lie on the IOM (TECH FIG 2).

Structural Corticocancellous Autograft Bone Grafting

- Structural autograft harvested from the anterior or posterior iliac crest is used for larger defects.

- Expose the superior crest and define the inner and outer tables.

- Utilize a water-cooled sagittal saw and osteotomes to harvest a tricortical block of bone from the iliac crest. Additionally, harvest cancellous bone to fill defects that may present.

- The graft should be slightly larger than that required based on preoperative planning.

- Precisely contour the graft to fit snugly into the defect. Square the ends of the graft to match the ends of the bone fragments.5

- Alternatively, cut both the bone ends of the radius or ulna and of the bone block chamfered, or on the bias, to increase the area of bony contact.3 This also allows the graft to be wedged securely in place.

- Insert the graft before plate fixation and fill any residual gaps with cancellous bone after plate application.

TECH FIG 1  •  A. Complete débridement of the nonunion site is the essential first step. Any fibrous or necrotic material must be removed and the bone ends delivered. B. Medullary canals are opened using increasing-diameter drill bits to allow vascular ingrowth.

TECH FIG 2  •  The nonunion gap is distracted if necessary to recreate the normal anatomic bone length. A 3.5-mm plate with a minimum of three screws proximal and distal should be used. Cancellous bone graft is inserted and packed in the nonunion gap.
**Nonvascularized Structural Fibula Autograft With Cortical Allograft Bone Grafting**

- An appropriate-length segmental graft is harvested from the fibula and placed into the defect.
- The fibula is approached laterally, via the intramuscular plane between the peroneal muscles and the soleus.
- A cuff of muscle 2 to 3 mm in thickness should be left to protect the periosteum.
- The IOM is incised longitudinally, taking care to avoid the posterior neurovascular bundle.
- The fibula is osteotomized proximally and distally to create an appropriate-length graft.
- Complications of fibular harvest are rare but include transient motor weakness, peroneal nerve palsy, and flexor hallucis longus (FHL) contracture.
- A minimum of 6 cm of the distal fibula must be retained to avoid adversely affecting the distal tibiofibular syndesmosis and ankle joint function.
- Insert the fibula graft into the defect and then apply the plate as described below, first placing the two screws just proximal and just distal to the nonunion to gain initial compression.
- Select a cortical allograft several centimeters longer than the defect.

**TECH FIG 3** • Combined intercalary autograft and allograft strut technique described by Moroni et al.8 After débridement of the nonunion site, an intercalary graft of appropriate length is harvested from the patient’s fibula and placed in the gap. A cortical allograft is placed opposite to the plate, and screws are placed passing through the plate, the patient’s radius or ulna, and finally the allograft strut.

**COMPRESSION PLATE FIXATION**

- Select a 3.5-mm (small fragment) compression plate of adequate length to ensure a minimum of three or four screws (six to eight cortices) on either side of the nonunion.
- Always err on the side of a longer plate.
- Thinner locking plates may be considered when structural fibular autografts are combined with cortical allograft struts.
- Fix the plate to the bone in compression (ensuring that proper length is maintained) with one screw proximal and one screw distal to the nonunion, then use full-length fluoroscopic views or radiographs of the forearm to ensure restoration of length, bow, and joint alignment.
- Compare with the contralateral forearm.
- Insert the remaining screws.
- Ideally, screws are not placed into the graft itself and the graft is stabilized by the compression created by the plate (TECH FIG 4).
- Close the wound routinely and apply an above-elbow or sugartong splint.

- Tibial allograft is recommended due to its suitable thickness and mechanical characteristics, which provide excellent screw purchase.8
- Place the cortical allograft along the outer cortex of the bone, opposite the plate, spanning beyond the length of the fibula allograft.
- Insert the remainder of the screws so that they pass through the plate and then the patient’s bone and finally into the cortical allograft on the opposite side (TECH FIG 3).
Débridement of all necrotic, sclerotic, and avascular tissue from the nonunion site is essential. Bone graft substitutes may offer alternatives to autograft, but no comparative studies exist at this time. Compression must be created across all structural grafts. An intraoperative infection workup, including Gram stain and culture, should be performed and an alternative plan should be available if infection is encountered. Differentiation should be made between hypertrophic and atrophic nonunions, as treatment differs. A negative preoperative workup does not rule out infection. Opening the sclerotic bone ends and gentle reaming of the medullary canals promotes ingrowth of medullary blood vessels. Periosteal stripping and cautery must be minimized to preserve periosteal blood supply. Anatomic restoration of length and bow is necessary to allow full rotational motion of the forearm. Contralateral radiographs must be used to determine the appropriate length of the forearm bones and degree of radial bow. Anatomic restoration of length and bow is necessary to allow full rotational motion of the forearm. A complete preoperative infection workup should be done for all patients with a nonunion. Defects up to 3 cm are successfully managed with cancellous autograft and appropriate fixation. Careful evaluation of the patient’s pain and functional limitations must be done before surgical management is planned. Postoperative care is delayed after surgery, the greater the chance the patient will develop stiffness. Therefore, early active range of motion (ROM) should be initiated at the first postoperative visit, except in cases with more tenuous fixation. Use of the arm for activities of daily living is encouraged. If the patient has difficulty in achieving satisfactory ROM with active, active-assisted, and gentle passive ROM, static progressive splints may be used. Having the patient sleep in a static extension splint may significantly improve elbow extension. Heavy lifting, pushing, and weight bearing are delayed until radiographic evidence of healing is present, often 3 to 6 months after the index procedure. When precise surgical techniques are used, such as creating stable compression across structural grafts, high rates of union are expected. Rates of healing from 95% to 100% are reported for all of the methods described in this chapter. Failure of union is related to recurrence of previous infection in nearly all cases. The prognosis for infected nonunions should be guarded. Patient satisfaction does not correlate directly with bony healing. In multiple studies only two thirds of patients achieved good or excellent results. Unsatisfactory results are associated with poor postoperative motion in the majority of cases. Other injuries to the upper extremity (common in high-energy trauma associated with nonunions) contributed to unsatisfactory overall function in a minority of patients. Because nonunion of the forearm diaphysis is a rare condition, no comparative studies of treatment methods exist, including the use of bone graft substitutes. Recurrent nonunion and hardware failure. Loss of motion. Synostosis. Pain or other complications at the autograft harvest site.

Postoperative Care

- The longer motion is delayed after surgery, the greater the chance the patient will develop stiffness. Therefore, early active range of motion (ROM) should be initiated at the first postoperative visit, except in cases with more tenuous fixation.
- Use of the arm for activities of daily living is encouraged.
- If the patient has difficulty in achieving satisfactory ROM with active, active-assisted, and gentle passive ROM, static progressive splints may be used.
- Having the patient sleep in a static extension splint may significantly improve elbow extension.
- Heavy lifting, pushing, and weight bearing are delayed until radiographic evidence of healing is present, often 3 to 6 months after the index procedure.

Outcomes

- When precise surgical techniques are used, such as creating stable compression across structural grafts, high rates of union are expected.
- Rates of healing from 95% to 100% are reported for all of the methods described in this chapter.
- Failure of union is related to recurrence of previous infection in nearly all cases. The prognosis for infected nonunions should be guarded.
- Patient satisfaction does not correlate directly with bony healing. In multiple studies only two thirds of patients achieved good or excellent results.
- Unsatisfactory results are associated with poor postoperative motion in the majority of cases.
- Other injuries to the upper extremity (common in high-energy trauma associated with nonunions) contributed to unsatisfactory overall function in a minority of patients.
- Because nonunion of the forearm diaphysis is a rare condition, no comparative studies of treatment methods exist, including the use of bone graft substitutes.

Complications

- Infection
- Graft displacement

References

DEFINITION
- Distal radius fractures occur at the distal end of the bone, originating in the metaphyseal region and often extending to the radiocarpal and distal radioulnar joints.
- Distal radius fractures can be classified as stable or unstable and extra- or intra-articular to assist in treatment decisions.
- Fractures may angulate dorsal or volar and may have significant comminution, depending on the energy of the injury and the quality of the bone.
- Percutaneous pins or K-wires, typically 0.062- or 0.045-inch, can be used for unstable intra-articular or extra-articular fractures with mild comminution and no osteoporosis.
- Percutaneous pins can aid reduction and stabilize the fragments in a minimally invasive manner.
- Percutaneous pins can support the subchondral area of the distal radius and maintain the articular reduction in highly comminuted fractures, which is useful in combined fixation methods.
- Smooth percutaneous pins may also be placed across the physis to maintain a reduction in children without causing a growth arrest.
- Highly comminuted fractures are more difficult to fix rigidly and often require internal and external fixation to maintain alignment during healing.
- External fixators can be hinged or static, and may or may not bridge the wrist joint.

ANATOMY
- The distal radius consists of three articular surfaces: the scaphoid fossa, the lunate fossa, and the sigmoid notch.
- Ligamentotaxis aids in the reduction of intra-articular and comminuted fractures.
  - Volar ligamentous attachments include the radioscapohamate, long radiolunate, and short radiolunate ligaments.
  - Dorsal ligamentous attachments include the dorsal intercarpal and radiocarpal ligaments.
- Dorsal and radial to the second metacarpal lie the first dorsal interosseous muscle and the terminal branches of the radial sensory nerve.

PATHOGENESIS
- Distal radius fractures are the most common fractures of the upper extremity in adults, representing about 20% of all fractures seen in the emergency room.17
- Mechanism of injury typically is a fall on an outstretched hand with axial loading, but other common histories include motor vehicle accidents or pathologic fractures.
- Higher-energy injuries cause increased comminution, angulation, and displacement.
- Osteoporosis, tumors, and metabolic bone diseases are risk factors for sustaining pathologic distal radius fractures.
- In children, fractures typically occur along the physis due to its relative weakness compared to the surrounding ligaments.

NATURAL HISTORY
- Distal radius fractures needing no reduction and those that are stable after reduction typically recover functional range of motion with minimal long-term sequelae.
Three parameters that affect outcome include articular congruity, angulation, and shortening.\(^{16,20}\)
- 1 to 2 mm of articular surface incongruity of the distal radius can lead to degenerative changes, pain, and stiffness.
- Dorsal angulation can lead to decreased range of motion and increased load transfer to the ulna.
- Radial shortening can lead to decreased range of motion, pain, and ulnar impaction of the carpus.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- The history of a fall on an outstretched hand is the most common presentation for a patient with a distal radius fracture.
- Motor vehicle or motorcycle accidents and osteoporosis account for most comminuted fractures.
- It may be clinically indicated to implement a workup for osteoporosis.
- Pain, tenderness, swelling, crepitus, deformity, ecchymosis, and decreased range of motion at the wrist are typical symptoms and warrant radiographic evaluation.
- Physical examination should include the following:
  - Inspection: Evaluate the integrity of the skin, cascade of the digits, direction of displacement, and presence of any swelling.
  - Identify points of maximal tenderness to differentiate between distal radius injuries and carpal or ligamentous injuries.
  - Touch or press specific areas of the wrist and hand to differentiate distal intra-articular, DRUJ, and carpal injuries.
  - Two-point discrimination: Higher than normal (5 mm) results in the form of progressive neurologic deficit may signify an acute carpal tunnel syndrome or ulnar neuropathy.
  - Passive finger stretch test to assist with diagnosis of compartment syndrome.
  - EPL tendon function should be evaluated.
  - EPL assessment: Assess the resting position of the thumb interphalangeal joint and the patient’s ability to lift the thumb off of a flat surface to determine the continuity of the EPL tendon.
  - Palpation of forearm and elbow to assess for concomitant injury proximally.
  - The DRUJ must be assessed for displacement.
  - The bony anatomy must be carefully evaluated to avoid missing minimally displaced fractures, which may displace without treatment.
  - Skin should be assessed to avoid missing an open fracture.
  - Swelling should be monitored to allow for early diagnosis of compartment syndrome.
  - Sensory examination should be monitored for progressive changes, which may represent acute carpal tunnel syndrome.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographic evaluation should include posteroanterior (PA), lateral, and oblique views to assess displacement, angulation, comminution, and intra-articular involvement, and allow for radiologic measurements.\(^{14,17}\)
- Lateral articular (volar) tilt is the angle between the radial shaft and a tangential line parallel to the articular margin as seen on the lateral view (FIG 2A). The normal angle is 11 degrees.
- Radial inclination, measured on the PA view (FIG 2B), is the angle between a line perpendicular to the shaft of the radius at the ulnar articular margin and the tangential line along the radial styloid to the ulnar articular margin. The normal angle is 22 degrees.
- Ulnar variance, also measured on the PA view (see Fig 2B), is the distance between the radial and ulnar articular surfaces. Ulnar variance is compared to the contralateral side.
- Traction radiographs help assess intra-articular involvement, intercarpal ligamentous injury, and potential fracture reduction through ligamentotaxis.
- CT scans are useful in fully elucidating the anatomy of the fracture, including impaction, comminution, and size of the fragments.
- CT scans often significantly alter the original treatment plan.\(^{11}\)
- MRI is rarely performed acutely but can diagnose concomitant ligamentous injuries, triangular fibrocartilage complex injuries, and occult carpal fractures.

**DIFFERENTIAL DIAGNOSIS**
- Bony contusion
- Radiocarpal dislocation
- Scaphoid or other carpal fracture
- Perilunate or lunate fracture dislocation
- Distal ulna fracture
- Wrist ligament or triangular fibrocartilage complex injury
- DRUJ injury

**NONOPERATIVE MANAGEMENT**
- Conservative treatment consists of splinting or casting for stable fracture patterns using a three-point mold.
- Fractures amenable to nonoperative treatment include fractures that are stable after reduction with minimal metaphyseal comminution, shortening, angulation, and displacement.
Evaluation for secondary displacement weekly for 2 to 3 weeks is critical as the swelling subsides.
- Unstable patterns will displace if not surgically stabilized.
- There is little role for nonoperative treatment in highly comminuted fractures.
- The physiologic age, medical comorbidities, and functional level of the patient should be considered in determining the need for surgical treatment.
- Early range of motion of the nonimmobilized joints is essential in the nonoperative treatment of all fractures near the wrist to prevent contracture.
- The cast or splint must not extend past the metacarpophalangeal joints so as to allow digital motion.

**SURGICAL MANAGEMENT**

- Surgical treatments are indicated to prevent malunion and improve pain control, function, and range of motion.
- Surgery is reserved for unstable fractures, including displaced, intra-articular, comminuted, or severely angulated injuries and fractures that displace following attempted closed management.
- Percutaneous pinning can assist in obtaining and maintaining reduction of displaced fractures with limited comminution in a minimally invasive manner.
- External fixators maintain radius length but cannot always control angulation and displacement; therefore, supplementation with percutaneous pins is typically performed.²
- Conversely, external fixators may augment percutaneous pins and plate fixation when extensive comminution is present.
- Supplemental external fixation should be considered for fractures with comminution of over 50% of the diameter of the radius on a lateral view.
- External fixation may be used as a neutralization device, because the distraction forces decrease soon after fracture reduction.
- External fixators also are useful for “damage control or-thopaedics” to temporarily stabilize wrist fractures, especially for complex, combined, open injuries.
- For nonbridging external fixation, there must be at least 1 cm of volar cortex intact and adequate fragment sizes to allow proper pin placement.
- A relative contraindication to pin fixation with or without external fixation is a volar shear injury, which should be reduced and stabilized using a volar plate and screws.

**Preoperative Planning**

- All radiographs should be reviewed before surgery and brought into the operating room.
- Analysis of the pattern and presumed stability of the fracture fragments determines whether percutaneous fixation, with or without external fixation, is suitable.
- For intra-articular fractures, the specific fragments to be reduced and fixed must be identified preoperatively to avoid incomplete reduction of the joint surface.
- The surgeon must be prepared to change his or her management decision intraoperatively if the fracture behavior is different than anticipated. A variety of fixation devices should be available in the operating room.

**Positioning**

- The patient is positioned supine on the operating table with a radiolucent arm board.

**FIG 3 • Positioning of patient supine on the hand table with tourniquet in place.**

- A tourniquet is applied near the axilla with the splint still in place (FIG 3).
- Fluoroscopy should be used for reduction confirmation and fixation throughout the procedure.
- There must be enough range of motion of the shoulder and elbow to allow standard AP, lateral, and oblique images.

**Approach**

- Various approaches can be used in the application of external fixators and the insertion of percutaneous pins.
- Distal external fixator half-pins may be placed directly into the second metacarpal or into other carpal bones (for injuries including the second metacarpal). Wires and half-pins, which are non-bridging fixators, may be placed in the distal radius itself.
- Percutaneous pins can be inserted through the radial styloid between the first and second dorsal compartments, through Lister’s tubercle, through the interval between the fourth and fifth dorsal compartments, and across the DRUJ (FIG 4).
- Caution is taken to avoid skewering tendons and nerves and to avoid penetrating the articular surface.

**FIG 4 • Areas for K-wire insertion at the distal radius.**
CLOSED REDUCTION OF A DISTAL RADIUS FRACTURE

- Closed reduction should be performed before fixation using distraction and palmar translation of the distal radius fragment and carpus.\(^1\)
- Use of a padded bump or towel roll will aid in the reduction (TECH FIG 1).
- Overdistraction will cause increased dorsal angulation due to the intact short, stout volar ligaments.\(^1\)
- Excessive palmar flexion of the wrist can restore volar tilt but leads to an increased incidence of stiffness and carpal tunnel syndrome.\(^7\)
- Overdistraction can be assessed by measuring the carpal height index, measuring the radioscaphoid and midcarpal joint spaces, checking full finger flexion into the palm, or evaluating index finger extrinsic extensor tightness.\(^8\)

CLOSED REDUCTION OF A DISTAL RADIUS FRACTURE

- Closed reduction is obtained using a bump, and the reduction is confirmed using fluoroscopy.
- This technique should be employed in patients younger than 55 years of age with minimal comminution. It should not be used in osteoporotic, elderly patients or those with comminution secondary to a higher loss of reduction. External fixation should be used to supplement pinning in these populations.\(^2\)

KAPANDJI TECHNIQUE FOR PERCUTANEOUS PINNING

- A stab incision is made radially, and a 0.062-inch pin is manually inserted into the fracture site, taking care to protect the sensory nerve branches and the first dorsal compartment tendons (TECH FIG 2A).
- The pin is angled distal, levering the bone back into its normal position and restoring the radial inclination (TECH FIG 2B). The pin is advanced through the far cortex using power, acting as a buttress to prevent loss of radial inclination (TECH FIG 2C).

**TECH FIG 1** • Closed reduction over a towel bump using traction and palmar translation.

**TECH FIG 2** • **A.** An incision is made over the radial styloid and a K-wire is manually inserted into the fracture site. **B.** The wire is levered distally to correct the radial inclination. **C.** The wire is advanced proximally, using power, into cortical bone. **D.** An incision is made over Lister’s tubercle, and a wire is inserted into the fracture site. **E,F.** The wire is levered distally to correct the dorsal angulation and advanced proximally using power into cortical bone.
A second stab incision is placed dorsally, and a second pin is manually inserted into the fracture (TECH FIG 2D). The pin is angled distal, levering the bone back into its normal position and restoring the volar tilt (TECH FIG 2E). The pin is advanced through the volar cortex using power, acting as a buttress to prevent loss of volar tilt (TECH FIG 2F). Using the modified technique, a third pin is placed retrograde using power, starting at the radial styloid and proceeding into the ulnar cortex of the radius proximal to the fracture line. The pins are buried and cut just below the skin, and the skin is sutured. Alternatively, the pins may be bent using two needle drivers and left outside the skin. The pins are then cut and covered with pin caps or antibiotic gauze. A sterile dressing is applied, followed by a splint.

**AUTHOR’S PREFERRED TECHNIQUE FOR PERCUTANEOUS PINNING**

- Closed reduction is obtained using a bump, and the reduction is confirmed using fluoroscopy (TECH FIG 3A,B).
- A small incision is placed over the bare spot on the radial styloid between the first and second dorsal compartments (TECH FIG 3C).
- Two 0.062-inch smooth K-wires are placed retrograde from the radial styloid across the reduced fracture, engaging the opposite cortex in a divergent fashion (TECH FIG 3D,E).
- A small incision is placed over the interval between the fourth and fifth dorsal compartments.
- One or two K-wires are placed retrograde from the dorsal ulnar corner of the distal radius across the reduced fracture, engaging the opposite cortex in a divergent fashion (TECH FIG 3F–H).
- The pins are cut just beneath the skin, which is closed with a 5-0 nylon suture. Alternatively, the pins are bent and cut and left outside the skin (TECH FIG 3I).
- A dressing and splint are then applied.

**TECH FIG 3 • A,B.** PA and lateral views demonstrating reduction of distal radius fracture. **C.** The incision is made over the radial styloid. **D.** A pin is inserted retrograde into the radial styloid. **E.** PA radiograph demonstrating the course of the radial styloid wire. **F.** Two radial styloid wires and two dorsoulnar wires are in place. *(continued)*
Distal Pin Placement

- A 3-cm incision is made over the dorsal index metacarpal, exposing the proximal two thirds.
- The distal sensory nerve branches are retracted, and the first dorsal interosseous muscle is elevated from the metacarpal to identify the insertion of the ECRL (TECH FIG 4A).

BRIDGING EXTERNAL FIXATOR APPLICATION

- The index metacarpophalangeal joint is flexed to protect the sagittal band and first dorsal interosseous aponeurosis.
- The metacarpal drill guide is placed on the radial base of the index metacarpal at the flare of the metaphysis. Partially threaded 3- to 4-mm pins are used, with or without predrilling.
A long threaded pin is placed through the index and long metacarpal bases, obtaining three cortices of fixation. Care is taken not to enter the carpometacarpal joint. The double drill guide is then placed over the first pin, and the distal short threaded pin is placed through both cortices of the index metacarpal shaft (TECH FIG 4B,C). Fluoroscopy confirms placement and length of the pins.

**Proximal Pin Placement and Frame Construction**

A 4- to 5-cm incision is made over the radial forearm, proximal to the first dorsal compartment musculature, through skin and subcutaneous tissue, avoiding the lateral antebrachial cutaneous nerve branches. The fascia overlying the interval between the brachioradialis and the ECRL is divided, and the radial sensory nerve is identified and retracted (TECH FIG 5A). The interval between the ECRL and ECRB also may be used to avoid the radial sensory branch.

The double drill guide is placed onto the diaphysis of the radius between the brachioradialis and the radial wrist extensors or between the ECRL and ECRB (TECH FIG 5B). Threaded 3- to 4-mm pins are placed, with or without predrilling. The fracture should be reduced, and the pins placed parallel to the metacarpal pins to facilitate alignment of the fracture. The proximal pin should be placed bicortically, just distal to the tendon of the pronator teres. The distal pin is then drilled bicortically through the double drill guide. Pin placement is confirmed using fluoroscopy. The incisions are closed using nylon suture, ensuring no tension is on the skin at the pin sites. Clamps and rods or adjustable fixators may then be applied to the pins to achieve and maintain final reduction (TECH FIG 5C). Supplementary K-wire fixation is added before or after external fixation (TECH FIG 5D).

**Nonbridging External Fixator Application**

Fracture reduction can be performed after insertion of the distal pins, allowing direct control of the distal fragment. The wrist is placed for a lateral fluoroscopic view, and a marker is used to determine the level of incision halfway between the radiocarpal joint and the fracture. A short transverse skin incision is made just proximal to the radiocarpal joint. A longitudinal incision is then made through the retinaculum on either side of Lister’s tubercle, and the EPL is protected. The first distal pin is drilled using power, parallel to the radiocarpal joint on the lateral view, halfway between the fracture and the joint surface (TECH FIG 6A).
The second distal pin is placed between the second and third dorsal compartments, between the radial wrist extensors and the EPL tendon.

This pin should be placed parallel to the first pin in both planes, with the starting point halfway between the radiocarpal joint and the fracture.

The two proximal radius pins are placed using the technique described for placement of a bridging external fixator.

The incisions are closed, after which the clamps are applied but not tightened.

Reduction is achieved by manipulation of the distal pins and clamps.

Pushing the pins in the dorsal/volar plane corrects dorsal tilt.

Adjusting the pin clamp can correct radial inclination.

Reduction is confirmed using fluoroscopy, and the clamps are tightened (TECH FIG 6B).

PEARLS AND PITFALLS

**Indications**
- Determine stability.
- Determine comminution and supplement fixation with external or internal fixation as necessary.

**Surgical approach**
- Make skin incisions for pin placement to avoid sensory nerves, tendons, and crossing veins.
- Obtain adequate exposure of the radial sensory branch at forearm and hand to avoid injury.

**Hardware placement**
- Choose pins of appropriate diameter.
- Supplement fixation with pins, using external or internal fixation as necessary.
- Do not leave pins more than 1 to 2 mm out of the cortex, and keep all pins extra-articular.
- If placing the proximal metacarpal pin in metaphyseal bone, ensure that three cortices are penetrated.
- Do not back out conical pins, because fixation will be lost.
- Evaluate the DRUJ after fixation to determine stability.
- Subcutaneous pins are more costly to remove, because that requires a second procedure, but they have a lower infection rate. Therefore, if fixation is needed for an extended period, bury the pins.
- Overdistraction of the carpus must be avoided, because it is associated with chronic pain-mediated syndromes and nonunion.

**Postoperative management**
- Allow for adequate immobilization.
- Encourage early range of motion of the fingers, elbow, and shoulder whenever possible.
- Educate the patient regarding appropriate pin care.
- Begin strengthening only after healing is complete and range of motion is maximized.

POSTOPERATIVE CARE

- After fixation with percutaneous pins, alone the wrist is immobilized in a short-arm splint to allow for swelling but provide stability. A cast is applied after the swelling goes down.
- Isolated radial styloid fractures fixed with pins can be placed in a volar wrist splint.

- External fixation devices typically require no additional immobilization, although a volar forearm-based Orthoplast (Johnson & Johnson, Langhorne, PA) splint may be used for support and patient comfort.
- The splint or cast is continued for 4 to 8 weeks, until healing occurs and the pins are removed.
OUTCOMES

A prospective randomized trial comparing percutaneous pinning and casting versus external fixation with augmentation (eg, pins, screws, bone graft) found no difference in clinical outcomes for fractures with minimal articular displacement.9

In patients over 60 years of age, percutaneous pinning has been shown to provide only marginal radiographic improvement over cast immobilization alone, with no correlation with clinical outcome.4

Ebraheim et al5 reported excellent outcomes for restoration of radiographic parameters and functional outcomes with intrafocal pinning and trans-styloid augmentation.

An evaluation of percutaneous pinning outcomes found the best results for metaphyseal fractures. Good results were found for intra-articular fractures. The worst results were seen in fractures with associated unlar styloid fractures and fractures in elderly persons.15

A retrospective review of radiographic and clinical outcomes of open reduction internal fixation (volar and dorsal) versus external fixation revealed no significant differences, except that palmar tilt was more effectively restored with dorsal plating.22

A meta-analysis found no evidence for the use of internal fixation over external fixation for unstable distal radius fractures.12

Women over 55 years of age with unstable intra-articular distal radius fractures treated with external fixation have a high rate of secondary displacement but can have acceptable functional outcomes.10

Patients over the age of 55 years have better results with external fixation and pinning than with pinning alone. Younger patients with two or more sides having comminution also have better results with supplemental external fixation.21

Nonbridging external fixation has been shown to maintain volar tilt and carpal alignment better than bridging external fixation while having significantly better function during the first year.13

Nonbridging external fixation was shown to have no clinical advantage in patients over 60 years of age with moderately or severely displaced distal radius fractures.3

A prospective, randomized comparison of bridging versus nonbridging external fixation revealed more complications in the nonbridging fixators and better outcomes in the bridged fixator group.18

A prospective study compared unrepaird ulnar styloid fractures to those without ulnar styloid fractures and found no significant differences in clinical outcome. However, DRUJ instability was not evaluated.19

COMPLICATIONS

Infection (pin tract or deep). Pin tract infections occur in 10% to 30% of patients.8,9

Finger, elbow, and shoulder range of motion are begun immediately, and wrist range of motion is begun as the fracture heals.

K-wires and half pins should be inspected and cleaned regularly using either soap and water or half-strength hydrogen peroxide and water.

Injury to tendons, vessels, and nerves due to percutaneous technique. Stiffness may result if tendons are inadvertently skewed, and the radial sensory branch can be injured.

Loss of range of motion

Posttraumatic arthritis

Weakness in grip or pinch

Tenosynovitis and tendon rupture

Malunion or nonunion

Compartment syndrome

Carpal tunnel syndrome

Hardware failure

Nonunion (associated with overdistraction with an external fixator)

Complex regional pain syndrome type I (associated with overdistraction with an external fixator)

REFERENCES

DEFINITION

- A bimodal age distribution exists for patients with distal radius fractures (ie, young adults vs elderly persons), and they frequently have a different mechanism of injury.
- Patients 65 years of age or older have an annual incidence of 8 to 10 fractures of the distal radius per 1000 person-years.
  - The incidence is seven times higher in women than in men.
  - Sixteen percent of white women and 23% of white men will sustain a fracture of the distal radius after the age of 50 years.
- Fractures of the distal radius are one of the most common skeletal injuries treated by orthopaedic surgeons.
- These injuries account for one-sixth of all fractures that are evaluated in the Emergency Department.
- Displaced intra-articular fractures of the distal radius are a unique subset of radius fractures.18
  - These fractures are a high-energy injury.
  - This high-energy injury results in comminuted fracture patterns.
  - These fractures are less amenable to traditional closed manipulation and casting.
  - The prognosis for these fractures depends on the amount of residual radius shortening, both radiocarpal and radioulnar articular congruity, and associated soft tissue injuries.22,24

ANATOMY

- The distal radius serves as a plateau to support the carpus.
- The distal radius has three concave articular surfaces: the scaphoid fossa, the lunate fossa, and the sigmoid notch.
- The distal articular surface of the radius has a radial inclination averaging 22 degrees and palmar tilt averaging 11 degrees.
- Radial-based volar and dorsal ligaments arise from the distal radius to support the wrist.
- The sigmoid notch of the distal radius articulates with the ulnar head about which it rotates.
  - The distal radioulnar joint (DRUJ) is primarily stabilized by the triangular fibrocartilage complex (TFCC).
  - The sigmoid notch angles distally and medially at an average of 22 degrees.

PATHOGENESIS

- The biomechanical characteristics of each fracture type depend on the mechanism of injury.
- Fernandez and Geissler4 developed a classification based on the mechanism of injury. They noted that the associated ligamentous lesions, subluxations, and associated carpal fractures are related directly to the degree of energy absorbed by the distal radius.
  - Type I fractures are bending fractures of the metaphysis in which one cortex fails to tensile stress and the opposite one undergoes a certain degree of comminution (eg, extra-articular Smith or Colles’ fractures).
  - Type II fractures are shearing fractures of the joint surface (eg, radial styloid fractures, Barton’s fracture).
  - Type III fractures are compression fractures of the joint surface with impaction of the subcondral and metaphyseal cancellous bone (ie, intra-articular comminuted fractures).
  - Type IV fractures are avulsion fractures of ligamentous attachments, including radial styloid and ulnar styloid fractures, and are associated with radiocarpal fracture-dislocations.
  - Type V fractures are high-energy injuries that involve a combination of bending, compression, shearing, and avulsion mechanisms or bone loss.
- Several studies have shown that a high incidence of associated soft tissue injuries is seen with displaced intra-articular distal radius fractures.9,11–13,17,19,20
  - Arthroscopic studies demonstrate a high incidence of injury to the triangular fibrocartilage complex, followed by the scapholunate interosseous ligament, and then the lunotriquetral interosseous ligament (which is the least injured).
  - A spectrum of injury occurs to the interosseous ligament in which it attenuates and eventually tears and the degree of rotation between the carpal bones increases.
- Geissler et al defined an arthroscopic classification of interosseous ligament tears that helps define the degree of ligament injury and secondary instability as well as proposes treatment (Table 1; see also Chap. HA-41).

NATURAL HISTORY

- Intra-articular fractures of the distal radius have two pathologies: the associated global injury to the soft tissues and the injury to the bone itself.
- The natural history for an intra-articular fracture of the distal radius depends on restoration of anatomy as well as detection and management of any associated soft tissue injuries.1,4
  - Knirk and Jupiter13 documented the importance of articular restoration over extra-articular orientation in predicting outcomes for fractures of the distal radius.
    - They showed solid evidence that the largest tolerable articular step-off is 2 mm.
    - They demonstrate that the better the restoration of the articular surface, the better the outcome.
  - A loss in radius length of 2.5 mm will shift the normal load transmitted across the ulna from 20% to 42%, which may lead to various stages of ulnar impaction syndrome.

<tbody>
<tr>
<td>I</td>
<td>Attenuation/hemorrhage of interosseous ligament as seen from the radiocarpal joint.</td>
<td>There is a loss of the normal concave appearance between the carpal bones, and the interosseous ligament attenuates and becomes convex as seen from the radiocarpal space. In midcarpal space, the interval between the carpal bones will still be tight and congruent, with no step-off.</td>
<td>Immobilization</td>
</tr>
<tr>
<td>II</td>
<td>Attenuation/hemorrhage of the interosseous ligament as seen from the radiocarpal joint. Incongruency/step-off as seen from the midcarpal space. A slight gap between the carpal bones may be present.</td>
<td>A slight gap (less than the width of a probe) between the carpal bones may be present. The interosseous ligament continues to become attenuated and is convex as seen from the radial carpal space. In the midcarpal space, the interval between the involved carpal bones is no longer congruent, and a step-off is present. In scapholunate instability, palmar flexion of the dorsal lip of the scaphoid will be seen as compared to the lunate. In lunotriquetral instability, increased translation between the triquetrum and lunate will be seen when palpated with a probe.</td>
<td>Arthroscopic reduction and pinning</td>
</tr>
<tr>
<td>III</td>
<td>Incongruency/step-off of carpal alignment is seen in both the radiocarpal and midcarpal spaces.</td>
<td>The interosseous ligament has started to tear, usually from volar to dorsal, and a gap is seen between the carpal bones in the radiocarpal space. A probe often is helpful to separate the involved carpal bones in the radiocarpal space. In the midcarpal space, a 2-mm probe may be placed between the carpal bones and twisted.</td>
<td>Arthroscopic/open reduction and pinning</td>
</tr>
<tr>
<td>IV</td>
<td>Incongruency/step-off of carpal alignment is seen in both the radiocarpal and midcarpal spaces. Gross instability with manipulation is noted.</td>
<td>A 2.7-mm arthroscope may be passed through the gap between the carpal bones. The interosseous ligament is completely detached between the involved carpal bones. This is the “drive-through” sign, when the arthroscope may be freely passed from the radiocarpal space through the tear to the midcarpal space.</td>
<td>Open reduction and repair</td>
</tr>
</tbody>
</table>

Untreated complete tears of the scapholunate interosseous ligament, which are highly associated with radial styloid fractures, may progress to a wrist with scapholunate advanced collapse.

PATIENT HISTORY AND PHYSICAL FINDINGS

A thorough history should be obtained, including the circumstances surrounding the injury as well as any additional injuries.

- Neurologic basis
- Cardiac basis
- Patients’ level of independence, dominant hand, status with assisted devices, work, activity level, and support structure should be determined.
- Physical examination, while concentrating on the wrist, should also include the hand, elbow, and shoulder to check for concomitant injuries.
- The hand, wrist, arm, and shoulder must be carefully inspected for open injury so that tetanus and antibiotic prophylaxis may be initiated if necessary.
- Thorough distal sensory and motor function examination should be carried out in an organized manner.
- Vascular examination should include palpation of both the radial and ulnar pulses and determination of capillary refill time.
- Precise palpation is used to define areas of potential trauma.

Diminished sensibility, pallor, altered capillary refill, increased tensesness of the soft tissues, and pain out of proportion should raise suspicion for significant soft tissue injury, including compartment syndrome.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Posteroanterior (PA), oblique, and lateral radiographs are the primary radiographic workup for distal radius fractures.
- Contralateral radiographs of the uninvolved extremity are useful to compare radial inclination, ulnar variance, and sigmoid notch anatomy.
- PA projections are useful to evaluate the radial inclination, radius height, presence of ulnar styloid fractures, widening of the DRUJ, widening of intracarpal spaces, and intra-articular involvement (FIG 1A).
- Standard radiographic parameters of the distal radius include radial inclination of 23 degrees (range 13–30), radius length of 12 mm (range 8–18 mm), and volar tilt of 12 degrees (range 1–21 degrees).
- Ulnar variance should be measured with the shoulder in 90 degrees of abduction, the elbow at 90 degrees of flexion, and the wrist in neutral pronation-supination.
- A lateral projection is used to assess volar and dorsal tilt of the distal fragment, dislocation or subluxation of the DRUJ or carpus, lunate angulation, and dorsal comminution (FIG 1B).
A modified lateral radiograph with the beam angulating 10 to 30 degrees proximally improves visualization of the articular surface and evaluation of the volar rim of the lunate facet represented by the anterior teardrop. An additional 30-degree anteroposterior (AP) cephalic projection is useful to evaluate the dorsal ulnar margin of the distal radius. Oblique radiographs are very helpful, because major fracture fragments may be rotated out of their anatomic planes. CT evaluation, particularly three-dimensional CT, can further delineate fragment location, joint compression, and rotation. MRI evaluation is useful in assessing for associated soft tissue injuries such as TFCC tears, interosseous ligament injuries, and carpal fractures.

Radiographic signs that demonstrate that the distal radius fracture is likely unstable and closed reduction would be insufficient include13:

- Lateral tilt greater than 20 degrees dorsal
- Dorsal comminution greater than 50% of the width
- Initial fragment displacement greater than 1 cm
- Volar translation greater than 2 mm
- Initial radius shortening more than 5 mm
- Intra-articular step-off greater than 2 mm
- Associated ulna fracture
- Severe osteoporosis.
- Age greater than 60 years

**DIFFERENTIAL DIAGNOSIS**

- Carpal bone fracture
- Metacarpal or phalangeal fracture
- DRUJ disruption
- Essex-Lopresti lesion
- Interosseous ligament tear
- Carpal dislocation (perilunate)

**NONOPERATIVE MANAGEMENT**

- Displaced fractures of the distal radius are reduced using an adequate anesthetic agent.
- Knowledge of the mechanisms of injury helps facilitate manual reduction. Force is applied opposite the force that caused the fracture.
- Gentle traction is necessary to disimpact the fracture fragments, followed by palmar translation of the hand and carpus in respect to the radius.
- The radius articular surface will rotate around the intact volar cortical lip to restore volar inclination with palmar translation.
- Care must be taken to avoid trauma to the skin during the reduction maneuver, particularly in elderly patients where the skin may be fragile.
- A splint is supplied following the reduction. No consensus has been established regarding wrist or forearm position, long-arm versus short-arm immobilization, or splint versus cast.
- Extreme positions of wrist flexion and ulnar deviation should be avoided.
- Postreduction radiographs are taken in plaster.
- Depending on stability of the fracture, most patients treated nonoperatively require weekly visits for the first 3 weeks to monitor fracture reduction.
- In patients older than 65 years, one third of initially undisplaced fractures subsequently collapsed to some degree.
- One study of elderly patients with moderately displaced fractures of the distal radius found that two thirds of the correction obtained by closed manipulation was lost at 5 weeks.
- Patients with minimally displaced or nondisplaced fractures of the distal radius treated nonoperatively must be made aware of possible complications, including rupture of the extensor pollicis longus tendon, carpal tunnel syndrome, and compartment syndrome.

**SURGICAL MANAGEMENT**

- Distal radius fractures without extensive metaphyseal comminution are ideal candidates for arthroscopic-assisted fixation with K-wires or cannulated screws.7,8
  - Radial styloid fractures
  - Impacted fractures
  - Die punch fractures
  - Three-part T-type fractures and four-part fractures with metaphyseal comminution are best treated with a combination of volar plate stabilization. Wrist arthroscopy is used as an adjunct to fine-tune the articular reduction and evaluate for associated soft tissue lesions.
  - Distal radius fractures that may be minimally displaced, and fractures with strongly suspected associated soft tissue injury, also are candidates for arthroscopic-assisted fixation to stabilize the fracture but, more importantly, to evaluate and treat the acute associated soft tissue injury.
  - Stabilization of associated ulnar styloid fragments is controversial.11 Wrist arthroscopy provides a rationale as to when to stabilize an ulnar styloid fragment.

**Preoperative Planning**

- All radiographic studies are reviewed.
- Equipment needed for arthroscopic treatment and for open stabilization is made available.
  - Small joint instrumentation is essential for arthroscopic-assisted fixation of distal radius fractures. The small joint arthroscope is approximately 2.7 mm in diameter, and even
smaller scopes may be used if desired. In addition, a small joint shaver (3.5 mm or less) is useful to clear fracture debris and hematoma.

- The ideal timing for arthroscopic-assisted fixation of distal radius fractures is 3 to 10 days following injury.6
- Earlier attempts at fixation may be complicated by soft tissue swelling and troublesome bleeding, obscuring visualization.
- After 10 days, the fracture fragments start to become sticky and more difficult to percutaneously elevate and reduce.

### Positioning

Arthroscopic-assisted fixation of distal radius fractures may be performed with the arm suspended vertically in a traction tower, horizontally in a traction tower, or with finger traps applied attached to weights hanging over the edge of the hand table.

- Wrist arthroscopy in the horizontal position may make it easier to simultaneously monitor the reduction fluoroscopically and place hardware. However, it does not allow for simultaneous volar access to the wrist.
- Suspending the wrist in a vertical position with a traction tower allows simultaneous access to both the volar and dorsal aspects of the wrist. This is particularly useful when wrist arthroscopy is used as an adjunct to volar plate fixation of the distal radius fracture.
- A new traction tower has been designed to allow simultaneous evaluation of the intra-articular reduction of the distal radius arthroscopically and fluoroscopically (FIG 2A).
- The surgeon may stabilize a comminuted fracture of the distal radius with a plate and simultaneously evaluate the articular reduction arthroscopically.
- The traction tower allows for traction of the wrist in either the vertical or horizontal planes, depending on the surgeon’s preference (FIG 2B).

### Approach

- The wrist is suspended in a traction tower, and the standard dorsal 3/4 viewing portal, 4/5 or 6R working portal, and 6U inflow portal are made.
- It is difficult to palpate the normal extensor tendon landmarks for traditional wrist arthroscopy in patients who sustain a fracture of the distal radius because of swelling.10 However, the bony landmarks usually can still be palpated. These bony landmarks include the bases of the metacarpals, the dorsal lip of the radius, and the ulnar head.
- The 3/4 portal is made in line with the radial border of the long finger. It is very useful to place a no. 18 needle into the proposed location of the 3/4 portal before making a skin incision.
- If the portal is placed too proximal, the arthroscope may be placed within the fracture pattern itself. If it is placed too distal, it can injure the articular surface of the carpus.
- Once the precise ideal location of the portal is located, the portal is made by pulling the skin with the surgeon’s thumb against the tip of a no. 11 blade. Blunt dissection is carried down with a hemostat, and the arthroscope, with a blunt trocar, is introduced into the dorsal 3/4 portal.
- This technique decreases potential injury to cutaneous nerves.
- Thorough irrigation of the joint is necessary to wash out fracture hematoma and debris and improve visualization. Inflow may be provided through the arthroscopy cannula or separately through a no. 14 needle into the 6U portal.
- Use of a separate 6U inflow portal is recommended. The small-joint arthroscopy cannula does not allow as much space between the cannula and the arthroscope, limiting the amount of flow through the cannula.
- Outflow to the wrist is provided through intervenous extension tubing connected to the arthroscopy cannula.
- The 4/5 working portal is made in line with the mid-axis of the ring metacarpal. Alternatively, the 6R working portal is made just radial to the palpable extensor carpi ulnaris tendon.
- A no. 18 needle is placed into the joint and should lie just distal to the articular disc.
- A 4/5 or 6R portal usually is located just proximal to the 3/4 portal because of the natural radial slope of the distal radius.

![FIG 2](image-url) • A. This traction tower (Acumed, Hillsboro, OR) uses a suspension bar at the side rather than at the center of the wrist. This allows easy fluoroscopic evaluation of the fracture reduction, with simultaneous full access to the volar and dorsal aspects of the wrist. B. The tower can be flexed into a horizontal position for surgeons who prefer to treat distal radius fractures in that position.
RADIAL STYLOID FRACTURES

- An isolated fracture of the radial styloid is an ideal fracture pattern to manage arthroscopically, especially for the surgeon beginning to gain experience in arthroscopic-assisted fixation of distal radius fractures.
- In addition, radial styloid fractures have a high incidence of associated injury to the scapholunate interosseous ligament, which is best assessed arthroscopically.
- Insert one or two guidewires from a cannulated screw system percutaneously into the radial styloid—not across the fracture site—using a wire driver in oscillation mode.
  - Evaluate the position of the wires under fluoroscopy to ensure they are centered in the radial styloid fragment.
- Suspend the wrist in a traction tower and establish the standard arthroscopic portals.
- Insert the scope in the dorsal 3/4 portal and clear the joint of debris and hematoma.
- Transfer the arthroscope to the 6R or 4/5 portal to look across the wrist and effectively judge rotation and reduction of the radial styloid fragment.
- Using the previously placed guidewires as joysticks, manipulate and anatomically reduce the fracture fragment under direct arthroscopic observation.
  - A trocar can be inserted through the 3/4 portal to help further guide the reduction of the radial styloid fragment (TECH FIG 1A,B).
- Once the fracture is judged to be absolutely anatomic, the guidewires are advanced across the fracture site into the radius shaft and evaluated under fluoroscopy (TECH FIG 1C).
  - In many cases, the fracture reduction may look anatomic under fluoroscopy, but when viewed arthroscopically, the radial styloid fragment is seen to be slightly rotated.³
- Guidewires alone can be used to stabilize the fracture, but cannulated screws (with or without heads) are recommended (TECH FIG 1D,E).
  - Cannulated screws decrease soft tissue irritation and potential pin track infection as compared with K-wires.

TECH FIG 1 • A. Arthroscopic view of the patient whose radiographs are seen in Figure 1. The arthroscope is in the 6R portal looking across the wrist, and a blunt trochar is in the 3/4 portal. The displaced radial styloid fragment is well visualized. B. A combination of joysticks inserted into the radial styloid fragment and a trochar inserted into the 3/4 portal allows anatomic reduction of the displaced radial styloid fragment and radiocarpal joint. C. The radial styloid fragment is anatomically reduced (with no residual rotation) and stabilized. D. PA view demonstrating anatomic reduction to the radial styloid fragment. Headless cannulated screws are used, if possible, to avoid soft tissue irritation. E. Lateral view showing anatomic restoration to the radial styloid fragment and restoration of the carpus in line with the radius.
THREE-PART FRACTURES

- Three-part fractures that involve a displaced fracture of the radial styloid and a lunate facet fragment without metaphyseal comminution are ideal for arthroscopic-assisted reduction (TECH FIG 2A,B).
- Reduce and provisionally stabilize the radial styloid fragment with guidewires under fluoroscopic guidance.
  - The radial styloid serves as a landmark to which the depressed lunate facet fragment is reduced.
- Suspend the wrist in the traction tower, establish portals, and evacuate the fracture debris and hematoma.
  - The depressed lunate facet fragment is best seen with the arthroscope in the 3/4 portal (TECH FIG 2C,D).
- Percutaneously place a no. 18 needle directly over the depressed fragment as viewed arthroscopically.
- Insert a large K-wire about 2 cm proximal to the previously placed no. 18 needle to percutaneously elevate the depressed lunate facet fragment.
  - Use a bone tenaculum to further diminish the gap between the radial styloid and lunate facet fragments.
  - Place guidewires transversely under the subchondral surface of the radius from the radial styloid into the anatomically reduced lunate facet fragment.
  - It is important to pronate and supinate the wrist following placement of the transverse pins to ensure the guidewires have not violated the DRUJ. The concave nature of the DRUJ makes radiographic assessment difficult.
  - Consider insertion of bone graft to support the reduced lunate fragment and avoid late settling.
  - Make a small incision between the fourth and fifth dorsal compartments.
  - Use cancellous allograft bone chips or bone substitutes.
  - If feasible, place headless cannulated screws to stabilize both the radial styloid and the impacted lunate facet fragments (TECH FIG 2E–H).

TECH FIG 2 • A. PA view showing a impacted scaphoid facet fracture fragment with an obvious injury to the scapholunate interosseous ligament. B. Lateral view showing a dorsal rim fracture fragment. C. The arthroscope is in the 6R portal, demonstrating the impacted scaphoid facet fracture fragment. This would be quite difficult to view through an open arthrotomy, but is well visualized arthroscopically under bright light and magnified conditions. D. The impacted scaphoid facet fragment is elevated back to the volar rim, using the rim as a landmark to judge rotation. E,F. Geissler grade III tear involving the scapholunate interosseous ligament as seen through the 3/4 portal (E) and the radial midcarpal portal (F). (continued)
THREE- AND FOUR-PART FRACTURES WITH METAPHYSEAL COMMINUTION

- A combination of open surgery, using a volar plate for stability, and arthroscopy, as an adjunct to assist the articular reduction, is used if metaphyseal comminution is present (TECH FIG 3).
- Volar plate stabilization is very stable and allows for early range of motion and rehabilitation as compared to K-wires or headless screws alone.

Open Reduction and Stabilization

- Perform a standard volar approach and do not open the radiocarpal joint capsule (TECH FIG 4A).
- The radial styloid fragment and the volar ulnar fragment are reduced to the shaft under direct visualization. The radial styloid fragment is provisionally pinned.
- Apply a volar distal radius locking plate to stabilize the volar bone fragments (TECH FIG 4B).
  - Place a screw in the proximal portion of the plate first, to reduce the plate to the shaft.
- Provisionally pin the distal fragments through the plate.
- Manipulate the articular fragments under fluoroscopy to obtain as anatomic a reduction as possible (TECH FIG 4C,D).
- Suspend the wrist in the traction tower and reduce the articular fragments arthroscopically (TECH FIG 4E,F).
  - If articular reduction is not anatomic, remove the pins and fine-tune the reduction.
- Once the fracture reduction is thought to be anatomic, place the distal screws through the plate (TECH FIG 4G–I).
  - It is important that the fracture be reduced to the plate, with no gap between the plate and the bone. This can be achieved by flexion of the wrist in the tower and by insertion of a non-locking screw first, before the insertion of standard locking screws.
  - Place the remaining proximal and distal screws if the reduction is anatomic under both fluoroscopy and arthroscopy.
TECH FIG 4 • A. A standard volar approach is made, centered over the flexor carpi radialis tendon, and the fracture site is exposed. B. A volar distal radius locking plate (Acumed, Hillsboro, OR) is applied. The initial screw is placed through the proximal plate to secure the plate to the shaft. C. The intra-articular reduction is viewed under fluoroscopy and provisionally pinned. A displaced intra-articular fracture fragment can still be identified. D. The arthroscope is in the 3/4 portal, showing the volar capsule blocking reduction of the radial styloid fragment. E. Joysticks previously inserted into the radial styloid fragment are then used to control and anatomically reduce the radial styloid fragment. F. The arthroscope is in the 6R portal looking across the wrist. Anatomic reduction of the radial styloid fragment is documented. G. Once the anatomic restoration of the articular surface is evaluated both arthroscopically and fluoroscopically, the distal screws are placed in the plate. H. Fluoroscopic view showing anatomic restoration to the articular surface of the distal radius. I. The patient had an associated osteochondral fracture of the lunate, not visible on plain radiographs. The displaced fragment is arthroscopically removed.
Reduction and Stabilization of a Dorsal Die Punch Fragment

- It is not possible to see the reduction of a dorsal die punch fragment through the volar approach when stabilized with a plate. Arthroscopy can be helpful in this scenario.
- Insert the volar plate as previously described and provisionally fix the device to the radius.
- Frequently, the dorsal fragment may still be slightly proximal in relation to the radial shaft.

ULNAR STYLOID FRACTURES

- Following anatomic reduction of the distal radius fracture, insert the arthroscope in the dorsal 3/4 portal and the probe in the 6R portal. Palpate the tension of the articular disc.
  - Good tension indicates that the majority of the peripheral TFCC fibers are intact or still attached to the proximal ulna.
  - A peripheral tear of the articular disc is repaired arthroscopically when detected.
- Stabilization of a large ulnar styloid fragment is considered when the articular disc is lax by palpation and no peripheral TFCC is identified (TECH FIG 5).
  - In this instance, the majority of the fibers of the TFCC are attached to the displaced ulnar styloid fragment.
- Make a small incision between the extensor carpi ulnaris and the flexor carpi ulnaris tendons and identify the fracture site.
- Retrieve the distal fragment, which often displaces in a distal and radial direction.
- Mobilize the styloid fragment using a no. 15 blade, taking care to protect the TFCC insertion.
- Reduce the fragment anatomically, under direct visualization, and insert a guidewire in a retrograde manner for provisional stability.
- Stabilize the ulnar styloid fragment using either a tension band technique (with wire and two K-wires) or, preferably, using a micro headless cannulated screw.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Timing of reduction</th>
<th>Arthroscopically assisted reduction of distal radius fractures is most ideal between 3 and 10 days following injury. Assisted fixation before 3 days usually is complicated by bleeding that can obscure visualization. Percutaneous fracture reduction more than 10 days after the injury is exceedingly difficult and often unsuccessful.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arthroscopic visualization</td>
<td>It is important to take the time to thoroughly irrigate and débride the joint of hematoma and debris. This especially helps visualization of fragment rotation. Irrigation through a separate 6U inflow portal is helpful. A Coban wrap (3M, St. Paul, MN) may be wrapped around the forearm to limit fluid extravasation into the soft tissues.</td>
</tr>
<tr>
<td>Instrumentation</td>
<td>Large-joint instrumentation will damage the articular cartilage and is not appropriate. A mobile traction tower is extremely helpful in arthroscopic-assisted management of distal radius fractures.</td>
</tr>
<tr>
<td>Fixation</td>
<td>Do not substitute poor fixation for an arthroscopically assisted procedure. Fixation should be chosen to fit the personality of the fracture. For example, K-wires should not be used to stabilize a volar Barton’s fracture when volar plate stabilization is the obvious choice. While K-wires are easy to insert, they hinder rehabilitation and have the potential for pin track infections.</td>
</tr>
</tbody>
</table>
Cannulated screws are recommended when arthroscopically stabilizing a fracture of the distal radius without metaphyseal comminution.

Volar plate fixation is recommended when metaphyseal comminution is present.

Arthroscopic evaluation of the wrist while the distal screws are being placed offers the advantage of seeing the screws penetrate into the fracture fragments, thereby ensuring stability. Arthroscopic evaluation is helpful in variable-angle volar locking plates to ensure the screws do not violate the joint.

POSTOPERATIVE CARE

- The degree of postoperative immobilization depends on numerous factors, including the mode of fracture stabilization, the quality of the bone for internal fixation, the stability of the fixation, and the management of any associated soft tissue injuries that were addressed during the arthroscopic evaluation.
- Immediate range of motion of the digits and wrist is initiated in patients with volar plate fixation with good bone stock and solid fixation.
- In patients with soft osteopenic bone with volar plate fixation, digital range of motion exercises are initiated immediately, but wrist range of motion is delayed approximately 3 to 4 weeks to permit some fracture healing.
- Soft bone may collapse around the rigid plate.
- In patients without metaphyseal comminution treated by arthroscopically assisted stabilization with cannulated screws, range of motion is initiated as the patient tolerates.
- In patients treated with percutaneous K-wires, the wrist is immobilized until the wires are removed, usually 4 to 6 weeks after surgery.
- A patient with an unstable DRUJ treated by TFCC repair or ulnar styloid reduction and fixation is restricted from pronation and supination for 2 to 4 weeks.

OUTCOMES

- The literature is relatively sparse regarding the results of arthroscopically assisted fixation of displaced intra-articular distal radius fractures.
- A comparison study of 12 open and 12 arthroscopic reductions of comminuted AO type VII and VIII fractures of the distal radius found that the arthroscopic group had increased range of motion as compared to the open stabilization group.\(^{23}\)
- A second comparison study of 38 patients who underwent arthroscopically assisted fixation compared to open reduction found the arthroscopically assisted group had better results and improved range of motion.\(^{2}\)
- One study compared 15 patients with arthroscopically assisted fixation to 15 patients who underwent closed reduction and external fixation.\(^{21}\) In this study, there were 10 tears of the triangular fibrocartilage complex in the group that underwent arthroscopic reduction, of which seven were peripheral and repaired. There were no signs of distal radioulnar joint instability at final follow-up visit. In the 15 patients who underwent stabilization by external fixation alone, four patients had continued complaints of instability of the distal radial joint, very possibly the result of undiagnosed and untreated TFCC tears.

COMPILATIONS

- Failure of fixation
- Late settling of the fracture despite fixation
- Flexor and extensor tendon irritation
- Painful metal requiring removal
- Neuromas of the dorsal sensory branch of the radial and ulnar nerves
- Carpal tunnel syndrome
- Reflex sympathetic dystrophy
- Wrist and hand stiffness

REFERENCES

DEFINITION

- Fragment-specific fixation is a treatment approach in which each major fracture component is identified and fixed independently using low-profile implants with a certain degree of "spring-like" elasticity.
- Each fracture component has a unique implant specifically designed for that particular fracture element (FIG 1).
- Surgical planning is extremely important to determine whether a single approach or a combination of surgical approaches is needed to visualize and fix each of the main fracture components present in a particular injury.
- At the start of surgery, a complete set of implants should be available to address fractures of the radial column, ulnar corner, volar rim, dorsal wall, and free impacted articular fragments. In addition, identification and treatment of distal radioulnar joint (DRUJ) disruptions or unstable fractures of the ulnar column may be required.
- As a rule, this technique avoids creating large holes in small distal fragments, with fixation based and often triangulated to the stable ipsilateral cortex of the proximal fragment.

- The goal of fragment-specific fixation is to create a multi-planar, load-sharing construct that anatomically restores the articular surface and has enough stability to allow immediate motion after surgery.

ANATOMY

- The radial column fragment is formed from the pillar of bone along the radial border (FIG 2). This fracture component is important to maintain radial length to support the carpus in its normal spatial position. The brachioradialis inserts on the base of the radial column and may result in shortening of the radial column fragment, leading to impaction of the carpus into remaining fragments. Metaphyseal comminution may also contribute to radial column instability.
- The volar rim of the lunate facet is a primary load-bearing structure of the articular surface. Instability of the volar rim occurs in two patterns:
  - In the volar instability pattern, shortening and volar translation of the volar rim result in secondary volar subluxation of the carpus.

FIG 1 • Fragment-specific implants.
In the axial instability pattern of the volar rim, axial impact of the carpus drives the volar rim into dorsiflexion, resulting in secondary axial and dorsal subluxation of the carpus.

- The ulnar corner fragment involves the dorsal half of the sigmoid notch. Typically a result of impaction of the lunate into the articular surface, this fragment migrates dorsally and shortens proximally. Residual displacement of the ulnar corner can result in instability of the DRUJ as well as restriction of forearm rotation.
- Dorsal wall fragmentation typically occurs with either dorsal bending injuries or axial loading injuries and may contribute to fracture instability.
- Free articular fragments may be impacted within the metaphyseal cavity and result in incongruity of the articular surface.

**PATHOGENESIS**
- Dorsal bending injuries result in extra-articular fractures with dorsal displacement. Comminution of the metaphyseal cavity or dorsal wall usually suggests a dorsally unstable fracture pattern.
- Volar bending injuries result in extra-articular fractures with volar displacement. Fractures with significant volar displacement are nearly always unstable and require some type of intervention to obtain and hold a reduction until union.
- Dorsal shearing injuries present as fractures of the dorsal rim and are often associated with dorsal instability of the carpus. (FIG 3C). Volar shearing injuries present as displaced fractures of the volar rim and result in volar instability of the carpus. (FIG 3D). Often, this pattern is comminuted and highly unstable and not suited to closed methods of treatment.
- Simple three-part fractures are usually the result of low-energy injuries that combine an axial loading and dorsal bending mechanism. This pattern is characterized by the presence of an ulnar corner fragment that involves the dorsal portion of the sigmoid notch, a main articular fragment, and a proximal shaft fragment.
- Unstable fractures with complex involvement of the articular surface to simplify complex articular fractures. In addition to articular comminution, this pattern may often generate a significant defect in the metaphyseal cavity or complete disruption of the DRUJ (FIG 3F).
The avulsion and carpal instability pattern is primarily a ligamentous injury of the carpus that has associated osseous avulsions of the distal radius (FIG 3G).

Extremely high-energy injuries present as complex fractures involving comminution of the articular surface as well as extension into the radial or ulnar shaft (FIG 3H).

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Posteroanterior (PA), standard lateral (FIG 4A,B), and 10-degree lateral views are routine views for radiographic evaluation of the distal radius. The 10-degree lateral view (FIG 4C,D) clearly visualizes the ulnar two thirds of the articular surface from the base of the scaphoid facet through the entire lunate facet. Oblique views may also be helpful for evaluating the injury.

- The radiographic features of distal radius fractures include the following:
  - Carpal facet horizon (FIG 5A,B). This is the radiodense horizontal landmark that is used to identify the volar and dorsal rim on the PA view. If the articular surface is in palmar tilt, the x-ray beam is parallel to the subchondral bone of the volar half of the lunate facet and the carpal facet horizon identifies the volar rim. However, if the articular surface is in dorsal tilt, the x-ray beam is parallel to the subchondral bone of the dorsal half of the lunate facet and the carpal facet horizon identifies the dorsal rim (not shown). The carpal facet horizon is the portion of the articular surface that is visualized on the 10-degree lateral x-ray projection.
  - Teardrop angle (normal 70 ± 5 degrees; FIG 5C,D). The teardrop angle is used to identify dorsiflexion of the volar rim of the lunate facet. Depression of the teardrop angle to a value less than 45 degrees indicates that the volar rim of the lunate facet has rotated dorsally and impacted into the metaphyseal cavity (axial instability pattern of the volar rim). This may be associated with axial and dorsal subluxation of the carpus. Restoration of the teardrop angle is necessary to correct this type of malreduction.
  - Articular concentricity (FIG 5E,F). The subchondral outline of the articular surface of the distal radius is normally congruent and concentric with the subchondral outline of the base of the lunate; a uniform joint interval should be present between the radius and lunate along the entire articular surface. When these articular surfaces are

FIG 5 • A. Carpal facet horizon (arrows). Used to differentiate between the volar and dorsal rim on the PA projection. B. Origin of carpal facet horizon. The carpal facet horizon is formed by that part of the articular surface that is parallel to the x-ray beam and depends on whether the articular surface is in volar or dorsal tilt. C. Normal teardrop angle. D. Depressed teardrop angle, in this case caused by axial instability of the volar rim. (continued)
Clinical and radiographic evaluations of the carpus, interosseous membrane, and elbow are used to identify the presence of other associated injuries that may affect the decision for a particular treatment.

SURGICAL MANAGEMENT

Operative Indications
- General parameters:
  - Shortening of more than 5 mm
  - Radial inclination of less than 15 degrees
  - Dorsal angulation of more than 10 degrees
  - Articular stepoff of more than 1 to 2 mm
  - Depression of teardrop angle of less than 45 degrees
  - Volar instability
  - DRUJ instability
  - Displaced articular fractures
  - Young, active patients are generally less tolerant of residual deformity and malposition.

Preoperative Planning
- Extra-articular fractures: multiple options:
  - Volar plating through a volar approach
  - Dorsal plating through a dorsal approach
  - Fragment-specific fixation
    - Radial pin plate (TriMed, Inc., Valencia, CA) and volar buttress pin (TriMed, Inc.) fixation through a limited incision volar or standard volar approach
    - Radial pin plate and either an ulnar pin plate dorsally or a dorsal buttress pin through a dorsal or combined approach
  - Intra-articular fractures: surgical approach is based on the fragmentation pattern
    - Unstable volar rim fragments require a standard volar or ulnar-volar approach for adequate visualization.
Fixation of the radial column can be done through either a limited-incision volar-radial approach, a volar approach with a radial extension combined with pronation of the forearm, or a dorsal approach with radial extension combined with supination of the forearm. Fixation of dorsal, ulnar corner, and free intra-articular fragments can be done through a dorsal approach.

**Positioning**
- The patient is supine.
- The affected arm is on an armboard out to the side.
- C-arm
  - If the armboard is radiolucent, the C-arm can be brought in from the end of the armboard and images taken directly with the wrist on the armboard.
  - If the armboard is not radiolucent, the C-arm is brought in along the side of the table from the foot, and the arm is brought off the armboard for each image.

**Operative Sequence**
- Radial column length is restored first with traction; a transstyloid pin is inserted to hold the reduction if needed.
- The volar rim is reduced and fixed.
- The dorsal ulnar corner is reduced and fixed.
- Free intra-articular fragments and the dorsal wall if needed are reduced and stabilized.
- Bone graft is applied if the metaphyseal defect is large.
- Fixation is completed with a radial column plate.

**Approach**
- The repair is undertaken by means of one of the following approaches:
  - Limited-incision volar approach
  - Dorsal approach
  - Extensile volar approach
  - Volar-ulnar approach

---

**LIMITED-INCISION VOLAR APPROACH**

- Make a longitudinal incision along the radial side of the radial artery.
- Proximally, insert the tip of a tenotomy scissors over the surface of the first dorsal compartment sheath and sweep distally to elevate a radial skin flap.
- Pronate the forearm and sharply expose the bone over the radial styloid in the interval between the first and second dorsal compartments (TECH FIG 1A).
- Leaving the distal 1 cm of sheath intact, open the first dorsal compartment proximally and mobilize the tendons.

Reflect the insertion of brachioradialis to expose the radial column (TECH FIG 1B).
- If needed, the dissection can be continued through the floor of the incision to expose the volar surface. Detach the insertion of the pronator quadratus radially and distally and reflect it to the ulnar side. Alternatively, create an ulnar skin flap superficial to the artery and continue the exposure through a standard volar approach.
- This approach cannot be used to access the ulnar side of the volar rim.
DORSAL APPROACH

- Make a longitudinal skin incision dorsally along the ulnar side of the tubercle of Lister (TECH FIG 2A).
- Identify the extensor digitorum communis (EDC) tendons visible proximally through the translucent extensor sheath. Incise the dorsal retinacular sheath.
- Develop the interval between the third and fourth compartment tendons for access to dorsal wall and free, impacted articular fragments. Resect a segment of the terminal branch of the posterior interosseous nerve (TECH FIG 2B).
- Transpose the extensor pollicis longus (EPL) from the tubercle of Lister if required for additional exposure.
- Develop the interval between the fourth and fifth extensor compartments to gain access to the ulnar corner fragment.
- A dorsal capsulotomy can be done to visualize the articular surface and carpus if necessary.
- To gain access to the radial column through a dorsal exposure, extend the incision as needed and elevate a radial subcutaneous flap and supinate the wrist.
- To gain access to the distal ulna, extend the incision as needed and elevate an ulnar subcutaneous flap.

EXTENSILE VOLAR APPROACH

- Start the skin incision at the distal pole of the scaphoid and angle it toward the radial border of the flexor wrist crease, then extend it proximally along the flexor carpi radialis (FCR) tendon (TECH FIG 3A).
- Open the FCR tendon sheath both proximally and distally and continue in the plane between the FCR tendon and the radial artery (TECH FIG 3B).
- Use blunt dissection with a finger or sponge to separate the interval between the contents of the carpal tunnel and the surface of the pronator quadratus. Retract the FCR, median nerve, and flexor tendons to the ulnar side.
- Divide the radial and distal attachment of the pronator quadratus and reflect it to the ulnar side. Limit the distal dissection to no more than 1 or 2 mm beyond the distal radial ridge to avoid detachment of the volar wrist capsular ligaments (TECH FIG 3C).
- Reflect the brachioradialis from its insertion on the distal fragment if needed. Bone graft can be applied through the radial fracture defect.
- If access to the radial column is needed, elevate a radial subcutaneous flap superficial to the radial artery and first dorsal compartment tendon sheath. Pronate the wrist and retract the radial skin flap to expose the radial column.
VOLAR-ULNAR APPROACH

- Make a longitudinal skin incision along the ulnar border of the flexor carpi ulnaris (FCU) tendon (TECH FIG 4A).
- Reflect the FCU tendon and the ulnar artery and nerve to the ulnar side (TECH FIG 4B).
- With blunt finger or sponge dissection, develop the plane on the superficial surface of the pronator quadratus.
- Retract the contents of the carpal tunnel to the radial side (TECH FIG 4C).
- Reflect the pronator quadratus from its ulnar and distal attachment. Do not dissect more than 1 to 2 mm beyond the distal radial ridge to avoid detaching the volar wrist capsule.

RADIAL COLUMN FIXATION WITH RADIAL PIN PLATE

- Expose the radial column with any of the approaches previously described. Sharply expose the interval between the first and second dorsal compartments over the tip of the radial styloid. Release the tendon sheath of the first dorsal compartment proximally, leaving the last 1 cm of tendon sheath intact.
- Retract the tendons of the first dorsal compartment dorsally or volarly as needed. Release the terminal insertion
of the brachioradialis to complete exposure of the radial column.

- After the initial fracture exposure, restore radial length with traction and ulnar deviation of the wrist. If needed, structural bone graft can be inserted through the radial fracture defect.

- Insert a 0.045-inch transstyloid Kirschner wire angled to engage the far cortex of the proximal fragment (TECH FIG 5A). When the advancing tip of the Kirschner wire hits the far cortex, place a drill sleeve over the Kirschner wire to use as a drill stop to limit penetration of the far cortex to 1 to 2 mm.

- Once the radial column is temporarily fixed with a transstyloid Kirschner wire, reduce and stabilize other volar, dorsal, and articular fracture elements before completing fixation of the radial column.

- Select a distal pin hole and slide a radial pin plate over the transstyloid Kirschner wire. Proximally, guide the plate under the tendons of the first dorsal compartment and secure it initially with a single 2.3-mm bone screw.

- Insert a second transstyloid Kirschner wire through a non-adjacent distal pin hole. Use the previous technique to limit penetration of the Kirschner wire through the far cortex to 1 to 2 mm.

- Mark a reference point where the Kirschner wire crosses the surface of the plate. Withdraw the Kirschner wire 1 cm and cut it 1 cm or more above the reference mark (TECH FIG 5B).

- Position the reference mark between the lower two posts of a wire bender and create a hook (TECH FIG 5C). The bend should start at the reference mark to make a Kirschner wire of proper length when completed.

- Complete the bend with a pin clamp, overbending slightly to allow the hook to snap into an adjacent pin hole or over the edge of the plate. With a free 0.045-inch Kirschner wire, predrill a hole to accept the end of the hook (TECH FIG 5D).

- Impact the Kirschner wire with a pin impactor and fully seat the hook (TECH FIG 5E). Repeat the procedure with the second Kirschner wire.

- Complete proximal fixation with 2.3-mm cortical bone screws (TECH FIG 5F,G).

**TECH FIG 5** - Radial column fixation. **A.** Insertion of transstyloid Kirschner wire. **B,C.** Creation of pin hook. **D,E.** Completion and impaction of pin hook. **F,G.** Completed radial column fixation.
ULNAR CORNER AND DORSAL WALL FIXATION

**Ulnar Pin Plate**
- Through a dorsal approach, expose and reduce the dorsal ulnar corner fragment, dorsal wall fragment, or both.
- Insert a 0.045-inch Kirschner wire through the fragment (TECH FIG 6A), angled proximally and slightly radially to purchase the far cortex of the proximal fragment.
- Insert structural bone graft into the metaphyseal defect if present to support the subarticular surface.
- If the plate is aligned over the ulnar half of the shaft, add a 15-degree torsional bend to the plate (twist the proximal end of the plate into slight supination). Often, a little extra extension can be contoured at the distal end of the plate (TECH FIG 6B).

**Dorsal Buttress Pin**
- Through a dorsal approach, expose and reduce the dorsal ulnar corner fragment, dorsal wall fragment, or both.

- Slide the plate over the Kirschner wire and fix it proximally with a 2.3-mm bone screw (TECH FIG 6C).
- Insert a second Kirschner wire if the fragment is large enough. Create and impact hooks as described for the radial pin plate (TECH FIG 6D–E).
- If the Kirschner wire tips protrude beyond the volar cortex, they can be cut flush to the bone surface through a volar incision.

TECH FIG 6 • Ulnar corner fixation with an ulnar pin plate. A. Insertion of the interfragmentary Kirschner wire. B. Contouring the plate. C. Application of the plate and insertion of the initial fixation screw. D. Fixation completed. E,F. Radial and ulnar pin plate fixation of a three-part articular pattern (radial column and ulnar corner fragment).
Insert structural bone graft into the metaphyseal defect if present to support the subarticular surface.

Insert two 0.045-inch Kirschner wires through the dorsal cortex and behind the subchondral bone; check the position with the C-arm (TECH FIG 7A). The Kirschner wires should be separated by about 1 cm and should be transverse to the longitudinal axis of the shaft. Initially placing a dorsal buttress pin upside-down on the bone is helpful to use as a template to visualize the proper position and insertion angle of the Kirschner wires (TECH FIG 7B).

Ensure that the leading tips of the legs of the dorsal buttress pin are straight and cut to the required length (TECH FIG 7C). Leave the ulnar leg 2 to 3 mm longer than the radial leg so one leg can be engaged at a time.

Place the ulnar leg of the buttress pin adjacent to the insertion site of the ulnar Kirschner wire, and then withdraw the Kirschner wire and immediately engage the leg in the hole. Repeat with the radial Kirschner wire to engage the radial leg of the buttress pin. Impact and seat the buttress pin (TECH FIG 7D).

Fine-tune the reduction and complete the fixation proximally with one or two 2.3-mm cortical bone screws and washers (TECH FIG 7E,F). If needed, a blocking screw can be placed just proximal to the end of the buttress pin to prevent shortening of the fragment.

**TECH FIG 7** Dorsal buttress pin fixation. A. The position of the Kirschner wires is checked with a C-arm before inserting the implant. B. Placing an implant upside-down on bone to template the trajectory of the Kirschner wires. C. Inserting the dorsal buttress pin. D. Buttress pin fixation completed. E,F. Fixation of a three-part articular fracture with radial column and ulnar corner fragment with radial column plate and dorsal buttress pin.

**VOLAR RIM FRAGMENT**

**Small-Fragment Plate Fixation**

Small-fragment volar plate fixation may be indicated for treatment of a volar instability pattern of the volar rim. The fragment must be of adequate size to allow buttressing on the volar surface by the plate (TECH FIG 8A,B).

If volar rim fragmentation is associated with an axial instability pattern, the fragment must be of adequate size and strength to allow distal locked screw purchase to obtain angular correction of the dorsiflexion deformity.

An appropriate volar approach is used to expose the volar rim fragment. If a shortened radial column fragment is present, first restore radial length and provisionally hold it with a transstyloid Kirschner wire to unload the lunate facet.
Reduce the volar rim fragment; this should restore normal carpal alignment.
- Apply a small-fragment volar plate and fix it proximally with cortical bone screws. If needed, secure the distal fragment with standard or locking bone screws (TECH FIG 8C,D).

**Volar Buttress Pin Fixation**
- Volar buttress pin fixation is indicated for unstable volar rim fragments and can be a particularly effective technique when faced with small distal fragments or axial instability patterns of the volar rim (depressed teardrop angle; TECH FIG 9A,B).
- Use an appropriate volar approach to expose the volar rim fragment. If necessary, restore radial length and provisionally hold it with a transstyloid Kirschner wire to unload the lunate facet (TECH FIG 9C).
- Continue exposure for up to 1 to 2 mm beyond the distal radial ridge. Reduce the volar rim fragment as much as possible and note the orientation of the teardrop on the 10-degree lateral view.
- Insert two 0.045-inch Kirschner wires transverse to one another starting at an entry site 1 to 2 mm beyond the distal radial ridge. They should be placed within the center of the teardrop on the lateral view. Confirm the position of the Kirschner wires with C-arm.
- If necessary, the volar buttress pin may be contoured with a wire bender to match the flare of the volar surface of the distal radius. Adjust the trajectory of the legs of the implant to make a 70-degree angle with the base of the wire form. Cut the legs to appropriate length, leaving the ulnar leg 2 to 3 mm longer than the radial leg (TECH FIG 9D,E).
- Noting the entry site of the Kirschner wire, carefully remove the ulnar Kirschner wire and engage the ulnar leg of the volar buttress pin. Repeat the procedure with the radial leg. Impact and seat the implant into the volar rim fragment (TECH FIG 9F).
- Fine-tune the reduction and fix it proximally with a minimum of two screws and washers (TECH FIG 9G,H).
FREE ARTICULAR FRAGMENT SUPPORT WITH A BUTTRESS PIN

- Free articular fragments impacted into the metaphyseal cavity require both a buttress to support the subchondral surface and circumferential peripheral cortical stability to prevent displacement (TECH FIG 10A).
- In some cases, impacted free articular fragments may be adequately supported by a properly applied locking plate that provides subchondral support.
- An alternative method is to use structural bone graft to support the free articular fragment in combination with fragment-specific fixation of the surrounding cortical shell, resulting in containment of the graft within the metaphysis.
- The dorsal buttress pin can also be used for direct subchondral support of impacted articular fragments. The legs of the implant are cut to length and inserted through the dorsal defect, slid distally directly behind the articular fragment, and then fixed proximally with a screw and washer (TECH FIG 10B). The articular fragment is sandwiched between the base of the lunate and the legs of the implant (TECH FIG 10C).
**POSTOPERATIVE CARE**

- At the end of the surgical procedure, confirm the stability of fixation as well as the stability of the DRUJ.
- If stable, apply a removable wrist brace and instruct the patient to initiate gentle range-of-motion exercises of the fingers, wrist, and forearm twice or more daily as tolerated. For non-compliant patients or injuries with tenuous fixation, use a cast for 2 to 3 weeks postoperatively.
- Avoid resistive loading across the wrist until signs of radiographic healing are present; typically this occurs by 4 weeks postoperatively. Specifically instruct older patients not to push up out of a chair or lift heavy objects after surgery.

---

**PEARLS AND PITFALLS**

**Determining whether a fragment is volar or dorsal on the PA view**
- Correlate the carpal facet horizon with the lateral view to determine whether a fragment is dorsal or volar.
- If the articular surface is tilted dorsally, the carpal facet horizon identifies the dorsal rim.
- If the articular surface is tilted volarily, the carpal facet horizon identifies the volar rim.

**Reduction of unstable fracture pattern**
- Identify and start reduction with the fragment that stabilizes the carpus to its normal spatial relationship. Often, initial reduction of the radial column with a provisional transstyloid Kirschner wire will restore carpal length. Alternatively, when this fragment is comminuted, fixation of the volar rim is often successful for reduction of the carpus.
- Adding structural bone graft, either through the fracture line at the base of the radial column or through a dorsal defect, can help stabilize the reduction during operative fixation.

**Widening of the DRUJ or carpal translation**
- Make sure the distal articular fragments are translated toward the ulna before completing volar fixation.
- An elastic, slightly overcontoured radial column plate can help close sagittal fracture gaps and seat the sigmoid notch against the ulnar head.
- Assess the clinical stability of the DRUJ and consider TFCC repair or suture or fixation of the ulnar styloid if needed.

**Small or dorsally rotated volar rim fragment; loss of fixation of small volar-ulnar fragment**
- Ensure adequate fixation of volar-ulnar corner fragment.
- Consider volar buttress pin fixation for an extremely distal or dorsally rotated volar rim fragment.
- Avoid release of the volar wrist capsule. When necessary, the legs of the implant can be inserted through the capsule.
- If needed, the volar buttress pin can be contoured as needed to match the arc of curve of the flare of the volar shaft.

**Unrecognized carpal ligament injury**
- Maintain a high index of suspicion for ligamentous injuries of the carpus. Consider arthroscopic injury evaluation, particularly in the context of radial or dorsal shear fractures, carpal avulsion and instability patterns, or articular fractures associated with a significant longitudinal stepoff between the scaphoid and lunate facets.

**Complications**

**Missed fragment: fracture displacement after surgery**
- Careful analysis of radiographic features both before and during reduction; CT scan when needed.
- Preoperative planning to select approaches that allow complete visualization of all major fragments.
- Complete set of implants and instruments available before surgery.

**Loss of radial length: proximal migration of articular surface**
- Graft the metaphyseal defect when needed with structural bone graft.
- Use implants that buttress the subchondral bone.

**DRUJ dysfunction: pain, instability, or limitation of forearm rotation**
- Assess clinical stability of DRUJ at end of procedure.
- Use radial column plate to push distal fragment against ulna to seat sigmoid notch against ulnar head.
- Evaluate and repair TFCC and capsular tears when necessary.
- Reduce and fix ulnar corner and volar rim fragments to restore congruity of sigmoid notch.
- Ensure that radial length is restored.

**Stiffness: slow, restricted return of movement of wrist, forearm, and fingers, often associated with pain**
- Early range of motion and mobilization of soft tissues.
- Avoidance of constricting bandages and postoperative swelling.

**Tendinitis or rupture: pain with resisted motion, loss of tendon function, clicking and pain**
- Use implants that have a low distal profile.
- Avoid placing sharp, bulky edges of hardware in proximity to tendons.
- Cover plates distally with retinacular flap when needed.
- Consider use of buttress pins (which have a very low profile) when possible.
- Remove any pins or hardware that back out or become prominent postoperatively.
- Ensure that volar plates do not extend up beyond distal volar ridge into soft tissues.
- Avoid long screws or pins, particularly when placed from volar to dorsal. Distal screws should normally be 2 to 4 mm shy of the dorsal cortical margin.
If there is persistent stiffness after 4 weeks, initiate physical and occupational therapy.

OUTCOMES

Konrath and Bahler\(^4\) reported 27 patients with at least 2 years of follow-up:
- One fracture lost reduction.
- Patient satisfaction was high (average DASH scores 17 and PRWE scores 19 at follow-up).
- In only three cases was hardware removed; no tendon ruptures occurred.
- Schnall et al\(^7\) reported on two groups of patients: group I had sustained high-energy trauma and group II had lower-energy injuries.
  - Group I patients averaged return to work in 6 weeks, with all fractures uniting without loss of position or deformity.
  - Two patients in group I required removal of painful hardware.
  - Group II patients averaged 2 degrees of loss of volar tilt, a 0.3-mm change in ulnar variance, and no loss of joint congruity at follow-up.
  - Grip strength in group II patients was 67% of the contralateral side.
- Benson et al\(^2\) reported on 85 intra-articular fractures in 81 patients with a mean follow-up of 32 months.
  - There were 64 excellent and 24 good results, with an average DASH score of 9 at final follow-up.
  - Flexion and extension motion was 85% and 91% of the opposite side at final follow-up.
  - Grip strength was 92% of the opposite side at final follow-up.
  - Sixty-two percent of patients had a 100-degree arc of flexion–extension and normal forearm rotation by 6 weeks postoperatively.
  - Postoperative radiographic alignment was maintained at follow-up.
  - There were no cases of symptomatic arthritis.

COMPLICATIONS

Stiffness: common early, uncommon at follow-up
- Recovery can be accelerated by anatomic fixation that is stable enough to start motion immediately after surgery. The relative degree of trauma to the bone and soft tissues, combined with underlying physiologic factors, is also a critical factor that can lead to slow recovery of motion or residual stiffness.
- Malunion or nonunion: rare
  - Loss of reduction may occur, particularly if a major fracture component is missed and left untreated. In addition, osteoporosis, failure to graft the metaphyseal defect, and associated DRUJ injuries may contribute to loss of reduction or malunion.
- Pin plates are able to resist translational displacements but are less effective for preventing loss of length; they require osseous contact between the proximal and distal fragments or additional support by a secondary implant that will buttress the subchondral surface.
- Nonunions are extremely rare.
- Tendinitis or tendon rupture: uncommon
  - If pins are noted postoperatively to back out, they should be removed. Leaving the distal 1 cm of tendon sheath of the first dorsal compartment intact helps avoid tendon contact with hardware.
  - Using low-profile implants dorsally, covering the distal ends with a strip of retinacular sheath, or both is also helpful.
  - The surgeon should avoid leaving screws or pins protruding from the dorsal or volar surfaces of the bone.
- Painful hardware: rare
  - Painful hardware can be related to migration of a pin or settling of the fracture proximally. Overbending pin hooks and using bone graft or buttressing implants can help avoid this problem.
  - Remove hardware when painful.
- Late arthritis is uncommon and probably related to the quality of the articular restoration.
- Infections, bleeding, carpal tunnel syndrome, and other nerve injuries are uncommon and often related to the primary injury.
- Complex regional pain syndrome is rare and may be related to initiation of early motion after surgery.

REFERENCES

DEFINITION
- Distal radius fractures typically originate in the radial metaphysis and occasionally enter the radiocarpal joint and distal radioulnar joint.
- These fractures may be stable or unstable, intra-articular or extra-articular, and can be associated with various other bony and soft tissue injuries about the wrist.
- Distal radius fractures are most commonly dorsally displaced or angulated (apex volar).
- Treatment is based on fracture stability, comminution, articular segment displacement, articular surface displacement, and the functional demand of the patient.
- Stability is related to initial dorsal angulation, residual dorsal angulation after closed reduction, dorsal comminution, age of the patient, and associated distal ulna fracture and intra-articular fracture extension.7,8

ANATOMY
- The distal radius has articulations at the scaphoid fossa, lunate fossa, and sigmoid notch.
- The normal bony anatomy includes volar tilt of 10 degrees, radial height of 11 mm, and radial inclination of 22 degrees.
- Ulnar variance (the length of the radius relative to the ulnar head at the sigmoid notch) is variable and patient dependent.
- Dorsal ligamentous structures include the dorsal intercarpal ligament and the dorsal radiocarpal ligament.
- The dorsal radiocarpal ligament originates from the dorsal lip of the radius and attaches on the ulnar carpus.
- The dorsal intercarpal ligament represents a capsular thickening on the dorsum of the carpus, with fiber alignment perpendicular to the long axis of the radius.
- Volar ligamentous origins include the radioscaphocapitate ligament, the long radiolunate ligament, and the short radiolunate ligament, among others.
- The triangular fibrocartilage complex (TFCC) consists of the triangular fibrocartilage and volar radioulnar and dorsal radioulnar ligaments.
- The volar radioulnar and dorsal radioulnar ligaments originate form the volar and dorsal edges of the sigmoid notch respectively, and become confluent and insert at the base of the ulnar styloid.
- The extensor retinaculum lies superficial to the extensor tendons and deep to the subcutaneous tissues. It has septations creating six dorsal compartments (FIG 1).
  - The first compartment lies over the radial styloid and contains the abductor pollicis longus and the extensor pollicis brevis tendons (each may have multiple slips).
  - The second compartment, containing the extensor carpi radialis longus and extensor carpi radialis brevis, lies radial to the tubercle of Lister.
  - The third compartment, containing the extensor pollicis longus, lies ulnar to the tubercle of Lister.
- The fourth compartment, containing the extensor indicis proprius and extensor digitorum communis, lies over the dorsal-ulnar distal radius.
- The fifth compartment, containing the extensor digiti minimi, lies over the distal radioulnar joint.
- The sixth compartment, containing the extensor carpi ulnaris, lies over the distal ulna.

PATHOGENESIS
- Distal radius fractures typically occur due to a fall on an outstretched hand.
- Fractures occur when the force of axial loading exceeds the failure strength of cortical and trabecular bone.9
- The fracture pattern is determined by the magnitude and direction of the force applied and the position of the hand during impact.3
- Dorsally displaced or angulated fractures occur when the wrist is neutral or extended and an axial or dorsally directed force is applied to the carpus.
- Osteoporosis, metabolic bone diseases, and bony tumors are risk factors for fracture.

NATURAL HISTORY
- Distal radius fractures are either stable or unstable.
- Stable fractures, treated nonoperatively, historically have excellent outcomes in terms of range of motion, pain, strength, and function.1
  - Nonoperative management consists of immobilization with either a cast or a splint, molded to prevent dorsal displacement.
  - Displaced, unstable, and comminuted fractures often require operative treatment.
- The goals of surgical treatment are to provide stability and improve bony alignment in order to achieve pain control, improve range of motion, and increase function.1,6

FIG 1 • Anatomy of the distal radius. The six dorsal extensor compartments at the level of the extensor retinaculum.
One to 2 mm or more of displacement of the articular surface of the distal radius leads to degenerative changes in young adults.6

Dorsal angulation of more than 20 degrees from normal (10 degrees dorsal tilt) can lead to pain, decreased range of motion, and decreased grip strength.10

Radial shortening can decrease range of motion and cause pain with ulnar impaction of the carpus.10

PATIENT HISTORY AND PHYSICAL FINDINGS

A history of trauma is the most common patient presentation.

Pathologic fractures may occur with minimal stress or trauma.

Patients complain of localized pain and present with swelling, decreased range of motion, and ecchymosis about the fracture.

A history of previous fractures in an older patient should alert the physician to the possibility of underlying osteoporosis.

The skin should be carefully examined to rule out the presence of an open fracture and to assess swelling before surgery or casting. If the wrist is markedly swollen or if swelling is anticipated, casting should be delayed and a splint should be placed.

Neurologic symptoms in the form of numbness, tingling, and radiating pain into the digits should alert the physician to the possibility of acute carpal tunnel syndrome. Careful neurologic assessments should be performed to rule out the presence of a progressive neurologic deficit.

Acute carpal tunnel syndrome represents a surgical emergency.

■ Examination:
  - Remove splints and dressings to visualize all areas of skin.
  - Palpate for areas of tenderness or deformity. Palpate anatomic snuffbox.
  - Visualize and palpate the elbow for swelling, ecchymosis, tenderness, crepitis, and deformity.
  - Visualize and palpate the hand and fingers for swelling, ecchymosis, tenderness, crepitus, and deformity.
  - Use two-point tool or paper clip bent to 5 mm and touch radial and ulnar aspects of all fingers with one or two points. Greater than normal (5 mm) two-point testing in the form of progressive neurologic deficit may signify an acute or chronic carpal tunnel syndrome.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Posteroanterior (PA), lateral, and oblique radiographic views are critical in evaluating all suspected distal radius fractures.

Consider imaging the uninjured wrist for comparison and to serve as a template for surgical reconstruction.

Radiographs of the elbow should be obtained in almost all cases, especially if any tenderness, swelling, or deformity is detected clinically.

Radiographic measurements taken from the PA view (FIG 2A) include\(^9,13\):

- Radial inclination, which is the angle between a line perpendicular to the shaft of the radius at the articular margin and a line along the radial articular margin
  - Normal angle = 21 degrees
- Radial length, which is the distance from a line tangent to the ulnar articular margin to a line drawn perpendicular to the long axis of the radius at the radial styloid tip
  - Normal length = 11 mm
- Ulnar variance, which is the distance from a line perpendicular to the long axis of the radius at the sigmoid notch and a line tangent to the ulnar articular surface
  - Ulnar variance is variable, so to establish a normal value, radiographs of the normal contralateral side should be obtained.

Lateral articular (volar) tilt is the angle between a line for the articular surface of the radius and a perpendicular line to the long axis of the radius.

- Normal angle = 11 degrees volar tilt (FIG 2B)\(^9,13\)
- CT scans can fully elucidate the anatomy of the fracture, particularly articular disruption or incongruity, and also help to determine the necessary surgical approach based on the location and extent of comminution.
  - CT scans increase the interobserver reliability of treatment plans and may actually alter the initial treatment plan based on plain radiographs.5
- MRI can be useful in evaluating for concomitant ligamentous injuries, TFCC injuries, stress fractures, and occult carpal fractures.

FIG 2 • A. PA radiograph demonstrating radial inclination, (black lines), ulnar variance (red), and radial height (white bracket). B. Lateral radiograph of the wrist demonstrating volar tilt (black lines).
DIFFERENTIAL DIAGNOSIS
- Bony contusion
- Wrist dislocation
- Scaphoid or other carpal fracture
- Carpal instability or dislocation
- Distal ulna fracture
- Wrist ligament or TFCC sprain or tear

NONOPERATIVE MANAGEMENT
- Closed reduction should be performed in the emergency department with longitudinal axial traction followed by volar displacement of the carpus. A bivalved, short-arm, well-molded cast or sugar-tong splint should be applied.
- Casting is the most commonly used method to definitively treat distal radius fractures and is preferred for nondisplaced or minimally displaced fractures and those that are stable after a reduction maneuver (ie, restored volar tilt with minimal dorsal comminution). A precise three-point mold is required to maintain fracture reduction.
- Removable splinting can be considered when treating completely nondisplaced stable fractures in young adults.
- If nonoperative treatment is chosen, repeat radiographs should be taken on a weekly basis for the first 3 weeks to ensure that the reduction is maintained. The physician should have a low threshold for changing the cast.
- Any sign of dorsal migration indicates instability, and operative stabilization should be considered.
- Finger range of motion is begun immediately and wrist range of motion can be started as the fracture heals and is managed in a removable splint.

SURGICAL MANAGEMENT
- Open reduction and internal fixation with a dorsal plate can be used successfully in the treatment of displaced, unstable, comminuted fractures of the distal radius that fail to respond to closed treatment.
- Dorsal plating buttresses the fracture to correct deformity and maintain fracture reduction.
- New intramedullary implants have been designed to alleviate some of the complications associated with traditional dorsal plates and allow a less invasive option for fixation of dorsally displaced fractures (FIG 3A,B).
- Indications for dorsal plating include:
  - Severe initial dorsal displacement (>20 degrees from normal, 10 degrees dorsal tilt)
  - Marked dorsal comminution (greater than or equal to 50% of the diameter of the radius shaft on the lateral radiograph)
  - Residual (after reduction) dorsal tilt greater than 10 degrees past neutral
  - 10 mm of radius shortening
  - Dorsal intra-articular fragments displaced more than 1 mm
- Stabilization using an intramedullary device is indicated for distal radius fractures without extensive articular involvement in which a limited incision and shorter procedure are desired (see Tech Fig 4E).
- Comminution of the volar metaphysis is a relative contraindication for the use of a dorsal intramedullary implant.
- The surgeon should be prepared to change management intraoperatively and must have additional stabilization options available, if necessary, such as percutaneous pins or an external fixator.

Preoperative Planning
- All radiographic imaging must be reviewed before surgery.
  - It is helpful to compare radiographs of the injured wrist to the uninjured wrist.
  - Displaced intra-articular fragments must be identified.
  - Dorsal comminution must be evaluated to determine fracture stability and the need for bone grafting.
  - The distal extent of the fracture must be determined to enable the buttress plate to function properly.
- Bone should be evaluated for osteopenia, osteoporosis, and tumors.

Positioning
- The patient is placed supine on a regular operating table.
- A tourniquet is placed near the axilla with the splint in place.

![FIG 3](image-url) • PA radiograph (A) and lateral radiograph (B) of a healed distal radius fracture fixed with an intramedullary plate. C,D. PA and lateral radiographs showing an unstable metaphyseal distal radius fracture. (C,D: copyright Thomas R. Hunt III, MD.)
After anesthesia has been administered, the arm is placed on a radiolucent hand table (FIG 4).
Motion of the shoulder and elbow should be adequate to allow adequate reduction and positioning.
Image intensification using fluoroscopy should be performed throughout the procedure to assess fracture reduction and the position of the hardware.

**Approach**
- The dorsal approach to the distal radius through the third dorsal compartment with subperiosteal elevation of the compartments provides the exposure needed to place a dorsal plate while protecting the extensor tendons from the plate and screws.
  - This approach helps to minimize adhesions and the risk of tenosynovitis and tendon rupture.
- The approach used to place an intramedullary device depends on the nature of the implant and the location and extent of the fracture.
  - Dorsal intramedullary implants are placed through a limited dorsal approach through the third extensor compartment.
  - Radial intramedullary implants are placed through a small radial incision with careful protection of the radial sensory nerve.

**DORSAL PLATE FIXATION OF DISTAL RADIUS FRACTURES**

**Incision and Dissection**
- The skin incision is centered over the tubercle of Lister (TECH FIG 1A).
- The subcutaneous tissues are dissected down to extensor retinaculum, with care to preserve any sensory nerve branches while obtaining hemostasis with bipolar electrocautery (TECH FIG 1B).
- The extensor retinaculum is incised just ulnar to the tubercle of Lister, exposing the extensor pollicis longus (EPL) tendon (TECH FIG 1C).
- The hematoma is evacuated and the EPL tendon is freed proximally and distally by incising the septa of the third compartment (TECH FIG 1D).
- The EPL tendon can then be removed from the third compartment and protected for the rest of the surgical procedure.
- The extensor compartments are subperiosteally elevated using a scalpel in radial and ulnar directions to expose the dorsal cortex of the distal radius (TECH FIG 1E,F).
- If properly maintained, the periosteum of the extensor compartments can be repaired after placement of the fixation device and will serve as a barrier between the dorsal plate and the extensor tendons.
- The tubercle of Lister is almost invariably involved in the fracture and should be completely removed using a rongeur (TECH FIG 1G).
The radius shaft is exposed with a periosteal elevator (TECH FIG 1H).

**Reduction and Plate Fixation**

- Reduction is obtained and confirmed using axial traction and palmar translation of the hand (TECH FIG 2A).
- If reduction of articular fragments is needed, the radial portion of the origin of the dorsal radiocarpal ligament can be elevated sharply off the radius to evaluate the articular surfaces.
- Kirschner wires can be used for temporary fixation.
- Bone graft is inserted to support reduced articular fragments.
- The dorsal plate is applied directly on the radius (TECH FIG 2B).
- The plate is secured beginning with a bicortical screw in the oval sliding hole.
- Fracture reduction and placement of the plate are confirmed using fluoroscopy.
- The plate is secured to the distal fragment with one or two cancellous screws. The surgeon should avoid placing...
the distal, ulnar screw if possible as this may irritate the overlying digital extensor tendons in the fourth dorsal compartment.

- Additional cortical screws are added in the radius shaft.
- Reduction and stability are confirmed (TECH FIG 2C,D).

**Wound Closure**

- The wound is copiously irrigated.
- The retinaculum is closed deep to the transposed EPL tendon, incorporating the periosteal layer that forms the floor of the extensor compartments (TECH FIG 3A).
- The skin is closed with nylon suture (TECH FIG 3B).
- A volar splint is applied.

**FIXATION OF DISTAL RADIUS FRACTURES USING A DORSAL INTRAMEDULLARY DEVICE (TORNIER)**

- The fracture is exposed using a limited version of the incision detailed for placement of a dorsal plate (TECH FIG 4A).
  - The extensor retinaculum is incised just ulnar to the tubercle of Lister, exposing the EPL tendon.
  - The EPL tendon is freed proximally and distally by incising the septa of the third compartment.
  - The EPL tendon can then be transposed for the rest of the surgical procedure.
  - A scalpel is used to subperiosteally elevate the fourth and portions of the second extensor compartment in radial and ulnar directions.
  - The dorsal cortex of the distal radius is exposed and room is created for seating of the extramedullary portion of the device.
  - The tubercle of Lister is removed and an awl is used to create an entry point in the dorsal cortex (TECH FIG 4B).
  - This usually involves a portion of the fracture line.
  - The canal is rasped until the rasp may be fully seated (TECH FIG 4C).
  - The implant is placed using the insertion device to control rotation (TECH FIG 4D).
  - Fracture reduction is typically achieved as the device is inserted and seated due to its buttress effect and three-point fixation in the canal.
  - Lag screws are inserted as required, followed by a cover lock to create fixed angle stability.
  - Reduction and stabilization are confirmed radiographically (TECH FIG 4E,F).
  - Wound closure and splinting are as described above.
A 2- to 3-cm incision is made over the radial styloid, between the first and second extensor compartments. Care is taken to protect branches of the radial sensory nerve. A cannulated drill is used to penetrate the cortex 2 to 3 mm proximal to the radiocarpal joint line to create the entry point. After insertion of a starter awl, the canal is broached sequentially under fluoroscopic guidance to fit the medullary canal. The implant is then inserted with the insertion jig, making sure the implant is countersunk into the radial styloid. The proximal interlocking screws are then placed using the insertion jig, using small incisions of the dorsal aspect of the forearm. The distal interlocking screws are placed last using the insertion jig. Small adjustments to radial height and tilt can be made at this time. Reduction and stabilization are confirmed radiographically. Wound closure and splinting are as described above.

**PEARLS AND PITFALLS**

**Indications**
- Determine the direction of fracture stability.
- Determine the area and extent of comminution.
- Ensure that an acute carpal tunnel syndrome does not exist.

**Surgical approach**
- Incise the extensor retinaculum sharply to allow easier repair.
- Expose only the third dorsal compartment.
- Remove the tubercle of Lister to allow better plate contouring.

**Hardware choice and placement**
- Choose a low-profile implant system that offers the flexibility needed to stabilize the fracture.
- Place the plate distally to ensure buttress effect.
- Place the oval plate hole screw initially.
- Do not place the plate distal to the dorsal lip of the distal radius.
- Avoid placing the distal, ulnar screw.
- Although titanium implants and their particulate debris have been implicated in the development of tenosynovitis and other tendon pathology, there is no clear scientific evidence to substantiate these claims.

**Postoperative management**
- Avoid casting for long periods.
- Encourage early active range of motion of the wrist and fingers.
- Avoid using a sling to prevent unnecessary shoulder and elbow stiffness.
- Do not begin strengthening until range of motion is restored.
POSTOPERATIVE CARE
- Postoperatively the patient is placed in a bulky dressing that allows motion of the digits, elbow, and shoulder. A volar resting splint may be used to support the wrist if there is any concern about fixation strength.
- The patient is encouraged to begin finger range-of-motion exercises immediately after surgery.
- Seven to 10 days after surgery the sutures are removed, Steri-Strips are applied, and the incision is allowed to get wet.
- The patient is evaluated by an occupational therapist, who provides a thermoplastic splint, and can start active and active-assisted range-of-motion exercises depending on fracture stability.
- When the fracture heals at about 6 weeks, gentle passive range of motion and strengthening may be started.

OUTCOMES
- Dorsal plating has recently been shown biomechanically to be stronger and stiffer than volar plating for dorsally unstable fractures.\(^\text{12}\)
- Dorsal plating has been associated with a higher complication rate than other means of stabilization.\(^\text{2,9,10}\)
- Extensor tenosynovitis and tendon rupture have been prevalent in the past, mainly due to bulky implants.
- There has been renewed interest in dorsal plating of the distal radius as it has been shown to have a low rate of tendon-related complications with the use of low-profile, anatomic implants.\(^\text{4,10,11}\)
- Clinical reports have suggested that low-profile systems are more important in satisfactory outcomes for dorsal plating, with a much lower rate of complications.\(^\text{10}\)
- Fixation with low-profile dorsal plates can result in at least 80% of contralateral wrist range of motion, about 80% to 90% of grip strength, and over 90% pinch strength, with minimal risk of tendon rupture.\(^\text{4,11}\)

COMPLICATIONS
- Infection (pin tract or deep)
- Injury to tendons, vessels, and nerves
- Stiffness
- Posttraumatic arthritis
- Weakness in grip or pinch
- Tenosynovitis and tendon ruptures
- Malunion or nonunion
- Compartment syndrome
- Carpal tunnel syndrome
- Late tendon rupture, potentially related to implant design and material
- Hardware failure
- Complex regional pain syndrome type I

DISCLOSURE
Dr. Beredjiklian is a stockholder with and consultant for Tornier, Inc.

REFERENCES
DEFINITION
- Distal radius fractures are defined by their involvement of the metaphysis of the distal radius.
- They are assessed on the basis of fracture pattern, alignment, and stability:
  - Articular versus nonarticular
  - Reducible versus irreducible
  - Stable versus unstable
- Irreducible or unstable fractures require surgical reduction and stable fixation.
- Volar plating historically has been the method of choice for volar shear-type fractures.
- Recently developed fixed-angle plates have now made it a preferred method of fixation for most types of distal radius fractures.

ANATOMY
- The distal radius serves as a buttress for the proximal carpus, transmitting 75% to 80% of its forces into the forearm.
- The remaining 20% to 25% of force is transmitted through the distal ulna and the triangular fibrocartilage complex (TFCC).
- Dorsally
  - The distal radius is the origin for the dorsal radiocarpal ligament.
- Volarly
  - The distal radius is the origin for the extrinsic ligaments of the carpus, including the radioscaphocapitate ligament.
  - It also is the origin of the pronator quadratus.
- Distally
  - It is the floor of the fibro-osseous extensor tendon compartments and includes Lister’s tubercle, assisting in extensor pollicis longus function (FIG 1A).
  - The extensor tendons are in immediate contact with the dorsal surface of the distal radius.
- Volarly
  - The distal radius is the origin for the extrinsic ligaments of the carpus, including the radioscapohocapitate ligament.
  - It also is the origin of the pronator quadratus.
  - The flexor tendons are separated from the distal radius by the pronator quadratus.
- Ulnarly
  - The distal radius is the origin for the radial triangular fibrocartilage (FIG 1A).
  - It also contains the sigmoid notch, which articulates with the head of the distal ulna, contributing to forearm rotation.
- Distally
  - The surface is divided into a triangular, radiocapitate fossa and a square, radiocapitate fossa articulating with the respective carpal bones (FIG 1B).
- The distal articular surface is inclined approximately 22 degrees ulnarly in the coronal plane and 11 degrees volarly in the sagittal plane (FIG 1C,D).
- The metaphysis is defined by the distal radius within a length of the articular surface that is equivalent to the widest portion of the entire wrist.

FIG 1 • A. Axial MR image of the wrist at the level of the distal radius. Lister’s tubercle is marked with an asterisk. Dotted lines represent dorsal and volar borders of the triangular fibrocartilage that helps stabilize the distal radioulnar joint. The dorsal distal radius acts as an attachment for dorsal extensor compartment sheaths. B. The distal articular surface of the radius is divided into a triangularly shaped scaphoid fossa (SF) and a square-shaped lunate fossa (LF). The distal ulna and the triangular fibrocartilage complex (TFCC) act as ulnar buttresses for the wrist. C. MR coronal cut of the distal radius. The articular surface of the distal radius is inclined about 22 degrees relative to the forearm axis (dotted lines). The ulnar aspect of the distal radius (ie, the lunate fossa) usually is distal to the end of the distal ulna (ie, negative ulnar variance). Note the solid lines marking ulnar variance. D. MR sagittal cut of the distal radius. The articular surface of the distal radius is inclined approximately 11 degrees palmar relative to the forearm axis (dotted lines). Proximally, there exists relatively thinner dorsal cortical bone versus the thicker volar bone.
The dorsal cortical bone is less substantial than the volar cortical bone, contributing to the characteristic dorsal-bending fracture pattern of distal radius fractures.

PATHOGENESIS
- The mechanism of injury in a distal radius fracture is an axial force across the wrist, with the pattern of injury determined by bone density, the position of the wrist, and the magnitude and direction of force.
- Most distal radius fractures result from falls with the wrist extended and pronated, which places a dorsal bending moment across the distal radius.
  - Relatively weaker, thinner dorsal bone collapses under compression, whereas stronger volar bone fails under tension, resulting in a characteristic “triangle” of bone comminution with the apex volar and greater comminution dorsal.
- Other possible mechanisms form a basis for some fracture classifications such as the one proposed by Jupiter and Fernandez.5

- Bending
- Compression
- Shear
- Avulsion
- Combinations
- Articular involvement and its severity are the basis of some fracture classifications, such as the AO9 and Melone8 classifications.
- Articular involvement splits the distal radius into distinct fragments separate from the radius shaft (FIG 2):
  - Scaphoid fossa fragment
  - Lunate fossa fragment. Further comminution can split the lunate fossa fragment into dorsal and volar segments, creating the so-called four-part fracture.

NATURAL HISTORY
- Clinical outcome usually, but not always, correlates with deformity.
- Variable residual deformity can be tolerated best by individuals with fewer functional demands.
- As wrist deformity increases, physiologic function is progressively altered.
  - Intra-articular displacement of 1 to 2 mm results in an increased risk of osteoarthritis.3,6
  - Radial shortening of 3 to 5 mm or more results in increased loading of the ulnar complex.1,12
  - Dorsal angulation greater than 10 degrees shifts contact forces to the dorsal scaphoid fossa and the ulnar complex, causing increased disability.13,16
  - The incidence of associated intracarpal injuries increases with fracture severity. Such injuries can account for poor outcomes. These injuries often are not recognized at first, with the result that treatment is delayed.4,14
  - Triangular fibrocartilage (TFC) tears
  - Scapholunate and lunotriquetral ligament tears
  - Chondral injuries involving the carpal surfaces
  - Distal radioulnar joint injury
  - Distal ulna fractures

By predicting the stability of a distal radius fracture, deformity and its complications can be minimized. Several risk factors have been suggested by LaFontaine et al7 and others. The presence of three or more indicates instability:
- Dorsal angulation greater than 20 degrees
- Dorsal comminution
- Intra-articular extension
- Associated ulna fracture
- Patient age over 60 years

PATIENT HISTORY AND PHYSICAL FINDINGS
- The mechanism of injury should be sought, to assist in assessing the energy and level of destruction.
- Associated injuries are not uncommon and should be carefully ruled out.
  - Injuries to the hand, carpus, and proximal arm, including other fractures or dislocations
  - Injuries to other extremities or the head, neck, and torso
  - Establish the patient’s functional and occupational demands.
  - Document co-existing medical conditions that may affect healing, such as osteoporosis or diabetes.
  - Determine possible risk factors for anesthesia and surgery, such as cardiac disease.
- The physical examination should document the following:
  - Condition of surrounding soft tissues (ie, skin and subcutaneous tissues)
  - Quality of vascular perfusion and pulses
  - Integrity of nerve function
  - Sensory two-point discrimination or threshold sensory testing
  - Motor function of intrinsic, thenar, and hypothenar muscles of the hand
- Examination of the distal ulna, TFCC, and distal radioulnar joint should rule out disruption and instability.
- Reliable physical examination of the carpus often is difficult, making radiographic review even more critical and follow-up examinations important.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Imaging establishes fracture severity, helps determine stability, and guides the operative approach and choice of fixation.
Plain radiographs should be obtained before and after reduction: PA, lateral, and two separate oblique views.

- Oblique views, in particular, help evaluate articular involvement, particularly the lunate fossa fragment (FIG 3A,B).
- The lateral view should be modified with the forearm inclined 15 to 20 degrees to best visualize the articular surface (FIG 3C; see Tech Fig 5BC).

- Fluoroscopic evaluation can be useful, because it gives a complete circumferential view of the wrist and, with traction applied, can help evaluate injuries of the carpus.
- CT helps define intra-articular involvement and helps detect small or impacted fragments, which may not be apparent on plain radiographs, particularly those involving the central portion of the distal radius (FIG 3D,E).

**DIFFERENTIAL DIAGNOSIS**

- Diagnosis is directly confirmed by radiographs.
- Associated and contributory injuries should always be considered.
  - Pathologic fracture (eg, related to tumor, infection)
  - Associated injuries to the carpus (eg, scaphoid fracture, scapholunate ligament injury)

**NONOPERATIVE MANAGEMENT**

- Nonoperative treatment is reserved for distal radius fractures that are reducible and stable based on the criteria previously discussed.
- The goal of nonoperative treatment is to immobilize the wrist using a method that will maintain acceptable alignment until the fracture is healed.
  - Radial inclination greater than 10 degrees
  - Ulnar variance less than 4 mm positive
  - Palmar tilt less than 15 degrees dorsal or 20 degrees volar
  - Articular congruity less than 2-mm gap or step-off

**SURGICAL MANAGEMENT**

- The goal of operative treatment is to achieve acceptable alignment and stable fixation.
- Various methods of fixation are available: pins, external fixators, dorsal plates, intramedullary devices, and volar plates.

**Preoperative Planning**

- The standard preoperative medical and anesthesia evaluation for concurrent medical problems is done.
- Discontinue blood thinning medications (anticoagulants and nonsteroidal anti-inflammatory drugs).
- Request necessary equipment, including fluoroscopic and power equipment.
- Confirm the plate fixation system to be used and check the equipment before beginning surgery for completeness (ie, all appropriate drills, plates, and screws).
- Have a contingency plan or additional fixation (external fixator, bone graft, or bone graft substitute).
- Review previous radiographic studies.
- Consider use of a regional anesthetic for postoperative pain control.

**Positioning**
- Place the patient in the supine position with the affected extremity on an arm table.
- Apply an upper arm tourniquet, preferably within the sterile field.
- Incorporate weights or a traction system to apply distraction across the fracture (FIG 4).
- The surgeon is seated on the side, toward the patient’s head, particularly if he or she is right-hand dominant.
- The assistant is seated opposite the surgeon.
- The fluoroscopy unit is brought in from the end or corner of the table.

**Approach**
- Dorsal exposure allows for direct visualization of the articular surface when necessary.
- Fracture comminution is more severe dorsally, making overall alignment more difficult to judge.
- The thicker volar cortex is less comminuted, allowing for more precise reduction and buttressing of bone fragments.
- Sometimes both dorsal and volar exposures may be necessary to achieve articular congruency and volar reduction and fixation, respectively.
- An extended volar–ulnar exposure may be necessary to perform a carpal tunnel release if indicated.
- The techniques described in this chapter use the volar approach to distal radius, as described by Henry (FIG 5).

**FIG 4** • Traction is applied over the arm table with finger traps and hanging weights. The surgeon sits on the volar side, and the assistant on the dorsal side. Fluoroscopy can be brought in from any direction, but preferably from the side adjacent or the opposite surgeon.

**FIG 5** • The volar incision is represented by the dotted line just proximal to the wrist flexion creases and radial to the flexor carpi radialis longus. Care is exercised to avoid dissection ulnar to the flexor carpi radialis, because the palmar cutaneous nerve branch of the median nerve (arrow) is at risk.

### VOLAR FIXED-ANGLE PLATE FIXATION OF THE DISTAL RADIUS

#### Incision and Dissection
- Palpate the flexor carpi radialis tendon and make a 4- to 8-cm longitudinal incision from the proximal wrist flexion crease, extending proximally along the radial border of the flexor carpi radialis tendon.
  - If the incision must cross the wrist flexion creases, use a zigzag incision in that area.
- Carefully avoid the palmar cutaneous branch of the median nerve along the ulnar side of the flexor carpi radialis within 10 cm of the wrist flexion crease.
- Branches of the dorsal radial sensory nerve and lateral antebrachial cutaneous nerve sometimes appear along the path of the incision and also need to be protected.
- At the distal end of the incision, protect the palmar branch of the radial artery to the deep arch.
  - It usually is not necessary to dissect out the radial artery (TECH FIG 1A).
- Incise the anterior sheath of the flexor carpi radialis tendon and retract the tendon ulnarly to help protect the median nerve (TECH FIG 1B).
- Incise the posterior sheath of the flexor carpi radialis tendon.
- The deep tissues likely will bulge out from the pressure of swelling and fracture hematoma.
- The median nerve lies within the subcutaneous tissues along the ulnar portion of the wound (TECH FIG 1C,D).
- The flexor pollicis longus tendon sits along the radial margin of the wound.
- Using blunt dissection with a gauze-covered finger, sweep the tendons and the nerve ulnarly.
- A self-retaining retractor is carefully placed between the radial artery radially and the tendons and median nerve ulnarly.
TECH FIG 1 • A. The interval between the radial artery (arrow) and the flexor carpi radialis tendon (*) is seen. B. The posterior sheath (*) of the flexor carpi radialis is visible after retracting the flexor carpi radialis ulnarly (arrow). Be careful during deeper dissection, because swelling and hematoma may distort the position of the median nerve beneath the sheath. C. Following incision in the flexor carpi radialis posterior sheath, the deep tendons are visible, including the flexor pollicis longus (FPL) and the flexor digitorum superficialis of the index finger (FDS). The median nerve also is visible (*). D. The palmar cutaneous nerve branches of the median nerve (arrow) and median nerve (asterisk) are both at risk for injury during this approach. Be careful regarding placement of retractors and during dissection and plate placement. E. The pronator quadratus (PQ) is incised distally, radially, and proximally and then reflected ulnarly after dissection off the volar distal radius. F. The brachioradialis (arrow) can be a deforming force, especially in comminuted fractures and in those for which treatment has been delayed. This tendon can be released if necessary.

- The pronator quadratus is now visualized at the floor of the wound.
- Incise the pronator quadratus at its radial insertion, leaving fascial tissue on either side to aid in closure. Also, determine the proximal and distal extent of the muscle, and make horizontal incisions at both of those points (TECH FIG 1E).
- The distal margin of the pronator quadratus attaches along the distal volar lip of the distal radius, along the “teardrop.”
- The radial margin is in proximity to the tendons of the first dorsal compartment and the brachioradialis.
- Subperiosteally dissect the pronator quadratus off the volar surface of the distal radius as an ulnarly based flap with a knife or elevator.
- Retract the pronator ulnarly with the flexor tendons and median nerve.
- Particularly if significant shortening of radial-sided fracture fragments has occurred, incise the broad insertion
of the brachioradialis to eliminate the deforming force (TECH FIG 1F).
- Release the first dorsal compartment and retract the tendons before releasing the brachioradialis.
- Alternatively, Z-lengthen the brachioradialis tendon to allow for repair at the completion of the case.

**Fracture Reduction and Provisional Fixation**

- Apply a lobster-claw clamp around the radius shaft at a perpendicular angle to the volar surface at the most proximal portion of the wound (TECH FIG 2A).
  - This allows for excellent control of the proximal shaft for rotation and translation.
  - It also provides an excellent counterforce when correcting the dorsal angulation collapse.
- With the fracture now exposed, apply traction distally to distract and disimpact the fragments.

- Carefully clean the fracture of any interposed muscle, fascia, hematoma, or callus while maintaining the bony contours.
- In the case of significant volar comminution, reduce and provisionally stabilize the fragments with K-wires.
- Take plate positioning into account when placing these K-wires.
- The articular surface is first reduced, if necessary.
- Under fluoroscopic guidance, manipulate the articular fragments through the fracture with a periosteal elevator, osteotome, or K-wires (TECH FIG 2B,C).
- Longitudinal traction is important during this reduction phase. It can be performed by an assistant or using cross-table weights and finger-traps.
- A dorsal exposure is performed at this stage if there is significant impaction, particularly centrally, that cannot be corrected using the extra-articular technique described here.

**TECH FIG 2**

- **A.** A lobster-claw clamp (double arrow) is applied to the radius shaft well proximal to the fracture. This instrument helps the surgeon control the radius during reduction and define the lateral margins of the radius. A Freer elevator is inserted into the fracture to help disimpact the fragments and assist in their reduction. **B.** The brachioradialis (white arrow) is released, and the first compartment extensor tendons are visible in the background (black arrow). An instrument can now be placed to assist in the reduction (arrow). **C.** The Freer elevator is used to reduce the fragments. In this case, the intra-articular step-off is being corrected, and the radial length and inclination are being restored. **D.** K-wires are placed across the radial styloid into the reduced ulna fossa fragment. An assistant usually applies traction, and the lobster-claw clamp can be used for powerful leverage. If there is no articular involvement, this K-wire can be placed into the radius metaphysis or diaphysis proximally. **E.** The K-wire should be placed as close as possible to the subchondral bone, avoiding areas of comminution. **F.** The K-wire should maintain the articular reduction without any support.
- Place K-wires from the radial styloid fragment into the lunate fossa fragment to maintain the articular reduction (TECH FIG 2D).
  - The K-wires should be placed as close as possible to the subchondral plate (TECH FIG 2E,F).
- Once the distal articular reduction is complete, reduce the distal radius as a single unit to the radius shaft.
- Insert K-wires as required to maintain the provisional reduction between the distal fragments and the proximal shaft fragment.
  - If radial collapse and translation are prominent, a large K-wire can be introduced into the radial portion of the fracture and advanced proximally and ulnarly to behave like an intrafocal pin and provide a radial buttress by pushing the distal fragment ulnarly.
  - A similar technique can be applied through the dorsal fracture to assist in maintaining the palmar tilt correction.

**Plate Application**

- Apply a fixed-angle volar plate to the volar surface of the distal radius and shaft. Position the plate to accommodate for the unique design characteristics of the plating system as well as the location of the fracture fragments.
  - Each plating system has unique characteristics that determine its optimal placement.
  - Ideally, the plate should be placed as close to the articular margin as possible without the distal locking pegs or screws penetrating the joint.
  - If the fracture has not yet been fully reduced, this must be taken into account when placing the device.
- Clamp the previously applied lobster claw to the proximal portion of the plate to keep the plate centralized on the radius shaft.
- Place provisional K-wires through the plate to maintain position (TECH FIG 3). Then fluoroscopically confirm proper plate position in both the distal-proximal and radioulnar directions.
  - Proper alignment of the plate can be determined only using a true anteroposterior (AP) image in which the distal radioulnar joint is well visualized.
- The K-wires allow for fine adjustment in plate position before committing to insertion of a screw.
- Drill and insert a provisional screw in the oblong hole in the plate.
- If the bone is osteopenic, a screw longer than the initial measurement should be placed to ensure that both cortices are engaged. Otherwise, the plate may not be held securely, and the reduction will be compromised. After the remaining screws have been secured, this screw can be replaced with one of the appropriate length.
- Insert at least one additional proximal screw and remove the provisional K-wires holding the plate in place.

**Distal Fragment Reduction**

- Once the proximal plate has been secured, execute any additional reduction needed.
  - A well-designed plate serves as an excellent buttress for correction of the palmar tilt (TECH FIG 4A).
- Apply counterforce through the lobster-claw clamp in a dorsal direction while the distal hand and wrist are translated palmarly and flexed (TECH FIG 4B).
- This maneuver reduces the distal radius to the plate, effectively restoring volar tilt by pushing the lunate against the volar lip of the distal radius (TECH FIG 4C,D).
- Additional distraction and ulnar deviation correct radial collapse and loss of radial inclination.

**TECH FIG 3** • Keep the plate centered on the radius and as distal as possible. The lobster-claw clamp helps keep the plate centered. K-wires (arrows) are helpful as provision fixation until alignment can be confirmed radiographically and screws placed.

**TECH FIG 4** • A. The final reduction is performed with traction on the hand and with the radius held proximally with a clamp. Once the reduction is confirmed radiographically, the assistant places the distal screws or K-wires. B. The hand is translated (not appreciably flexed) palmarly while the radius shaft is held with the clamp. (continued)
Plate Fixation

- While the reduction is held, drill the holes in the distal plate (TECH FIG 5A).
  - Some plate systems allow for provisional fixation using K-wires placed through the distal plate.
  - Do not penetrate the dorsal distal radius with the drill, to protect the dorsal extensor tendons.
  - Drill and place the distal ulnar screws first and then proceed radially and proximally.
  - Judge the placement of all distal screws or pegs precisely using fluoroscopic imaging in multiple planes.
  - Perform a “true” lateral view of the wrist with the x-ray beam at a 20-degree angle to the radius shaft (TECH FIG 5B,C). This is facilitated by lifting the wrist off the table with the elbow maintained on the table and the forearm at a 20-degree angle to the table (TECH FIG 5D,E).
  - Lister’s tubercle can be mistaken for the dorsal cortex, resulting in screws that are too long.
  - The extensor pollicis longus is at greatest risk of injury from a protruding screw.
  - Sequentially insert the remaining distal screws or pegs, followed by the remaining proximal plate screws (TECH FIG 5F).
  - If necessary, add bone graft or bone graft substitute around the plate into the fracture site or through a small dorsal incision.

(TECH FIG 5A). The remaining holes can now be drilled and screws placed where needed. B. This screw (arrow) looks as though it has penetrated the joint when in reality it is simply the angle of the radiographic beam that throws its projection into the joint. C. A true lateral view of the distal radius is necessary to judge placement of the radial screws. D. A radiograph is being taken with the wrist perpendicular to the x-ray beam (arrow). This is not a true lateral image, because the distal surface of the radius is inclined 20 degrees radially. (continued)
Precisely assess the stability of the construct after the plate has been applied. If appropriate, remove the provisional K-wires. If the K-wires are deemed critical for fracture stability, they can be left in place and removed 4 to 8 weeks later. If residual instability exists, add additional fixation with K-wires, an external fixator, a dorsal plate, or a combination.

**Closure**

Repair the pronator quadratus to its insertion site with a series of 3-0 absorbable horizontal mattress sutures (TECH FIG 6A). In many cases it is impossible to repair the pronator quadratus because the muscle and fascia are extremely thin or the muscle is damaged. In this situation, the muscle can be debrided or simply left in place.

Before skin closure, obtain final radiographs (TECH FIG 6B, C), and assess stability of the distal radioulnar joint. Place a drain only if excessive bleeding is anticipated. Consider methods to minimize postoperative pain: percutaneous placement of a pain pump catheter, injection of a long-acting local anesthetic, close the subcutaneous tissues with 4-0 absorbable suture and reapproximate the skin with interrupted 4-0 or 5-0 nylon sutures or a running subcuticular stitch. Place two layers of gauze and a nonadherent gauze over the wound, wrap the wrist and forearm with thick Webril (Kendall, Mansfield, MA), and apply a below-elbow splint in a neutral wrist position (TECH FIG 6D). If there is injury to the ulnar wrist (eg, ulna styloid fracture, distal radioulnar joint injury), immobilize the forearm with an above-elbow or Munster splint.

**TECH FIG 6**

A. The pronator quadratus has been repaired. B. AP radiograph demonstrating correction of the articular surface, radial height (lines), and radial inclination (dotted line). C. Lateral radiograph demonstrating correction of the palmar tilt (dotted line). D. A bulky dressing is applied with a volar splint holding the wrist in a neutral position. A pain pump catheter has been inserted for additional pain control.
We do not recommend use of the volar fixed-angle plate as a reduction tool in the acute setting. It is best employed (if at all) for a malunion, or perhaps for a fracture with minimal articular comminution.

This technique is difficult, because it has to account for the longitudinal and translational alignment of the plate before the reduction has been achieved.

Perform the surgical approach previously described.

Address first any distal articular involvement with reduction and K-wire fixation.

Affix the plate to the distal fragment, accounting for where the plate will sit on the radius shaft once the reduction is completed.

Place the screws so that they are parallel to the articular surface on the lateral x-ray view (TECH FIG 7A, B).

On the AP radiograph, align the plate with the perpendicular of the radial inclination of the distal radius (20 degrees; TECH FIG 7C, D).

Once distal fixation is complete, secure the proximal plate to the radius shaft, thereby completing the reduction.

Close and splint as described previously.

**TECH FIG 7** • A. The volar plate is applied with the distal screws placed first (parallel to distal articular surface). B. Reducing the plate to the diaphysis proximally accomplishes the reduction. C. The plate is applied at approximately a 20-degree angle relative to the distal articular surface or to the amount of angulation that is estimated. D. By reducing the plate to the diaphysis, the distal angulation is corrected.

**PEARLS AND PITFALLS**

**Preoperative planning**
- Obtain multiple radiographs in different positions (eg, several oblique views), especially in the setting of comminution or articular involvement.
- Obtain a CT scan if assessing the pattern of fracture when radiographs alone are difficult or uncertain.

**Surgical approach**
- Avoid crossing the distal flexion creases of the wrist.
- Avoid exposure ulnar to the midline of the flexor carpi radialis.
- Use extra care with deep dissection in the presence of hematoma or significant swelling.

**Fracture reduction**
- Employ traction across the wrist with a device or weights.
- Use a lobster-claw clamp on the proximal radius shaft for control of the forearm and as a reference for the lateral margins.
- Use instruments to disimpact and reduce articular fragments through the fracture itself, either volarly, dorsally, or both.
- Employ a temporary K-wire to stabilize the reduction before placement of the plate.

**Plate alignment**
- Confirm appropriate radial-ulnar positioning of the proximal plate using a true AP radiograph (ie, forearm in supination with open view of the distal radioulnar joint).
POSTOPERATIVE CARE

- The wrist is splinted in a neutral position, leaving the digits free.
- If the fracture is particularly tenous or there is injury to the ulnar wrist, a long-arm or Munster splint is applied.
- The patient is instructed to perform active ROM exercises for the digits every hour and to engage in strict elevation for at least 3 days.
  - It is critical to emphasize edema prevention and immediate ROM of the digits.
- At 1 week postoperatively, the splint is removed and the wound is examined.
- If swelling permits, the therapist fabricates a molded Orthoplast splint (Johnson & Johnson Orthopedics, New Brunswick, NJ) to be worn at all times.
- Active ROM exercises of the wrist are implemented 1 week postoperatively.
- At 4 to 6 weeks, putty and grip exercises are added.
- At 6 to 8 weeks, the splint is discontinued, and progressive strengthening exercises are advanced.
- If necessary, progressive passive ROM can begin, including use of dynamic splints.
- At 10 to 12 weeks, the patient usually can be discharged to all activities as tolerated.

OUTCOMES

- Overall good to excellent results can be expected in over 80% of patients with ROM, strength, and outcomes scoring.\textsuperscript{10,11,15,17}
- Studies comparing volar fixation to other forms of fixation (eg, external fixators, pins, and dorsal plating) have revealed similar if not superior results.
  - Results appear to be superior in the early recovery period, with the final outcome yielding equivalent results among all fixation groups.
  - Some studies suggest better maintenance in overall reduction compared to other forms of fixation.

COMPLICATIONS

- Complication rates as high as 27% have been reported.
- Complications can be categorized into those involving hardware, fracture, soft tissues, nerves, and tendons.\textsuperscript{7}
- Failures of hardware, such as plate or screw breakage, can occur but are rare. Usually such failures are an indication of other problems, such as nonunion.
- The hardware becomes unacceptably prominent in a minority of patients.
  - This complication may become evident only after some time has elapsed, as swelling of fibrous tissue subsides and bone remodels.
  - The most common sites include the dorsal wrist, when screws have been inserted, and the radial wrist, when a plate has been used.
  - It can be avoided with careful screw and plate placement and radiographic verification of their position.
  - Nonunion and delayed union are unusual. Consider a diagnosis of osteomyelitis or other risk factors such as smoking.
  - Loss of fracture reduction and fixation can occur, and is most common in patients with osteopenic bone or comminuted and articular fractures.
  - This can be avoided with frequent and early follow-up with repeat radiographs.
  - If instability is suspected, the fracture can be casted.
  - In the operating room, if instability is suspected, additional fixation should be considered (eg, external fixator, pins, bone graft).
  - Soft tissue complications are proportional to the energy of the initial injury.
  - Open wounds usually can be addressed with local measures.
  - Significant swelling must be addressed with early aggressive modalities. Swelling can lead to other complications, such as joint stiffness and tendon adhesions.
  - Nerve injuries can be the result of initial trauma or subsequent surgical trauma.
    - Assess and document neurologic status before surgery.
    - Avoid further injury to nerves with careful placement of retractors.
    - The palmar cutaneous branch of the median nerve can be injured during incision and exposure.
    - Postoperative neuromas can cause pain and sensitivity along scar.
    - Avoid the nerve with a well-placed incision radial to the flexor carpi radialis and careful deep dissection.
    - Postoperative swelling also can lead to median neuropathy. Carpal tunnel release should be performed if there is any suspected compression neuropathy or if this is to be anticipated as a result of postoperative swelling.
    - Tendon complications include adhesions and ruptures.
    - Most tendon adhesions involve the dorsal extensor tendons resulting in extrinsic extensor tightness.
    - Flexor tendon adhesions are uncommon and involve primarily the flexor pollicis longus.
    - Tendon ruptures have been described, especially involving the flexor pollicis longus and the extensor pollicis longus, as a result of plate and screw prominence, respectively.
      - The distal screws must not be left prominent, and caution must be applied when drilling.
      - The sagittal and coronal profiles of the plate being used must be taken into consideration—some plates are very prominent and extend far radially.
REFERENCES

DEFINITION
- High-energy fractures of the distal aspect of the radius with extensive comminution of the articular surface and extension into the diaphysis represent a major treatment challenge. Standard plates and techniques may be inadequate for the management of such fractures.
- Before the introduction of the bridge plating technique, treatment of these injuries was limited to cast immobilization or external fixation with or without Kirschner wire augmentation. Both of these methods are associated with unacceptably high complication rates.

ANATOMY
- The articular surface of the distal radius is tilted 21 degrees in the anteroposterior plane and 5 to 11 degrees in the lateral plane.
- The dorsal cortex surface of the radius thickens to form the tubercle of Lister.
- A central ridge divides the articular surface of the radius into a scaphoid facet and a lunate facet.
- Because of the different areas of bone thickness and density, fractures tend to occur in the relatively weaker metaphyseal bone and propagate intra-articularly between the scaphoid and lunate facets.
- The degree, direction, and magnitude of applied load may cause coronal or sagittal splits within the lunate or scaphoid facets.

PATHOGENESIS
- Two subsets of patients with distal radius fractures continue to represent unique treatment challenges:
  - Patients with high-energy wrist injuries with fracture extension into the radial diaphysis
  - Patients with multiple injuries who require load bearing through the injured wrist to assist with mobilization and nursing care

NATURAL HISTORY
- Lafontaine et al. showed that the end results of comminuted distal radius fractures treated by closed methods resembled the prereduction radiographs more than any other radiographs during treatment, even when the reduction successfully restored wrist anatomy.
- A number of studies clearly show that restoration of normal anatomy after distal radius fracture provides better function.
- Functional outcome scores in patients without anatomic reduction are poor.
- Malunion of the distal radius has been associated with pain, stiffness, weak grip strength, and carpal instability in a substantial percentage of patients. Long-term consequences include degenerative arthritis in up to 50% of patients with even minimal displacement in the young adult population.
- As surgical treatment (plating in particular) ensures more consistent correction of displacement and maintenance of reduction, there has been a trend toward operative treatment in both the elderly and the young population.

PATIENT HISTORY AND PHYSICAL FINDINGS
- In the management of high-energy distal radius fractures, a complete history should include the mechanism of injury. These fractures are commonly the result of axial loading as opposed to the bending forces, which are all low-velocity fractures.
- Examination of the soft tissue envelope of the wrist should be performed to rule out open fractures.
- Because of the high-energy nature of these fractures, patients are at increased risk of neurovascular compromise. Careful examination for signs of impending compartment syndrome as well as median nerve dysfunction from an acute carpal tunnel syndrome should be clearly documented.
- Associated injuries should be ruled out, and appropriate patient clearance according to advanced trauma life support guidelines should be obtained.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Good-quality pre- and post-reduction wrist radiographs should be obtained preoperatively to assess the fracture pattern and rule out associated injuries to the carpus or distal radioulnar joint (DRUJ).
- CT scans may be helpful to assess complex intra-articular distal radius fractures.

NONOPERATIVE MANAGEMENT
- There is no acceptable nonoperative management for high-energy comminuted distal radius fractures.

SURGICAL MANAGEMENT
- The use of internal distraction plating or bridge plating for distal radius fractures was introduced by Burke and Singer. The technique was expanded by Ruch et al., who described the use of a 12- to 16-hole 3.5-mm plate dynamic compression plate (DCP) (Synthes, Paoli, PA) placed in the floor of the fourth dorsal extensor compartment to span from the intact radius diaphysis to the third metacarpal.
- The bridge plating technique provides strong fixation and allows for distraction across impacted articular segments.
- The technique can be combined with a limited articular fixation approach for fracture patterns with intra-articular extension.
Bridge plating of the distal radius was further refined by Hanel et al.9 The authors described a variant of the bridge plating technique using 2.4-mm AO plates passed extra-articularly through the second dorsal compartment and secured onto the dorsal-radial aspect of the radius diaphysis and the second metacarpal (Table 1).

Preoperative Planning

- A 22-hole 2.4-mm titanium mandibular reconstruction plate (Synthes, Paoli, PA) or a 2.4-mm stainless steel plate specifically designed for use as a distal radius bridge plate (DRB plate, Synthes, Paoli, PA) is used for distal radius bridge plating.
- The mandibular reconstruction plate is made of titanium and has square ends and scalloped edges and threaded holes to accept locking screws. The DRB plate that the authors currently use is made of stainless steel and has tapered ends to facilitate sliding the plate within the extensor compartment; it also has locking screws.

</table>

Positioning

- With the patient anesthetized and supine on the operating table, the involved extremity is draped free and centered on a radiolucent hand table.
- Finger traps are applied to the index and middle fingers and 4.5 kg of longitudinal traction is applied through a rope and pulley system.
- A C-arm comes in from above or below the hand table (FIG 1).

Approach

- Under image intensification, the closed reduction maneuver described by Agee1 is performed.
- Plates are passed extra-articularly through the second dorsal compartment and secured onto the dorsal-radial aspect of the radius diaphysis and the second metacarpal.
- The interval between the extensor carpi radialis longus (ECRL) and brevis (ECRB) is developed and the diaphysis of the radius exposed.
- The DRB plate is introduced beneath the muscle bellies of the outcroppers extraperiosteally and advanced distally between the ECRL and ECRB tendons.

**CLOSED REDUCTION MANEUVER OF AGEE**

- Longitudinal traction is first used to restore length and to assess the benefit of ligamentotaxis for the restoration of articular stepoff (TECH FIG 1A,B).
- Next, the hand is translated palmarly relative to the forearm to restore sagittal tilt and to assess the integrity of the volar lip of the radius (TECH FIG 1C-F).
- Finally, pronation of the hand relative to the forearm is performed to correct the supination deformity.
- Once the initial reduction maneuver is completed, the bridge plate is then applied.

**TECH FIG 1** Radiographs show an AP projection of the wrist injury before (A) and after (B) distraction is applied. (continued)
**APPROACH AND PLATE INSERTION**

- The DRB plate is superimposed on the skin from the radial diaphysis to the distal metadiaphysis of the second metacarpal. The position of the plate is verified with image intensification and markings are placed on the skin at the level of the proximal and distal four screw holes of the plate (TECH FIG 2A–C).
- The subcutaneous tissues are infiltrated with 0.25% bupivacaine with epinephrine to promote hemostasis.
- A 5-cm incision is made at the base of the second metacarpal and continued along the second metacarpal shaft. In the depths of this incision, the insertions of the ECRL and ECRB are identified as they pass beneath the distal edge of the second dorsal wrist compartment to insert on the second and third metacarpal bases respectively.
- A second incision is made just proximal to the outcropper muscle bellies (abductor pollicis longus and extensor pollicis brevis), in line with ECRL and ECRB tendons. The interval between the ECRL and ECRB is developed and the diaphysis of the radius exposed (TECH FIG 2D,E).
- The DRB plate is introduced beneath the muscle bellies of the outcroppers extraperiosteally and advanced distally between the ECRL and ECRB tendons (TECH FIG 2F).
- Some resistance may be encountered as the plate emerges distally but can usually be easily overcome with gentle manipulation of the plate (TECH FIG 2G).
- Occasionally, the plate will not pass through the compartment. In these cases, a guidewire or stout suture...
TECH FIG 2 • (continued) D. The ECRL and extensor carpi radialis brevis (ECRB) tendons just proximal to the abductor pollicis longus in the forearm. E. Development of the interval between the ECRL and ECRB tendons to gain access to the radius shaft. F. The proximal aspect of the plate over the radius and in between the ECRL and ECRB. It is important to ensure that the plate runs within the second compartment and not superficial to the first and third compartment tendons. G. The plate is advanced proximal to distal and emerges distally over the second metacarpal. H. A third incision is marked out just ulnar to the tubercle of Lister. I. The extensor pollicis longus tendon has been released from its compartment, and bone graft is inserted through the dorsal fracture line just ulnar to the bridge plate.

PLATE FIXATION AND ARTICULAR FIXATION

- After the bridge plate is passed, it is then secured to the second metacarpal by placing a nonlocking fully threaded 2.4-mm cortical screw through the most distal plate hole. The proximal end of the plate is then identified in the forearm.
- If the radial length has not been restored, then the plate, secured to the second metacarpal, is pushed distally until the length is reestablished and a fully threaded 2.4-mm nonlocking screw is placed in the most proximal plate hole. By using nonlocking screws the plate is effectively lagged onto the intact bone.
- Plate alignment along the longitudinal axis of the radius is guaranteed by securing the most distal and most proximal screw holes first.
- The remaining holes are secured with fully threaded locking screws inserted with bicortical purchase.
- It has been our experience that as the plate is passed along the radial diaphysis, through the second compartment and along the second metacarpal, extra-articular alignment, radial inclination, volar tilt, and radial length are restored.
- Intra-articular reduction may be further adjusted by using limited periarticular incisions to allow for direct...
Manipulation of articular fragments, placement of subchondral bone grafts, repair of intercarpal ligament injuries, and augmentation of fracture fixation with Kirschner wires and periarticular plates.

- Displaced volar medial fracture fragments that are not reduced with this technique require a separate volar incision and appropriate buttress support.
- The biomechanical stability of spanning plates is strong and predictable. Behrens et al., studying the rigidity of external fixator configurations, demonstrated that rigidity is directly proportional to how close the longitudinal fixator bar is to the bone and the fracture. A bridge plate, resting directly against the radius proximally and metacarpals distally, therefore optimizes the conditions to obtain the strongest possible fixator construct.
- A DRB plate fixed with a minimum of three screws at either end of the plate confers significantly more stability than would an external fixator used to stabilize a comparable fracture (TECH FIG 3).

**DISTAL RADIOULNAR JOINT MANAGEMENT**

- DRUJ stability is assessed after radius reconstruction. If the DRUJ is stable, the limb is immobilized in a long-arm splint with the forearm in supination for the first 10 to 14 days postoperatively.
- If the DRUJ is unstable, and there are no contraindications to prolonging the operation, repair or reconstruction of DRUJ and triangular fibrocartilage complex is undertaken.

**PEARLS AND PITFALLS**

**Hardware removal**
- At the time of hardware extraction, if a mandibular reconstruction plate was used, the screws are removed and the plate is twisted axially 720 degrees to break up the soft tissue adhesions and callus that tend to grow around and onto the scalloped edges of the titanium plate. This maneuver is not usually required when the smooth-edged stainless steel DRB is used.
- A removable short-arm splint is worn for 2 to 3 weeks after plate removal. Hand therapy at this point is directed at regaining motion and strength.

**POSTOPERATIVE CARE**

- Digit range-of-motion exercises start within 24 hours of surgery. Load bearing through the forearm and elbow is allowed immediately, as well as the use of a platform crutch when the patient is physiologically stable. One month postoperatively the platform is removed and weight bearing is allowed through the hand grip of regular crutches. Lifting and carrying are restricted to about 4.5 kg until fracture healing.
- DRUJ stability and forearm motion are assessed 2 weeks after reduction. If the patient can supinate the forearm with lit-
tle effort and the DRUJ is stable, then splinting is discontinued and axial loading through the extremity is allowed at this point.
- If the patient has difficulty maintaining supination, or if the DRUJ was reconstructed acutely, a removable long-arm splint is fabricated.
- If the DRUJ was transfixed with Kirschner wires, then the wires are removed on the third postoperative week and DRUJ stability is reassessed.
- Supplemental Kirschner wires for articular fixation are removed 6 weeks postoperatively.
- The DRB plate and screws are removed usually no earlier than 12 weeks after injury.

OUTCOMES
- The bridge plating technique for distal radius fractures was reviewed in a retrospective study consisting of 62 consecutive patients treated in this fashion.9 The series represents the senior author’s 10-year experience with the technique at a Level 1 trauma center. Patients managed with bridge plating either for distal radius fractures with extensive metadiaphyseal comminution or for distal radius fractures associated with other injuries requiring weight bearing through the affected extremity represented 13% of distal radius fractures treated with operative fixation during this period. Fracture healing occurred in all 62 patients.
- In each case radial length was within 5 mm of neutral ulnar variance, radial inclination was greater than 5 degrees, and palmar tilt was at least neutral.
- There were also no articular gaps or stepoffs greater than 2 mm and the DRUJ was stable in all cases.
- The plates were removed on average 112 days after placement.
- Forty-one of the 62 patients have returned to their previous levels of employment. Of the remaining 21 patients, 8 were unemployed at the time of injury and remain so.
- Thirteen patients sustained multiple injuries requiring considerable changes in occupation and lifestyle. Only 1 of these 13 patients considers the wrist fracture to be the limiting factor in failing to return to work.
- Overall these results compare favorably with the findings of Burke and Singer5 and Ruch et al.17
- Similarly, Ruch et al.17 showed that 64% of patients obtained excellent radiographic and functional results and another 27% of patients obtained good results in their prospective cohort of patients with comparable pathology.
- The authors of each of these studies propose that distraction plating allows fracture reduction and fixation over a broad metadiaphyseal area while effectively diverting compression forces away from the fracture site.
- The use of bridge plating in the treatment of distal radius fractures avoids the complications of external fixation. A bridge plate can remain implanted for extended periods without deleterious effects on functional outcome. All patients in our series went on to heal with acceptable metadiaphyseal and intra-articular alignment. In patients with multiple traumatic injuries, bridge plating allowed earlier postoperative load bearing across the affected wrist. This enabled independent transfers and the use of ambulatory aids. Application of bridge plates is simple and surgical time is comparable with the application of an external fixator.

COMPLICATIONS
- There was one documented hardware failure in the series in a patient who initially refused to have the implant taken out and continued to work in heavy manual labor for 19 months before the bridge plate failed.
- In addition, there were no cases of excessive postoperative finger stiffness or reflex sympathetic dystrophy.
- This reflects the overall infrequent complications reported in the literature for bridge plating of the distal radius. In fact, Burke and Singer5 reported no complications, and Ruch et al.17 reported no hardware failures and only three patients who developed long finger extensor lag of 10 to 15 degrees.

REFERENCES
**DEFINITION**
- The distal ulna is the fixed point around which the radius and the hand function (FIG 1A).
- Fractures of the distal ulna are often inadequately treated in comparison to its larger counterpart, the radius (FIG 1B, C).
- The current literature gives little guidance as to the management of these fractures and associated injuries.

**ANATOMY**
- The ulnar head forms the fixed point on which the hand and radius rest (FIG 2A).
- The radius rotates around the distal ulna through the distal radioulnar joint (DRUJ) during forearm pronation and supination.3,4
- This joint is connected to the carpus by a complicated ligament apparatus, the triangular fibrocartilage complex (TFCC).
- The stability of the DRUJ is achieved through bony congruity between the sigmoid notch of the radius and the ulnar head supported by the ulnoradial ligaments1,4 (FIG 2B).
- The spheres of the two articular surfaces differ (FIG 2C).
- Sixty percent of the joint surfaces are in contact in neutral forearm position.1
- In full pronation and supination there is only 10% bony contact.1
- The ligaments run from the fovea of the ulnar head and the base of the ulnar styloid to the dorsal and palmar edges of the sigmoid notch on the distal radius1,9 (Fig 2B).

**PATHOGENESIS**
- Isolated ulnar fractures most commonly occur when the forearm is struck by an object, explaining the eponym “nightstick fracture.”
- Distal ulnar fractures are most often due to a fall on an outstretched hand.
- It is a common understanding that ulnar-sided injuries are more often caused by falls backward in which the forearm is in supination, loading the ulnar side of the distal forearm and wrist and causing distal ulnar fractures, triquetral chip fractures, TFCC injuries, and so forth.
- In contrast, radial-sided injuries are more often caused by falls forward, loading the radial side of the forearm and wrist and causing scaphoid fractures, distal radius fractures, and so forth.

**NATURAL HISTORY**
- Many distal ulnar fractures leave only marginal long-term problems.
- Some distal ulnar malunions cause DRUJ incongruency with subsequent instability or blocked forearm rotation (FIG 3). This is why management of these deceptive fractures is important.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Posteroanterior, lateral, and oblique radiographs typically reveal the pathology.
FIG 2 • A. The distal ulna is the fixed point around which the radius rotates in pronation and supination. Through the ulnocarpal ligament the distal ulna relates to the hand, allowing daily hand activities. B. The distal radio-ulnar joint is stable because of bony congruity between the ulnar head and the sigmoid notch on the radius. The ulnorialar ligament inserts in the fovea and the base of the ulnar styloid and has a dorsal and palmar ligament attached to the dorsal and palmar part of the sigmoid notch respectively. They act as reins in the pronation and supination motion. C. The spheres of the two articular surfaces differ: the curvature of the ulnar head has a shorter radius, whereas the curvature of the sigmoid notch has a greater radius.

FIG 3 • A,B. Radiographs showing a distal radius fracture together with an ulnar head and styloid fracture. The complexity of the ulnar-sided injury was underappreciated. C. Intraoperative fluoroscopic image after fixation of the distal radius fracture, revealing displaced and unstable ulnar fractures. (continued)
CT is useful in examining articular fractures of the ulnar head.
MRI is sometimes needed to evaluate the integrity of the TFCC.
Arthroscopy should be considered if a radiograph leads the physician to suspect DRUJ dissociation without radiographic explanations, such as a displaced ulnar styloid base fracture.

**SURGICAL MANAGEMENT**

**Findings and Indications**

**DRUJ Dissociation**
- Radiographs occasionally reveal DRUJ dissociation in the absence of an ulnar-sided fracture (FIG 4). This results from detachment of the unioradial ligament (FIG 5A).
- Such unioradial ligament injuries have been found to cause DRUJ laxity and a worse outcome after distal radius fractures in patients without osteoporosis (FIG 5B).
- Arthroscopically assisted repair or open repair and reattachment of the unioradial ligament to the fovea of the ulnar head are required to restore stability in the DRUJ (FIG 5C) (see Chap. HA-49).

**Ulnar Styloid Fractures**
- The importance of ulnar styloid fractures and the need for operative intervention depends on the involvement of the unioradial ligament insertion site around the fovea of the ulnar head at the base of the styloid (FIG 6A).
- Generally, ulnar styloid fractures should be operated on if the fracture is at the base of the ulnar styloid and is displaced more than 2 mm (FIG 6B,C).
- Radial translation of the fractured ulnar styloid is caused by the detachment of the unioradial ligament. This increases the indication (FIG 6D) more than axial, distal fracture displacement (detaching the ulnotriquetral collateral ligament).
- Ulnar styloid fractures at the tip are likely to be stable and do not require fixation, as the unioradial ligament remains attached to the ulnar head at the base of the styloid (FIG 6E,F).
- Ulnar-sided injuries associated with distal radius fractures should be carefully assessed radiographically and clinically after open reduction and internal fixation (ORIF) of the radius fracture.
- Ulnar fracture reduction and DRUJ joint stability are often improved after treatment of the radius fracture.
- Stable DRUJ means that the unioradial ligament is not attached to the fractured ulnar styloid and therefore can be treated nonoperatively.
- Unstable DRUJ indicates that the unioradial ligament is detached with the styloid fracture. The styloid should be reduced and stabilized or the ligament reattached.

**FIG 3 • (continued)**

D,E. The distal radius fracture was stabilized using a volar locking plate. The ulnar head and styloid fractures were partially reduced and fixed with two Kirschner wires. The surgeon adequately secured the ulnar styloid fracture but not the ulnar head fracture and postoperatively did not restrict forearm rotation. F,G. These radiographs reveal the eventual ulnar head malunion that resulted in distal radioulnar joint instability and diminished forearm rotation. The situation was salvaged using an ulnar head replacement prosthesis.

**FIG 4 •**

A. An undisplaced distal radius fracture with no obvious distal ulna pathology. B. The same fracture with a stress test to the distal radioulnar joint (DRUJ), and an obvious DRUJ dissociation is seen as a sign of a complete unioradial ligament detachment in the absence of an ulnar styloid fracture.
A B C

**FIG 6** • A. The ulnar ligament has superficial and deeper components, which insert at the fovea of the ulnar head and partly attach to the base of the ulnar styloid. Consequently, a fracture at the base of the ulnar styloid may or may not detach the main distal radioulnar joint-stabilizing ligament. B,C. Ulnar styloid fractures at the base may detach the ulnar ligament and should be operated on if they are displaced more than 2 mm. D. Radial displacement (detaching the ulnar ligament) increases the indication for surgical treatment. E,F. Ulnar styloid tip fractures represent avulsion fractures from the ulnotriquetral collateral ligament. They demand no further treatment.
Ulnar Styloid Nonunion
- The main physical findings of ulnar styloid nonunion are ulnar-sided wrist pain worse with loading in rotation and tenderness over the ulnar styloid. Symptoms from an ulnar styloid nonunion are related to the following:
  - DRUJ instability from a malfunctioning ulnoradial ligament (peripheral TFCC detachment) (Fig 5B)
  - Impingement of the overlying extensor carpi ulnaris (ECU) tendon
  - Abutment on the carpus (Fig 7A,B)
  - Soft tissue irritation from the loose body (Fig 7C,D)

Ulnar Head Fractures
- Ulnar head fractures are most often associated with distal radius fractures, and the pattern of the distal radius fracture will have a strong influence on the overall functional outcome.
- Ulnar head fractures are seen either alone or with involvement of extra-articular portions of the distal ulna, proximally toward the diaphysis or distally including the styloid (Fig 3A,B).

Distal Ulnar Neck and Shaft Fractures
- A distal ulnar neck or distal shaft fracture is a fracture that occurs within 4 cm of the distal dome of the ulnar head (Fig 8A-D).

FIG 7 • A,B. Abutment of the ulnar styloid into the triquetrum on the ulnar side of the carpus. C,D. An ulnar styloid nonunion causing problems as a loose body.

FIG 8 • A,B. This ulnar shaft fracture is by definition within 4 cm of the distal dome of the ulnar head. C,D. This ulnar shaft fracture is more proximal and should be considered an isolated ulnar fracture. However, there may still be involvement in the distal radioulnar joint (DRUJ), which needs to be taken into account. The DRUJ should be examined for stability after open reduction and internal fixation. (continued)
Some distal ulnar fractures in association with distal radius fractures realign after manipulation and are considered to be stable once the radius is reduced. It is difficult to immobilize unstable fractures with a cast alone. Three-point fixation, even in an above-elbow cast, is not effective (FIG 8E,F).

Comminuted Intra-Articular Distal Ulnar Fractures
- Comminuted distal ulnar fractures that are irreducible and cannot be reconstructed have been mentioned in the literature in only one case report.

It is generally recommended that the initial approach be geared toward restoring the anatomy and maintaining the overall alignment of the ulna and DRUJ.

Approach
- The described approach is used for all distal ulnar fractures, including the ones extending into the neck of the ulna and into the distal shaft.
- This approach can, for instance, access an ulnar styloid fracture or nonunion and at the same time visualize, assess, and allow treatment of any associated TFCC pathology.

INCISION AND EXPOSURE
- Approach the distal ulna through a dorsal zigzag incision centered over the DRUJ (TECH FIG 1AB).
- This approach allows reattachment of all crucial stabilizing structures at the time of wound closure.
- Carefully protect the dorsal sensory branches of the ulnar nerve (TECH FIG 1C).
- Incise the retinaculum overlying the fifth extensor compartment (TECH FIG 1D).
- Elevate the ulnar retinacular flap in the interval between the extensor retinaculum and the separate dorsal sheet for the ECU tendon.
- Preserve the integrity of the separate ECU compartment (TECH FIG 1E).
- Open the dorsal capsule of the DRUJ using an ulnary based flap raised from the 4–5 septum (TECH FIG 1F).
- Identify the 4–5 intercompartmental artery.
Options for fixation of ulnar styloid base fractures include the following:
- Single or double Kirschner wires (TECH FIG 2A,B)
- Tension band wiring (TECH FIG 2C)
- Wire loop or suture
- Screw fixation (TECH FIG 2D)

Begin the capsular incision at the neck of the ulna and extend it to the 4-5 intercompartmental artery, which is diathermied.

The incision continues along this line to the level of the radiocarpal joint, where it then extends distally and ulnarly along the dorsal radiotriquetral ligament to the triquetrum.
- By staying in a flat layer along the dorsal cortex of the radius, the dorsal ulnoradial ligament attachment is not violated.
- The DRUJ and the spanning TFCC are then readily visualized. The ulnocarpal joint is often hidden behind the synovium over the meniscus homolog (TECH FIG 1G).
- If required, remove the synovium dorsal to the ulnoradial ligament to gain access to the ulnar styloid and the ulnocarpal joint.
- In cases of a distal neck fracture without any intra-articular involvement or soft tissue components, the approach stays proximal to the capsular flap. However, the retinacular flap needs to be raised to address the distal metaphyseal fractures.
Chapter 14  ORIF OF ULNAR STYLOID, HEAD, AND METADIAPHYSEAL FRACTURES

**TECH FIG 2** • The ulnar styloid can be fixed in various ways to secure reattachment of the ulnaradial ligament and thereby stabilize the distal radioulnar joint. **A,B.** Single (not rotationally stable) or double Kirschner wires. **C.** Tension band wiring. **D.** Screw fixation (not rotationally stable).

**ULNAR STYLOID NONUNIONS**

- Reattachment of the nonunited fragment to the ulnar head is indicated if the fragment is large.5
- If the fragment is small, it should be excised and the ulnaradial ligament reattached directly to the fovea of the ulnar head.5
- If the fragment is small and located distally and there is no DRUJ instability, the ulnar styloid can be excised without any associated ligament procedure.5

**ULNAR HEAD FRACTURES**

- Ulnar head fractures without a proximal extra-articular component
  - Fractures that are displaced (with an intra-articular stepoff) or unstable are treated with ORIF using buried headless compression screws6 or Kirschner wires.
  - Immobilization after fixation depends on the stability of the fracture and its fixation.
- Ulnar head fractures with a proximal extra-articular component
  - The intra-articular component is reduced and stabilized.
  - If the extra-articular component extends proximally toward the neck of the distal ulna a condylar blade plate is recommended (**TECH FIG 3**), whereas tension band wiring is recommended if the extra-articular component involves the ulnar styloid (Tech Fig 2C).
  - Immobilization after fixation depends on the stability of the fracture and its fixation.

**TECH FIG 3** • Irreducible or unstable distal forearm fractures require open reduction and internal fixation.10 AP and lateral radiographs show a dorsally displaced distal forearm fracture fixed with a blade plate.
DISTAL ULNAR NECK AND SHAFT FRACTURES

- Irreducible or unstable fractures require ORIF.\textsuperscript{10}
- This can be achieved using either a condylar blade plate\textsuperscript{10} (Tech Fig 3) or tension band wiring supplemented by intrafragmentary screws (TECH FIG 4).

![Tech Fig 4](image)

**TECH FIG 4 •** A, B. AP and lateral radiographs show a dorsally displaced distal forearm fracture. Open reduction and internal fixation was performed using both a dorsoradial and a dorsoulnar approach to stabilize the fractures. C. Because of the comminution around the ulnar styloid base, fixation was achieved with a suture loop.

COMMINUTED INTRA-ARTICULAR DISTAL ULNAR FRACTURES

- Three treatment options exist for comminuted intra-articular distal ulnar fractures:
  - Restoration of the anatomy and overall alignment of the ulna and DRUJ as mentioned above
  - This can be accomplished with manipulation and above-elbow cast immobilization alone or alternatively by surgical means with temporary wiring or external fixation.
  - The potential problems with this management technique are wrist stiffness and reduced forearm rotation that may not be corrected with a late salvage procedure.
  - Primary distal ulnar head replacement\textsuperscript{2}
    - Theoretical advantage is reduced stiffness (from having early movement) and less DRUJ pain.
  - Total or partial excision of the ulnar head as well as DRUJ arthrodesis with distal ulnar neck resection (Sauve-Kapandji procedure)

POSTOPERATIVE CARE

- Stable fixation of the distal ulnar complex still requires protection postoperatively with a below-elbow splint.
- Intermediate stable fixation requires 4 weeks of protection using a sugartong-type splint to allow flexion and extension of the elbow but protect against uncontrolled pronation and supination.
- Unstable fixation after internal, external, or nonoperative treatment requires above-elbow protection in neutral forearm rotation to limit movement for the first 6 weeks. There is otherwise a risk that rotational forces will cause a nonunion or malunion.

OUTCOMES

- Outcome is influenced by the fact that most distal ulnar fractures are neglected in comparison to the more common and more extensively treated distal radius fractures.
- The outcome can surely be improved if distal ulnar fractures are treated more directly and aggressively.
- The outcome will also improve if the relationship between the ulnar styloid and the ulnoradial ligament is fully understood and addressed.

COMPLICATIONS

- Stiffness of the DRUJ with limited pronation and supination
- Infection
- Nonunion
- Malunion

REFERENCES

DEFINITION
- Distal radius malunion is best defined as malalignment associated with dysfunction.
  - Malalignment does not always result in dysfunction. In particular, the vast majority of older, low-demand patients function very well with deformity.
  - Dysfunction can include loss of motion, loss of strength, or pain.\textsuperscript{1,2,5}
- Pain can be the most difficult to associate with deformity. Osteotomy for pain—as with any surgery for pain—is relatively unpredictable and should be undertaken with caution. Carpal malalignment, ulnocarpal impaction, and distal radioulnar joint malalignment are all potentially painful and can be variably addressed.
- The relationship between distal radius malunion and carpal tunnel syndrome is disputed. Some surgeons claim a direct causal relationship as well as the ability to improve carpal tunnel syndrome with osteotomy alone.

ANATOMY
- Loss of alignment can be measured on radiographs.
  - Angulation of the articular surface on the lateral view is measured as the angle between a line connecting the dorsal and palmar lips of the distal radius articular surface on the lateral view and a line perpendicular to the radius shaft.
  - Ulnarward inclination (often called radial inclination, a misnomer since the articular surface tilts toward the ulna) is measured as the angle between a line connecting the ulnar limit and the radial limit of the distal radius articular surface on the posteroanterior (PA) view and a line perpendicular to the radial shaft.
  - Ulnar variance is a better measure of shortening of the radius than radial length. It is measured as the distance between two lines drawn perpendicular to the radial shaft on the PA view, one at the level of the most ulnar corner of the lunate facet and the other at the distal limit of the ulnar head.
  - Positive ulnar variance means that the ulna is longer than the radius. Negative means the ulna is shorter.
- Loss of articular surface alignment can be measured on radiographs as gap, step, or subluxation.
  - This is most accurately measured using CT images (FIG 1).
  - Sources of variability in radiographic measurements include variation in the radiographs, imprecision in the measurement techniques, and imprecision in the selection of the points of reference.

PATHOGENESIS
- Fractures of the distal radius heal rapidly. A malaligned healing fracture can be considered a malunion within 4 to 6 weeks of injury.
- Risk factors for fracture instability include age, metaphyseal comminution, dorsal tilt, ulnar variance, and lack of functional independence.
- Manipulation of previously reduced fractures that redisplace in a cast or splint signifies instability and is not worthwhile.
- Limitations of various treatment techniques may contribute to creation of a malunion.
  - Percutaneous pins alone may not be sufficient to maintain alignment when there is substantial metaphyseal comminution.
  - External fixation alone without ancillary percutaneous pin fixation of the fracture
  - Early removal of pins or an external fixator. Settling of the fracture can also be observed after implant removal more than 6 weeks after injury, particularly when there is substantial metaphyseal comminution.
  - Nonlocked plates may loosen in the osteopenic metaphyseal bone.
- Complacency must be avoided. Many older patients desire optimal wrist alignment and function, and treatment decisions should not be made on chronological age alone.

NATURAL HISTORY
- Ulnar-sided wrist pain can improve for a year or more after fracture of the distal radius, so patience is warranted.
- Lack of forearm rotation may be related to capsular contracture or bony malalignment. For slight malunions, patience with exercises and rehabilitation is advisable.

Risk factors for fracture instability include age, metaphyseal comminution, dorsal tilt, ulnar variance, and lack of functional independence.

- Ulnar-sided wrist pain can improve for a year or more after fracture of the distal radius, so patience is warranted.
- Lack of forearm rotation may be related to capsular contracture or bony malalignment. For slight malunions, patience with exercises and rehabilitation is advisable.
While it is often stated that an extra-articular distal radius malunion leads to future arthrosis, there are no data to support this contention.

After a recovery period of 1 to 2 years from fracture, the functional deficits seem fairly stable.

Articular incongruity or subluxation in relatively nonarticular areas can be reasonably well tolerated, but in most cases intra-articular incongruity will lead to arthrosis, pain, and dysfunction. There is no clear time frame for these changes—indeed, symptoms do not correlate well with radiographic anatomy and the predictors of arthrosis are not well established.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Pain should be very discrete and specific. It is important that there be a direct correlation of the pain with a clear operative target. Vague, diffuse, or disproportionate pain should not be treated with osteotomy. Pain alone is not a good indication for osteotomy, so the interview should elicit specific aspects of the pain for which there is a good operative target and the risks of surgery are justified.
- Lack of motion should be clearly due to malalignment and not due to pain or squeamishness—likewise for instability of the distal radioulnar joint (DRUJ).
- Range of motion: A goniometer is used to measure wrist flexion, extension, radial and ulnar deviation, supination, and pronation.
- Ulnocarpal compression: The carpus is forcefully ulnarily deviated toward the ulna.
- Consistent reproduction of usual pain with ulnar deviation tasks is consistent with ulnocarpal impaction.
- The examiner can test for DRUJ instability by stabilizing the radius and trying to subluxate the distal ulna dorsal and volar from the sigmoid notch of the radius.
- Substantially less stability than the opposite side may correlate with symptomatic DRUJ instability, but this is a very difficult and subjective test.
- Scaphoid shift test: Instability would indicate a possible scapholunate interosseous ligament tear, indicating a potential dissociative rather than the typical nondissociative carpal malalignment usually associated with distal radius malunion.
- Grip strength is one measure of wrist dysfunction, but it is largely determined by pain and effort—both strongly influenced by psychosocial factors.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Posteroanterior and lateral radiographs of the wrist (FIG 2A–D) can be supplemented by specific radiographs for evaluation of the joint surface, particularly for potential articular malunions.
- Comparison with the opposite, uninjured wrist is useful and serves as a template for surgical correction.
- CT, particularly three-dimensional CT, is useful to precisely evaluate the joint surfaces (FIG 2E).
- Neurophysiologic tests (nerve conduction velocity and electromyography) are ordered to evaluate any symptoms or signs of carpal tunnel syndrome that may need to be addressed.

**DIFFERENTIAL DIAGNOSIS**

- Stiffness: capsular stiffness and tendon adhesions
- Numbness: idiopathic carpal tunnel syndrome
- Pain: another discrete source of pain or even idiopathic pain

**NONOPERATIVE MANAGEMENT**

- Nonoperative management is appropriate for low-demand and infirm individuals. Splints are weaned after 6 weeks of cast immobilization. Patients who struggle to regain motion may benefit from working with an occupational therapist or a certified hand therapist. Normal activities are resumed in 3 or 4 months. The patient may return every 2 or 4 months or so until satisfied with the result.
- Patience is warranted in many situations, particularly for patients with ulnar-sided wrist pain thought due to an extra-articular malunion.
- This discomfort is the last pain to go away after a distal radius fracture and routinely lasts up to a year.

---

**FIG 2 • A,B. AP and lateral radiographs of extra-articular dorsally angulated malunion. C,D. PA and lateral radiographs of an extra-articular dorsally displaced malunion. E. CT shows rotational deformity associated with a volarly displaced extra-articular fracture. (Copyright Diego Fernandez, MD, PhD.)**
Surgical Management

- Surgery is appropriate when a radiographic deformity correlates with a specific anatomically correctable problem and the deformity is associated with a substantial risk of dysfunction and arthrosis.
- The patient must understand the risks and benefits of intervening.
- The surgeon should be wary of pain as the primary complaint, because pain is strongly influenced by psychosocial factors, and pain relief is an achievable goal only when consistent with an objective, correctable anatomic deformity such as discomfort clearly associated with a substantial ulnocarpal impingement.
- When the issue is restriction of motion and there is less than 20 degrees of dorsal tilt or less than 5 mm of ulnar positive variance, a nonoperative approach may be warranted.
- There are no fixed rules or thresholds for acceptable alignment. The correlation with symptoms and dysfunction is more important.
- Intra-articular osteotomies should be considered only when the malalignment is simple and the planned correction is straightforward.
- For instance, malalignment of volar shearing fracture would be considered when the fragment is large, there is little or no articular comminution or impaction, and the dorsal fragments are not healed in a malaligned position.

- Distal radius osteotomy need not be performed urgently. The patient should have demonstrated excellent exercise skills and full finger motion, and there should be no significant nerve or tendon dysfunction or edema.
- In the case of an intra-articular malunion, intervening early (optimally within 6 months, definitely within 1 year of the fracture) when the fracture is not completely healed may take precedence over these concerns.

Preoperative Planning

- The desired angular, rotational, and length corrections are planned based on preoperative radiologic studies, including a radiograph of the opposite wrist if uninjured (FIG 3A,B).
- It can be useful to draw and write out a reconstruction plan, particularly for complex malunions (FIG 3C–E). In that way every contingency is anticipated and the surgery is likely to go more smoothly.

Positioning

- The patient is positioned supine with the arm supported on a hand table.
- A nonsterile pneumatic tourniquet is used and inflated after exsanguination and before the skin incision.

Approach

- The operative approach is either dorsal or volar, depending on the deformity and the chosen surgical technique.

---

**FIG 3 • A,B.** Preoperative plans for dorsal osteotomy in the patient in Techniques Figures 1 to 3: preosteotomy plan (A) and postosteotomy and corticocancellous bone grafting plan (B). **C.** Preoperative plan for an extra-articular osteotomy through a volar approach in the patient in Techniques Figures 4 and 5. (continued)
Exposure

- Make a longitudinal incision centered over the tubercle of Lister, in line with the third metacarpal (TECH FIG 1A).
- Elevate skin flaps, taking care to protect the branches of the superficial radial nerve in the radial skin flap.
- Incise the retinaculum over the third extensor compartment. Remove the tendon of the extensor pollicis longus (EPL) and transpose it radialward (TECH FIG 1B).
- The EPL tendon will be left in the subcutaneous tissues at the completion of the procedure.

Dorsal Extra-Articular Distal Radius Osteotomy: Corticocancellous Graft

- Elevate the fourth dorsal compartment and its tendons subperiosteally.
- Preserve the integrity of this compartment.
- It is usually not possible to elevate the second dorsal compartment subperiosteally, so simply retract the extensor carpi radialis brevis and longus tendons radially after opening the compartment.

Osteotomy and Realignment

- Kirschner wires drilled parallel to the articular surface can facilitate monitoring of realignment (TECH FIG 2A).
- A distractor or small external fixator may facilitate realignment and provisionally stabilize the fracture.
- The proximal threaded pin is drilled into the radial diaphysis perpendicularly in a position that will not interfere with implant application.
- The distal threaded pin is drilled at an angle equal to the desired correction of the lateral tilt of the distal radius articular surface so that distraction of the two pins will bring this pin parallel to the proximal pin (perpendicular to the radius), thereby restoring alignment.
- The pins should be drilled so that they also help restore the appropriate ulnarward inclination of the distal radius articular surface when distracted.
- Planned angular corrections can be monitored with sterile geometric templates.
- The osteotomy is made parallel with the distal Kirschner wire and as close to the original fracture site as possible using an oscillating saw (TECH FIG 2B).
- If the fracture is not yet completely healed (nascent malunion—usually within 4 months of injury), recreate the original fracture line by carefully removing fracture callus at the fracture site.
- This callus can be saved and used as bone graft.
- If the fracture is solidly healed, attempt to identify the prior fracture site. If this is uncertain, choose a site that creates a distal fragment large enough to facilitate manipulation and internal fixation while trying to stay distal enough to take advantage of the healing capacity of metaphyseal bone.
A lamina spreader can be used to help realign the distal fragment as well (TECH FIG 2C,D).
- Care must be taken when operating on osteoporotic bone.
- Additional provisional stability can be provided by placing 1.6-mm smooth Kirschner wires.
- If the ulnar variance can be restored with angular realignment alone, the volar cortex can be cracked and hinged open in an attempt to maintain some stability of the osteotomy. If lengthening of the volar cortex is required to restore ulnar variance, a second distractor in another plane (eg, direct radial) may prove useful for obtaining and maintaining alignment.

Graft Insertion and Fixation
- Once the osteotomy is created and the radius realigned, bone graft is inserted.
- Harvest bone graft (TECH FIG 3A). Either a corticocancellous (structural) bone graft or cancellous bone graft can be used.
  - Potential advantages of a structural graft include immediate structural support (TECH FIG 3B) and the possibility of using a smaller implant and thereby avoiding tendon irritation.
  - A cancellous (nonstructural) bone graft can be harvested using trephines (TECH FIG 3C). This avoids tedious, difficult, and unpredictable harvest and contouring of corticocancellous grafts, as well as the morbidity associated with harvest of a standard iliac crest bone graft.
- Apply a single T- or Pi-shaped plate or two 2.0- or 2.4-mm plates (one applied dorsally, ulnar to the tubercle of Lister, and the other applied radially between the first and second dorsal compartments).
- When a structural, corticocancellous bone graft is used, a single plate or a plate and separate screw may be adequate (TECH FIG 3D–H).
- Plates with angular stable screws or blades in the distal fragment may be more reliable than standard screws, particularly if the bone is of poor quality and if nonstructural graft is chosen.
- Once implants are placed and stability is ensured, remove all provisional fixation devices.
- This entire process is monitored using image intensification to confirm appropriate osteotomy site, correction of alignment, and implant placement.
- Repair the extensor retinaculum with absorbable suture.
- In some cases, a flap of retinaculum is brought deep to the tendons to add a layer of protection between the implants and extensor tendons.
- We usually do not close the retinaculum, and we no longer make retinacular flaps.
- The tourniquet is deflated and hemostasis ensured.
- The skin is closed.
- A bulky dressing incorporating a volar plaster wrist splint is applied.
Exposure

- Use a volar-radial Henry (flexor carpi radialis [FCR]) approach for both dorsally and volarly angulated malunions (see Fig 2C,D).
- Make a 5- to 7-cm longitudinal incision over the FCR tendon ending at the wrist flexion crease.
- If more exposure is required, the incision is angled or zigzagged at least 45 degrees toward the scaphoid distal pole.
- Incise the FCR sheath, retract the tendon ulnarly, and incise the floor.
- Leave the radial artery undissected and protected in the radial soft tissues.

**TECH FIG 3**  
A. Corticocancellous bone graft is harvested from the iliac crest. B. After final sculpting it is applied to the osteotomy site. C. Autogenous cancellous bone graft is harvested from the iliac crest using a trephine. D. A 2.0-mm condylar blade plate can provide fixed-angle internal fixation. E,F. Intraoperative photographs of the fixation. G,H. Final AP and lateral radiographs. (Copyright Diego Fernandez, MD, PhD.)
Sweep the fat overlying the pronator quadratus together with the digital flexors and median nerve ulnarward with a sponge or blunt elevator.

Proximally in the incision, elevate the most distal aspect of the origin of the flexor pollicis longus from the volar distal radius (taking care to cauterize a consistent artery in this region) and retract it ulnarly with a small Hohmann retractor placed around the ulnar border of the radius.

Expose the radial border of the radius using a blunt elevator and Hohmann retractors.

Incise the pronator quadratus over its most radial and distal limits (L-shaped incision) and elevate it subperiosteally.

Leaving the periosteum with the muscle can facilitate later repair.

For dorsally angulated malunions, release of the radial and dorsal soft tissues facilitates realignment.

The brachioradialis is Z-lengthened and the periosteum is elevated from the radius shaft proximally.

After osteotomy in the manner detailed above (for the dorsal approach to malunions), pronate the proximal radius shaft out of the wound, providing access to the dorsal periosteum, which can be isolated and divided.

With the release of the brachioradialis and the dorsal periosteum, realignment of the radius is usually comparable to an acute fracture.

Volarly angulated malunions do not need an extensive soft tissue release in most cases. The plate can facilitate realignment by pushing the distal fragments into position as the proximal screws are tightened.

### Realignment and Provisional Fixation

- The fragments are realigned using the techniques described above (Tech FIG 4).
- The techniques are similar to those for acute fractures once an adequate soft tissue release has been performed.
- Apply a fixed-angle volar implant.
- Insert provisional Kirschner wires either through or adjacent to the plate (see Tech Fig 4).

### Plate Fixation

- Placement of the plate will frequently help reduce the proximal and distal fragments (Tech FIG 5A,B).
- After final plate fixation and removal of provisional fixation, apply cancellous graft to the osteotomy site (Tech FIG 5C–F).
- Excellent access is available radially for placement of the bone graft.
- The tourniquet is deflated and hemostasis ensured.
- Repair the pronator quadratus if possible.
- It can be sutured to the brachioradialis tendon.
- The skin is closed.
- A bulky dressing incorporating a volar plaster wrist splint is applied.
Intra-articular osteotomy should be attempted only when there is a simple fracture line that can be clearly identified by direct visualization as well as under image intensification (TECH FIG 6A–C).

- Incompletely healed fractures (fewer than 3 to 4 months since injury) are ideal.

- Depending on the locations of the malunited articular fragments, perform either a dorsal or a volar exposure in the manner detailed above.

- When a dorsal exposure is used, a transverse capsulotomy allows access to the joint and monitoring of the articular osteotomy and realignment.

- In the case of a volar exposure, the capsule is not incised, but articular exposure may be possible through the osteotomy site.

- The osteotomy should recreate the original fracture line. This is monitored directly and under image intensification.

- Reduction is accomplished by soft tissue release and direct fragment manipulation. For many malunions it is necessary to remove bone or callus from the fracture site to realign the fracture fragment. Callus or bone is removed until the fracture fragment fits properly (TECH FIG 6D).

- Provisional Kirschner wires are used to hold the reduction (TECH FIG 6E,F).

- The implants are then applied.

- Dorsally a single T- or Pi-shaped plate or two 2.0- or 2.4-mm plates (one applied dorsally, ulnar to the tubercle of Lister, and the other applied radially between the first and second dorsal compartments) can be used (TECH FIG 6G,H).

- Volarly, a T-shaped plate is usually used.

- After final plate fixation, provisional fixation is removed.

- This entire process is monitored using image intensification to confirm appropriate osteotomy site, correction of alignment, and implant placement.

- Deflate the tourniquet, close the wound, and apply the splint in the manner detailed above.
Preoperative plan

- A poor or incomplete preoperative plan will increase the amount of uncertainty and hesitation during surgery. This will increase the operative time and the frustration level and will decrease the satisfaction with the surgery.
- Making a detailed preoperative plan will improve the efficiency and efficacy of the procedure.

Extra-articular malunions

- Manipulating the distal fragment can be much more difficult with poor-quality bone.
- The use of a distractor or small external fixator greatly facilitates realignment and provisional stabilization of the fragments.
- Consider using two distractors in perpendicular planes (eg, one dorsal and one direct radial) to help obtain and maintain alignment.
- Restoration of length in addition to that gained with angular realignment (ie, lengthening of both the dorsal and volar cortices) is much more difficult.
- The most difficult part of performing an osteotomy for a dorsal angulated malunion from a volar approach is realignment of the bone.
- An extended FCR exposure allows release of the dorsal periosteum and Z-lengthening of the brachioradialis, both of which facilitate realignment of the radius.

Intra-articular malunions

- Handling small articular fracture fragments can be difficult.
- Each fragment can be realigned using a Kirschner wire as a joystick.
- The articular osteotomy is easiest when the original fracture lines can be identified.
- Try to intervene within 3 months of injury when articular malunion is identified.
POSTOPERATIVE CARE

- Active and active-assisted exercise of the fingers and forearm, finger exercises to reduce swelling, and active functional use of the limb for light tasks are encouraged immediately.
- The initial plaster splint is exchanged for a custom Orthoplast removable splint 2 weeks after the surgery.
- The patient gradually weans out of the splint between 4 and 6 weeks after surgery and initiates active and active-assisted wrist exercises.
- Strengthening and forceful use of the arm are restricted until early radiographic union is apparent.
- Unrestricted use of the limb is allowed when solid union is present clinically and radiographically.

OUTCOMES

- Fernandez’ articles describing dorsal osteotomy with cortico-cancellous bone graft with and without Bower arthroplasty of the DRUJ established the value of the technique for improving function in patients with symptomatic distal radius malunions.
  - He documented good or excellent results in 75% and 80% of patients respectively, noting that satisfactory results depend upon the absence of degenerative changes in the radiocarpal and intercarpal joints, and the presence of adequate preoperative range of motion of the wrist.
- Corrective osteotomy with carefully preoperatively planned structural corticocancellous bone graft does not reliably achieve the planned correction.
- Nonunions, loss of alignment, and major complications were not reported in these series.
- Jupiter and Ring demonstrated that early correction of distal radius deformity shortened the period of disability without increasing complications, and that the combination of cancellous autograft and locking plates was as reliable as corticocancellous bone grafting.
  - Nonunions, loss of alignment, and major complications were not reported in these series.
- Several small articles have established the safety and efficacy of volar osteotomy for a dorsally displaced fracture.
- Shea et al established the safety and efficacy of osteotomy for volar extra-articular malunions in a case series.
- Fernandez et al established the safety and efficacy of osteotomy for a radially deviated extra-articular malunion in a case series.
- Several case series have documented the safety and efficacy of intra-articular osteotomy.

COMPLICATIONS

- Nonunion
- Loss of alignment
- Loss of fixation
- Infection
- Wound problems
- Nerve injury

Percutaneous Fixation of Acute Scaphoid Fractures

Peter J.L. Jebson, Jane S. Tan, and Andrew Wong

DEFINITION

- Located in the proximal carpal row, the scaphoid serves as an important link between the proximal and distal carpal rows. It is the most commonly fractured carpal bone, accounting for about 1 in every 100,000 emergency room visits.12
- There are about 345,000 scaphoid fractures annually in the United States.
- A scaphoid fracture classically occurs in a young, active adult due to a fall onto an outstretched hand.
- The Herbert classification categorizes scaphoid fractures into acute stable, acute unstable, delayed union, and established nonunion patterns.

ANATOMY

- The scaphoid has a complex three-dimensional geometry that has been described as a "twisted peanut."8 Anatomically the scaphoid is organized into proximal pole, waist, and distal pole regions.
- The scaphoid articulates with the radius, lunate, capitate, trapezium, and trapezoid; thus, its surface is almost completely covered with hyaline cartilage. This feature has several important implications, including articular disruption during wire or screw insertion, paucity of vascular supply, and the absence of periosteum.
- Lacking periosteum, the scaphoid heals almost completely by primary bone healing, resulting in minimal callus and a biomechanically weak early union.17
- Blood supply comes from branches of the radial artery that enter the scaphoid via two main routes7:
  - A dorsal branch, which enters the scaphoid via the dorsal ridge, provides the primary supply and 70% to 80% of the overall vascularity, including the entire proximal pole (via retrograde endosteal branches).
  - A volar branch, which enters through the tubercle, supplies 20% to 30% of the internal vascularity, all in the distal pole.
- The precarious blood supply contributes to the high incidence of nonunion after a fracture at the scaphoid waist or proximal pole. It also places the proximal pole at risk for the development of avascular necrosis.

PATHOGENESIS

- The typical mechanism of injury involves a fall onto the wrist. Studies have demonstrated that wrist extension of more than 95 degrees combined with more than 10 degrees of radial deviation is required for a scaphoid fracture to occur. In this position, the scaphoid abuts the distal radius, resulting in fracture.
- Seventy to 80% of scaphoid fractures occur at the waist region, while 10% to 20% involve the proximal pole and 5% occur at the distal pole and tuberosity.
- In children, the most common location for a scaphoid fracture is the distal pole.2

NATURAL HISTORY

- The true natural history of an untreated scaphoid fracture is unknown due to limitations in the existing literature, particularly with respect to study design.14 However, several retrospective studies have suggested that if a nonunion occurs, a predictable pattern of wrist arthritis develops usually within 10 years of the injury.14,16
- Unrecognized, untreated, or inadequately treated scaphoid fractures have an increased likelihood of nonunion and secondary carpal instability. A fracture through the proximal pole has the highest likelihood of nonunion, followed by a fracture of the scaphoid waist.
- If the scaphoid fracture is unstable, extension forces at the proximal fragment (via the lunate and scapholunate ligament) and flexion forces at the distal fragment result in a flexion (“humpback”) deformity of the scaphoid.
- This loss of scaphoid support results in carpal instability, most frequently a dorsal intercalated segment instability (DISI) pattern, which eventually leads to arthritis as previously described.
- The overall incidence of nonunion after fracture of the scaphoid waist region is about 5% to 10%.13

PATIENT HISTORY AND PHYSICAL FINDINGS

- A patient with an acute or subacute scaphoid fracture presents with radial-sided wrist pain, swelling, and loss of motion, particularly with dorsiflexion.
- Classic physical examination findings include:
  - Edema over the dorsoradial aspect of the wrist
  - Tenderness to palpation volarly over the distal tubercle
  - Pain with axial compression of the wrist (scaphoid compression test)
  - Acutely, swelling and ecchymoses over the volar radial wrist

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Initial imaging studies for a suspected scaphoid fracture should include a posteroanterior (PA) view with the wrist in ulnar deviation, semipronated and semisupinated 45-degree oblique views, and a lateral view.
- The PA ulnar deviation view produces scaphoid extension, permitting visualization of the entire scaphoid.
- The semipronated view permits visualization of the waist and distal-third regions.
- The semisupinated view provides visualization of the dorsal ridge.
- The lateral view can demonstrate a waist fracture, fracture displacement and angulation, and overall carpal alignment.
Displaced and unstable fractures are defined by the following criteria:
- At least 1 mm of displacement
- More than 10 degrees of angular displacement
- Fracture comminution
- Radiolunate angle of more than 15 degrees
- Scapholunate angle of more than 60 degrees
- Intrascaphoid angle of more than 35 degrees
- CT scan is helpful in identifying and characterizing an acute fracture and evaluating for a nonunion. Thin 1-mm cuts are obtained in the sagittal and coronal planes.
- MRI is useful for diagnosing an occult fracture and, when combined with gadolinium administration, can be used to assess the vascularity of the proximal pole and the presence of avascular necrosis.
- Technetium bone scan has been shown to be up to 100% sensitive in identifying occult fractures but lacks specificity. It is optimally used 48 hours after injury.

Differential Diagnosis
- Scapholunate injury
- Wrist sprain
- Wrist contusion
- Fracture of other carpal bones
- Distal radius fracture

Nonoperative Management
- Nonoperative management, specifically cast immobilization, is indicated for a nondisplaced, acute (less than 4 weeks from injury) fracture of the distal pole. For a nondisplaced, acute waist fracture, there is debate regarding the preferred treatment approach—cast immobilization or surgical stabilization.
- With cast immobilization, there is no consensus regarding the preferred position of the wrist, the need to immobilize other joints besides the wrist, and the duration of immobilization.4
  - Clinical studies have demonstrated no benefit with thumb immobilization, nor any influence of wrist position on the rate of union.
  - Studies have also demonstrated no difference in union rates with use of a long-arm versus short-arm cast; however, a small randomized prospective study by Gellman et al5 demonstrated a shorter time to union and fewer nonunions and delayed unions with the initial use of a long-arm cast.

In general, cast immobilization is required for 6 weeks after a distal pole fracture and 10 to 12 weeks following a nondisplaced waist fracture.
- Confirmation of fracture union requires serial plain radiographs demonstrating progressive obliteration of the fracture line and clear trabeculation across the fracture site.6
- If there is any question regarding fracture union, a CT scan should be obtained.

Surgical Management
- Operative treatment is advocated for fractures that are unstable or displaced (see above criteria) and following a significant treatment delay.
- Percutaneous fixation is indicated for:
  - Nondisplaced fractures of the scaphoid waist
  - Displaced fractures of the scaphoid waist
  - Proximal pole fractures
- Percutaneous stabilization of scaphoid fractures may be performed using either the dorsal arthroscopically assisted reduction and fixation (AARF) approach17-19 or the volar approach.3,10
  - Regardless of the technique used, the screw must be inserted in the middle third or central axis of the scaphoid, as this provides the greatest stability and stiffness, improves fracture alignment, and decreases time to union.1,20,21

Preoperative Planning
- All imaging studies should be reviewed to identify the location of the fracture and the size of the scaphoid, both of which influence implant selection.
- Plain radiographs should be templated to determine the approximate screw length.
- Required equipment:
  - Portable mini-fluoroscopy unit
  - Kirschner wires
  - Cannulated headless compression screw system
  - Wrist arthroscopy equipment for AARF

Positioning
- The patient is positioned supine on the operating table, with the shoulder abducted 90 degrees and the arm on a radiolucent hand table.
- A pneumatic tourniquet is applied to the upper arm.
- The portable fluoroscopy unit is positioned at the end of the hand table.

Dorsal Arthroscopy-Assisted Reduction and Fixation

Nondisplaced Fracture of the Scaphoid Waist or Proximal Pole
- Position the wrist to obtain a PA view of the wrist.
- Under fluoroscopic guidance, gently pronate the wrist until the scaphoid appears as an oblong cylinder, indicating that the proximal and distal poles are aligned.
- Flex the wrist about 45 degrees until the cylinder rotates into the plane of imaging, forming a “ring” sign. The center of the ring indicates the central axis of the scaphoid (TECH FIG 1).
- Using a 14-gauge angiocatheter as a guide for wire insertion, place the tip of a 0.045-inch guidewire through the catheter and onto the proximal pole of the scaphoid, at the center of the scaphoid ring. Confirm correct positioning with fluoroscopy.
- Insert the guidewire down the central axis of the scaphoid using a wire-driver. Keep the wrist flexed to avoid bending the wire.
- Insert the guidewire through the trapezium and advance it until the proximal tip of the guidewire clears the radiocarpal joint such that the wrist can be extended for arthroscopic examination.
Confirm correct wire position with fluoroscopy.
- The radial midcarpal portal is used to evaluate the accuracy of fracture reduction.
- The 3-4 and 4-5 portals are used to assess the integrity of the radiocarpal and intercarpal ligaments.
- Suspend the hand vertically in finger traps and apply 10 lb of traction to the upper arm to distract the radiocarpal and midcarpal articulations.
- Create a small longitudinal incision over each portal site, and bluntly dissect down to the capsule with a hemostat.
- Enter the capsule with a blunt trocar.
- Perform a diagnostic arthroscopy to assess for any associated injuries and to evaluate the fracture reduction.
- Remove the hand from traction for screw insertion.
- Position the wrist again to obtain the “ring” sign, and maintain the wrist in flexion.
- Drive the guidewire from dorsal to volar, perpendicular to the fracture line, until the distal tip lies just within the distal pole of the scaphoid (TECH FIG 2A–C).
- Place a second guidewire of equal length against the tip of the proximal pole, parallel and next to the first guidewire. The difference between lengths of the protruding wires represents the length of the scaphoid.
- Subtract at least 4 mm from the length of the scaphoid to obtain the desired screw length.
- Make a small longitudinal incision around the guidewire, and bluntly dissect down to the joint capsule. Carefully retract the extensor pollicis longus and extensor digitorum communis tendons away from the surgical site.
- Use the cannulated reamer to ream to 2 mm short of the distal articular. It is critical not to ream closer than 2 mm, as this may cause loss of fracture compression during screw insertion.
- Insert an Acutrak or mini-Acutrak screw (Acumed, Beaverton, OR) of appropriate length (at least 4 mm shorter than the measured scaphoid length) to within 1 to 2 mm of the distal surface.
- The tip of the screw should not penetrate the distal surface, and the proximal end of the screw should rest 2 mm deep to the proximal articular cartilage (TECH FIG 2D,E).
- Confirm satisfactory screw position and fracture reduction with fluoroscopy. The screw should be inserted down the central axis of the scaphoid. If any doubt exists, use the arthroscopic portals to confirm that the screw is buried in the scaphoid.

Before screw insertion, the position of the Kirschner wire must be changed from its position used for arthroscopy. The Kirschner wire should be driven from volar to dorsal until the distal end lies just beneath the articular surface of the scaphoid. (continued)
The 3-4 portal and the radial midcarpal portals provide the best view to ensure that the fracture is adequately reduced and that there is no violation of the midcarpal joint.

**Displaced Scaphoid Waist Fracture**
- Insert two percutaneous 0.062-inch smooth Kirschner wires dorsally into each fragment perpendicular to the long axis of the scaphoid to be used as joysticks to reduce the fracture (**TECH FIG 3A,B**).
- Position the wrist as previously described.
- The guidewire from the Acurtrak system is inserted from proximal to distal, starting dorsally and aiming for the central axis of the distal fragment.
- The guidewire is driven through the distal fragment and out through the volar skin of the hand. The protruding tip is then pulled volarly until the wire is only in the distal fragment (**TECH FIG 3C**).
- The proximal fragment, which is now freely mobile, is reduced manually using the Kirschner wire joysticks.
- Once the fracture is reduced, the central guidewire is driven from volar to dorsal into the proximal fragment, securing it in place (**TECH FIG 3D**).

**TECH FIG 2** (continued) D,E. Screw fixation of minimally displaced scaphoid fracture via the dorsal percutaneous technique. The screw tip should rest within 1 to 2 mm of the distal cortex. Excellent compression should be obtained with this technique.

**TECH FIG 3** • A. Reduction of a displaced scaphoid waist fracture using Kirschner wire joysticks. B. The Kirschner wire joystick technique for fracture reduction. C. The guidewire is pulled volarly until it remains only in the distal fragment. (continued)
■ The guidewire is further advanced from volar to dorsal until its distal tip is just within the subchondral bone of the distal articular surface. This allows for measurement of the screw length as previously described.
■ An additional 0.045-inch Kirschner wire is inserted parallel to the guidewire to prevent rotation of the scaphoid fragments during reaming and screw implantation.
■ Maintenance of reduction during and after screw insertion is confirmed with fluoroscopy, and all wires are subsequently removed.

Alternatively, the guidewire may be placed directly through the trapezium into the scaphoid distal pole. We do not prefer this approach due to concerns about the development of scaphotrapezial arthritis.

Advance the guidewire to the subchondral bone of the proximal pole.

Place a second guidewire of equal length against the surface of the distal scaphoid, adjacent and parallel to the first guidewire. The difference between the lengths of the wires represents the length of the scaphoid.

Subtract 4 mm from the length of the scaphoid to obtain the desired screw length.

Use the cannulated reamer to ream to within 2 mm of the proximal cortex. It is critical not to ream closer than 2 mm from the proximal cortex, as this may result in a lack of compression during screw insertion.

Insert an Acutrak or mini-Acutrak screw of appropriate length, remove the guidewire, and confirm satisfactory screw position and fracture reduction with fluoroscopy.

VOLAR PERCUTANEOUS APPROACH

■ Position the patient in a supine position with the shoulder abducted and the forearm in supination. The wrist is placed into an extended and ulnarly deviated position over a rolled towel to gain access to the distal pole of the scaphoid.

■ Position the portable fluoroscopy unit such that PA and lateral views of the wrist can be obtained. Image intensification is used to locate the distal scaphoid tuberosity.

■ A small longitudinal stab incision is made at this point, and the soft tissues are bluntly dissected down to the scaphotrapezial articulation.

■ Introduce the guidewire on the distal scaphoid tuberosity. Under image guidance, the wire is advanced toward the center of the proximal pole, aiming for the tubercle of Lister (TECH FIG 4).

■ The volar prominence of the trapezium may be partially excised to facilitate the correct starting point and trajectory for the guidewire.

■ Alternatively, the guidewire may be placed directly through the trapezium into the scaphoid distal pole. We do not prefer this approach due to concerns about the development of scaphotrapezial arthritis.

■ Advance the guidewire to the subchondral bone of the proximal pole.

■ Place a second guidewire of equal length against the surface of the distal scaphoid, adjacent and parallel to the first guidewire. The difference between the lengths of the wires represents the length of the scaphoid.

■ Subtract 4 mm from the length of the scaphoid to obtain the desired screw length.

■ Use the cannulated reamer to ream to within 2 mm of the proximal cortex. It is critical not to ream closer than 2 mm from the proximal cortex, as this may result in a lack of compression during screw insertion.

■ Insert an Acutrak or mini-Acutrak screw of appropriate length, remove the guidewire, and confirm satisfactory screw position and fracture reduction with fluoroscopy.
POSTOPERATIVE CARE
- Dressings are applied and the limb is immobilized in a forearm-based splint, immobilizing only the wrist. The thumb and fingers remain free for range-of-motion exercises.
- The patient is instructed in the importance of limb elevation and finger range-of-motion exercises.
- At 2 weeks postoperatively, the sutures are removed, a removable wrist splint is applied, and a wrist range-of-motion exercise program is initiated.
- If the patient is noncompliant, the fracture is deemed unstable, or the fixation is less than ideal, then a short-arm cast is applied for at least 6 weeks.
- Plain radiographs are obtained at 2, 6, 12, and 24 weeks postoperatively.
- The splint (or cast) is discontinued when union is confirmed on serial plain radiographs. If there is any question regarding fracture union, a CT scan is obtained.
- Unprotected strenuous activity or contact sports are not permitted until 3 months postoperatively.

OUTCOMES
- Results of contemporary techniques of percutaneous fixation are excellent; it has been shown to allow for earlier mobilization and return to activity and high satisfaction rates compared to nonoperative measures. 5,17,22
- Earlier mobilization avoids complications such as muscle atrophy and joint stiffness.
- Percutaneous techniques result in decreased soft tissue damage compared to conventional open techniques. 22
- In a recent series of 27 consecutive patients, the union rate (confirmed by CT) was 100%. The average time to union was 12 weeks, with a prolonged time to union noted in patients with a proximal pole fracture. 18

COMPLICATIONS
- Complications are rare with percutaneous fixation techniques. The risks associated with open reduction and internal fixation, such as damage to the ligamentous support of the carpus and disruption of the dorsal blood supply, are minimized.
- Possible complications include15,19:
  - Nonunion
  - Malunion
  - Injuries to the dorsal sensory branch of the radial nerve
  - Extensor tendon injury
  - Infection
  - Technical problems: screw protrusion, screw malposition, bending or breakage of guidewire
  - Erosion of the trapezium and discomfort from the head of the screw has been reported with the use of a percutaneous cannulated screw inserted via the volar approach. 22

REFERENCES
DEFINITION
- The scaphoid is the most commonly fractured carpal bone, accounting for 1 in every 100,000 emergency department visits.12
- Scaphoid fractures typically result from a fall on an outstretched hand.
- Scaphoid nonunion or proximal pole avascular necrosis (AVN) after a fracture has been associated with considerable morbidity and a predictable pattern of wrist arthritis.15,17,18
- The complex anatomy and tenuous blood supply to the scaphoid make operative management of these fractures technically challenging.18
- The Herbert classification system organizes scaphoid fractures into four groups: acute stable, acute unstable, delayed union, and established nonunion.

ANATOMY
- The scaphoid has a complex three-dimensional geometry that has been likened to a “twisted peanut.” It can be divided into three regions: proximal pole, waist, and distal pole.
- The scaphoid functions as the primary link between the forearm and the distal carpal row and therefore plays a critical role in maintaining normal carpal kinematics.
- Articulating with the scaphoid fossa of the radius, the lunate, capitate, trapezium, and trapezoid, more than 70% of the scaphoid is covered with articular cartilage.
- Gelberman and Menon8 have described the vascular supply of the scaphoid. The main arterial supply is from the radial artery; it enters the scaphoid via two main branches:
  - A dorsal branch, entering through the dorsal ridge, is the primary supply and provides 70% to 80% of the vascularity, including the entire proximal pole via retrograde endosteal branches.
  - A volar branch, entering through the tubercle, supplies the remaining 20% to 30%, predominantly the distal pole and tuberosity.
- The proximal pole is at increased risk for avascular necrosis (AVN) secondary to disruption of its tenuous retrograde blood supply after a fracture of the scaphoid waist or proximal pole.
- Due to its tenuous vascular supply, the scaphoid heals almost entirely by primary bone healing, resulting in minimal callus formation.
- The size and shape of the scaphoid, in combination with its precarious blood supply, demands attention to detail and accurate implantation of fixation devices during fracture fixation.

PATHOGENESIS
- Scaphoid fractures are most commonly seen in young, active males who fall on an outstretched upper extremity.12
- With the wrist dorsiflexed greater than 95 degrees, in combination with 10 degrees or more of radial deviation, the distal radius abuts the scaphoid and precipitates a fracture.12
- Most of these fractures occur at the waist region, although 10% to 20% occur in the proximal pole.
- Proximal pole fractures are associated with an increased risk of nonunion, delayed union, and AVN.
- In children, scaphoid fractures are less common and are most frequently seen in the distal pole.

NATURAL HISTORY
- An untreated or inadequately treated scaphoid fracture has a higher likelihood of nonunion. The overall incidence of nonunion is estimated at 5% to 10%, but the risk is significantly increased with nonoperative treatment of a displaced waist or proximal pole fracture.
- The natural history of scaphoid nonunions is controversial, but they are believed to result in a predictable pattern of progressive radiocarpal and midcarpal arthritis.8,9,14,15,17,18
- In an established scaphoid nonunion, the distal portion of the scaphoid may flex, producing a “humpback” deformity of the scaphoid. The loss of scaphoid integrity can result in carpal instability and abnormal carpal kinematics, most frequently manifesting as a dorsal intercalated segment instability (DISI) pattern.
- The pattern of carpal instability and secondary arthrosis due to an unstable scaphoid nonunion has been termed a SNAC wrist (scaphoid nonunion advanced collapse pattern of wrist arthritis).11,17
- In the SNAC wrist, there is a loss of carpal height with proximal capitate migration, flexion and pronation of the scaphoid, and secondary midcarpal arthritis.17
- Factors associated with the development of a scaphoid fracture nonunion include14:
  - Delayed diagnosis or treatment
  - Inadequate immobilization
  - Proximal fracture
  - Initial and progressive fracture displacement
  - Fracture comminution
  - Presence of associated carpal injuries (ie, perilunate injury)

PATIENT HISTORY AND PHYSICAL FINDINGS
- Scaphoid fractures classically occur in the active, young adult population after a fall onto an outstretched hand. Patients present with radial-sided wrist pain.
- Classic physical examination findings include:
  - Swelling over the dorsoradial aspect of the wrist
  - Erythema over the volar radial aspect of the wrist
  - Tenderness to palpation in the “anatomic snuffbox”
  - Tenderness with palpation volarly over the distal tubercle
  - Pain with axial compression of the wrist (scaphoid compression test)
- Scaphoid fractures can be part of a greater arc injury.
- The physician should examine the entire wrist carefully for areas of tenderness and swelling.
Plain radiographs are scrutinized for an associated ligamentous injury or disruption of the midcarpal joint as seen in the transscaphoid perilunate fracture-dislocation.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The following plain radiographs should routinely be ordered in the patient with a suspected scaphoid fracture: posteroanterior (PA), oblique, lateral, and dedicated scaphoid views.
  - The PA view allows visualization of the proximal pole of the scaphoid.
  - The semipronated oblique view provides the best visualization of the waist and distal pole regions.
  - The semisupinated oblique view provides the best visualization of the dorsal ridge.
  - The lateral view permits an assessment of fracture angulation, carpal alignment, and carpal instability.
  - The dedicated scaphoid view is a PA view with the wrist in ulnar deviation. This results in scaphoid extension, allowing visualization of the scaphoid in profile (FIG 1A).
- The following criteria define a displaced or unstable fracture as noted on plain radiographs²,⁶,⁰¹⁴:
  - At least 1 mm of displacement
  - More than 10 degrees of angular displacement
  - Fracture comminution
  - Radiolunate angle of more than 15 degrees
  - Scapholunate angle of more than 60 degrees
  - Intrascaphoid angle of more than 35 degrees
  - CT with reconstruction images in multiple planes is used to identify an acute fracture not detected on plain radiographs (FIG 1B,C).
  - CT is most useful in evaluating an established scaphoid nonunion or malunion.⁶
- Since plain radiographs are often unreliable, CT is preferred for confirming union after a scaphoid fracture.
- MRI may be indicated in the evaluation of a suspected scaphoid fracture not detected on plain radiographs (FIG 1D,E). MRI is highly sensitive, with a specificity approaching 100% when performed within 48 hours of injury.¹³
  - MRI with gadolinium contrast is helpful in assessing the vascularity of the proximal pole, particularly in the patient with an established nonunion.
  - A technetium bone scan has been shown to be up to 100% sensitive in identifying an occult fracture.²⁰ Unfortunately, it is also associated with a low specificity and often will not be positive immediately after the fracture.

DIFFERENTIAL DIAGNOSIS
- Scapholunate injury
- Wrist sprain
- Wrist contusion
- Fracture of other carpal bone
- Greater arc injury
- Distal radius fracture

NONOPERATIVE MANAGEMENT
- Nonoperative management is indicated for a nondisplaced, stable scaphoid waist or distal pole fracture. Unstable fractures and nondisplaced fractures of the proximal pole are indications for internal fixation based on studies that have demonstrated a poor outcome with nonoperative treatment.²,⁴,¹⁴
- The appropriate type and duration of cast immobilization remain controversial. We recommend a long-arm thumb spica cast for the first 6 weeks, followed by a short-arm thumb spica cast.
cast until the clinical examination and radiologic studies (usually a CT scan) confirm fracture union.
- Clinical studies have failed to demonstrate any benefit from including the thumb or fingers in the cast.\(^2,4\)
- Similarly, wrist position has not been proven to improve scaphoid fracture healing.
- Numerous studies have revealed no difference in union rates for a long-arm versus short-arm cast; however, a randomized prospective study by Gellman et al.\(^10\) documented a shorter time to union and fewer nonunions and delayed unions with initial use of a long-arm cast.
- The morbidity of a nonoperative approach, specifically cast immobilization, has become of increasing concern. A prolonged duration of immobilization is often required for waist fractures, and this can be accompanied by muscle atrophy, stiffness, reduced grip strength, and residual pain. In addition, cast immobilization can cause significant inconvenience for the patient and interfere with activities of daily living. The prolonged duration of immobilization is of particular concern in the young laborer, athlete, or military personnel, who typically desire expedient functional recovery.\(^5,16,21\)
- If the clinical history and physical examination are suggestive of a scaphoid fracture but initial radiographs are negative, the wrist should be immobilized for 2 weeks. Repeat radiographs are then obtained. If a fracture is present, resorption of the fracture may be noted. If wrist pain and “snuffbox” tenderness persist but radiographs are negative, a bone scan may be obtained. A negative scan excludes the presence of a scaphoid fracture. A positive scan may indicate an occult fracture or ligamentous injury. CT or MRI is usually indicated for further evaluation.\(^13,20\)
- If it is determined that a scaphoid fracture is present, ORIF of the scaphoid fracture is recommended. Clinical studies have revealed no difference in union rates for a long-arm versus short-arm cast; however, a randomized prospective study by Gellman et al.\(^10\) documented a shorter time to union and fewer nonunions and delayed unions with initial use of a long-arm cast.

**SURGICAL MANAGEMENT**

- Indications for open reduction and internal fixation (ORIF) of scaphoid fractures include\(^2,14\):
  - Any proximal pole fracture
  - A displaced, unstable fracture of the scaphoid waist
  - Associated carpal instability or perilunar instability

- Associated distal radius fracture
- Delayed presentation (more than 3 to 4 weeks) with no prior treatment
- A nondisplaced, stable scaphoid waist fracture (Herbert A2 type) in a patient who wishes to avoid the morbidity of cast immobilization. In this clinical scenario, operative treatment should occur only after an explanation of the rationale for, and the risks and benefits of, operative treatment versus cast immobilization.

**Preoperative Planning**

- All imaging studies should be reviewed to accurately define the fracture pattern.
- Required equipment:
  - Portable mini-fluoroscopy unit
  - Kirschner wires
  - Cannulated headless compression screw system. We prefer to use the Accutrak or mini-Acutrak screw system (Accumed, Beaverton, OR), but any cannulated screw system that permits screw insertion beneath the articular surface may be used.

**Positioning**

- General or regional anesthesia may be used.
- The patient is positioned supine on the operating table with a radiolucent hand table at the shoulder level.
- The fluoroscopy unit is draped and positioned at the end of the hand table.
- A pneumatic tourniquet is carefully applied to the proximal arm.
- An intravenous antibiotic is provided before inflation of the tourniquet as prophylaxis for infection.
- The limb is prepared and draped, followed by exsanguination of the limb with an Esmarch bandage and tourniquet inflation, usually to a pressure of 250 mm Hg.

**Approach**

- ORIF of scaphoid fractures can be performed through either a dorsal or volar approach.
- The specific approaches that will be described include:
  - Open dorsal approach\(^16\)
  - Open volar approach

**TECHNIQUES**

**OPEN DORSAL APPROACH (AUTHORS’ PREFERRED APPROACH)**

**Exposure**

- If the fragments are displaced, requiring reduction, pronate the forearm and make a longitudinal skin incision, about 3 to 4 cm long, beginning at the proximal aspect of the tubercle of Lister and extending distally along the axis of the third metacarpal (TECH FIG 1A).
  - If the fracture is nondisplaced, a smaller skin incision and capsulotomy may be used.
  - Raise skin flaps at the level of the extensor retinaculum.
  - Incise the extensor retinaculum overlying the third compartment immediately distal to the tubercle of Lister and carefully release the fascia overlying the extensor pollicis longus (EPL) tendon, permitting gentle retraction of the EPL radially. Similarly incise the dorsal hand fascia longitudinally.
  - Gently retract the extensor digitorum communis (EDC) tendons ulnarly while retracting the extensor carpi radialis brevis (ECRB) and longus (ECRL) tendons radially with the EPL, thus exposing the underlying radiocarpal joint capsule (TECH FIG 1B).
  - Make a limited inverted T-shaped capsulotomy with the transverse limb placed just distal to the dorsal rim of the radius and the longitudinal limb directly over the scapholunate articulation (TECH FIG 1C).
  - The tubercle of Lister is helpful in locating the articulation.
Carefully elevate the capsular flaps from the dorsal lunate, the dorsal component of the scapholunate ligament, and the proximal pole of the scaphoid.
- Evacuate fracture hematoma.
- It is often helpful to extend the longitudinal limb of the capsulotomy to expose the scaphocapitate articulation and the radial aspect of the midcarpal joint.
- Especially when elevating the radial flap, take care to avoid stripping the dorsal ridge vessels entering at the scaphoid waist region.

Fracture Reduction and Provisional Fixation
- Distract the carpus manually via longitudinal traction on the index and long fingers.
- If the fracture is displaced, insert 0.045-inch Kirschner wire joysticks perpendicularly into the proximal and distal scaphoid fragments to assist in the reduction (TECH FIG 2A).
- The accuracy of the reduction can be determined by assessing congruency of the radioscaphoid and scaphocapitate articulations.
- When a satisfactory reduction has been achieved, obtain provisional fixation with derotational 0.045-inch Kirschner wires.
  - The first wire is inserted dorsal and ulnar to the central axis of the scaphoid, into the trapezium for enhanced stability.
  - The second derotational wire may be inserted volar and radial to the anticipated central axis insertion site if more fixation is needed.
  - The derotational wires must be placed such that they will not interfere with central axis guidewire placement, reaming, and screw insertion (TECH FIG 2B).

Guidewire Placement
- The starting position for guidewire is at the membranous portion of the scapholunate ligament origin (TECH FIG 3A,B).
- In very proximal fractures, the starting point for the guidewire is as far proximally in the scaphoid as possible, at the mid-aspect of the membranous portion of the scapholunate ligament complex. This point is critical to avoid propagation of the fracture into the proximal scaphoid during insertion of the screw.
With the wrist flexed over a bolster, insert the guidewire down the central axis of the scaphoid in line with the thumb metacarpal.

- Be very patient with this important step; proceed with reaming and screw insertion only after central placement has been confirmed on the PA, lateral, and 30-degree pronated lateral views (TECH FIG 3C).
- It is critical to insert the wire in the optimal position in all three views to avoid violating the midcarpal joint or the volar surface of the scaphoid.
- Take care to avoid bending the guidewire.
- Advance the wire up to but not into the scaphotrapezial joint.

**Screw Insertion**

- Determine screw length by measuring the guidewire (TECH FIG 4A).
- In the case of minimal fragment separation, subtract 4 mm from the measured length of the wire to allow recession of the proximal screw beneath the articular surface.
- If fragments are more displaced, consider compression and choose an even shorter screw.
- Advance the wire into the trapezium to avoid loss of position during drilling.
Use the cannulated drill (TECH FIG 4B), tap the bone if necessary, and manually insert the screw (TECH FIG 4C,D).

We use the larger Acutrak screw when feasible, but the mini-Acutrak system may be necessary in patients with a small scaphoid or if the fracture is located proximally such that insertion of an Acutrak screw may result in inadvertent propagation of the fracture to the insertion site with fragmentation of the proximal scaphoid.

Remove the guidewire and assess screw position via fluoroscopy using the same views.

**OPEN VOLAR APPROACH**

**Exposure**

- Radially deviate the wrist and palpate the scaphoid tubercle.
- Make a 3- to 4-cm incision centered over the scaphoid tubercle, directed distally toward the base of the thumb and proximally over the flexor carpi radialis (FCR) tendon sheath. If the superficial volar branch of the radial artery is encountered, cauterize it at the level of the wrist flexion crease.
- Open the FCR sheath and retract the tendon ulnarily. Open the floor of the sheath distally to expose the underlying volar wrist capsule.
- Distally, develop the interval by splitting the origin of the thenar muscles in line with their fibers over the distal scaphoid and trapezium.
- Incise the capsule longitudinally, taking care to avoid damage to the underlying articular cartilage.
- Proximally, divide the thickened radiolunate and radioscpahocapitate ligaments to allow exposure of the proximal scaphoid pole.
- Identify the scaphotrapezial joint with a Freer elevator and bluntly expose it.
- Dissection over the radial aspect of the scaphoid is limited to avoid injury to the dorsal ridge vessel.
- Define and clear the fracture site by irrigation, sharp excision of periosteal flaps, and curetting of debris and hematoma.
- Assess the instability of the fracture by wrist manipulation.
- It is critical to identify any bone loss, as compression during screw placement can result in an iatrogenic malunion.

**Fracture Reduction and Fixation**

- Obtain correct fracture alignment through longitudinal traction followed by wrist manipulation.
- An anatomic reduction may also be achieved by direct manipulation of the fragments with a dental pick, pointed reduction forceps, or joystick Kirschner wires.
- Place a provisional 0.045-inch Kirschner wire to secure the reduction. Insert the wire in a retrograde manner from volar distal to dorsal proximal, gaining fixation in the proximal pole.
- It is critical to place this wire such that it does not interfere with central axis screw placement.
- The central axis guidewire is placed, taking into consideration all the factors detailed above.
- To gain the needed dorsal starting position in the distal scaphoid pole, displace the trapezium dorsally with an elevator or resect a small portion of the proximal volar trapezium with a rongeur (TECH FIG 5).

The cannulated compression screw may be inserted using a freehand technique or a commercial device, which may facilitate simultaneous fracture reduction and guidewire positioning.

- Fluoroscopy is invaluable during wire and screw insertion and to confirm accurate placement and fracture reduction as described above.
- Precisely repair the volar wrist capsule and radiolunate and radioscpahocapitate ligaments with permanent suture.

**PEARLS AND PITFALLS**

POSTOPERATIVE CARE

- The patient is immobilized in a below-elbow volar thumb spica splint and discharged to home with instructions on strict limb elevation and frequent digital range-of-motion exercises.
- At 2 weeks, the patient returns for suture removal. Range-of-motion exercises are begun and a removable forearm-based thumb spica splint is worn. The splint is discontinued at 4 to 6 weeks postoperatively.
- If the fracture involves the proximal pole or if significant comminution was noted at surgery and there is concern regarding stability of the fixation, immobilization in a short-arm cast for 6 to 10 weeks is indicated. Typically, such fractures take longer to achieve union.
- After cast removal, a formal supervised therapy program is initiated to achieve satisfactory range of motion, strength, and function.
- Fracture healing is assessed at 2, 6, and 12 weeks postoperatively with plain radiography. Fracture union is defined as progressive obliteration of the fracture and clear trabeculation across the fracture site. (FIG 2).
- If there is any question regarding fracture union, a CT scan is obtained at 3 months postoperatively or before the patient is allowed to return to unrestricted sporting activities.

OUTCOMES

- Surgical fixation of unstable, displaced scaphoid fractures has been increasingly advocated, given the unsatisfactory outcomes that have been reported with nonoperative management.²,⁴,¹⁴
- Rigid internal fixation allows for early physiotherapy throughout the healing phase, a more rapid time to union, improved range of motion, and rapid functional recovery.⁵,¹⁰,¹⁶,²¹ Several studies have reported a high rate of union and excellent clinical outcome with minimal morbidity using both limited open and percutaneous techniques.¹,³,⁵,¹⁰,¹⁹,¹⁹,²¹
- Clinical and biomechanical studies have also recently documented the importance of screw position after fixation of scaphoid fractures.⁷,¹⁸ Central placement of the screw is biomechanically advantageous, with greater stiffness and load to failure. Trumble et al¹⁸ demonstrated more rapid progression to union with central screw position in cases of scaphoid nonunion.
- A volar approach has traditionally been used for screw insertion. However, recent studies have raised potential concerns regarding eccentric screw placement and damage to the scaphotrapezial articulation with this approach.²¹
- Our preferred technique for fixation of a scaphoid proximal pole or waist region fracture involves a limited dorsal approach with compression screw fixation.¹⁶ The technique is simple and permits visualization of a reliable starting point for screw placement within the central axis of the scaphoid, offering a significant potential advantage over the volar approach. We recently reported our clinical experience in a consecutive series of nondisplaced scaphoid waist fractures.³

COMPLICATIONS

- Postoperative wound infections are rare and can be prevented with routine preoperative antibiotic prophylaxis, thorough wound irrigation, and appropriate soft tissue management.
- Intraoperative technical problems
  - Inadvertent bending or breakage of the guidewire can occur if the wrist is dorsiflexed with the wire in position or during drilling before screw insertion.
  - Care should be taken to confirm that the screw is fully seated beneath the articular cartilage to avoid prominence and erosion of the distal radius articular surface. Similarly, failure to carefully judge accurate screw length intraoperatively can result in prominence and erosion of the scaphotrapezial articulation.
  - Nonunion with or without AVN can occur despite compression screw fixation, particularly with a proximal pole or displaced waist fracture. Stripping of the dorsal ridge vasculature should be avoided. Supplemental cancellous bone graft from the distal radius may be used at the time of fixation if desired.
- Other potential but rare complications
  - Hypertrophic scar
  - Injury to the dorsal branches of the superficial radial nerve
  - Damage to the scaphotrapezial articulation
  - Proximal pole fragment comminution

FIG 2 • A healed scaphoid waist fracture after ORIF via the dorsal approach. Although the screw may appear slightly long, both the proximal scaphoid and distal scaphoid are covered with hyaline cartilage not detected on diagnostic imaging. (Property of Peter J.L. Jebson, MD.)
REFERENCES

DEFINITION
- Scaphoid nonunion describes a wide spectrum of conditions.
- The classification system shown in Table 1 describes them in the context of treatment options.

ANATOMY
- The scaphoid is almost entirely covered with cartilage and provides the mechanical link between proximal and distal carpal rows.
- Blood supply is from volar and dorsal, entering distally. The volar artery supplies only the distal tubercle region. The proximal pole is primarily dependent on intraosseous blood supply, similar to the head of the proximal femur.

PATHOGENESIS
- Mechanical instability and decreased perfusion are the most common causes of scaphoid nonunion.
- These factors work to exacerbate each other. Micromotion disrupts vascular perforators (often the only blood supply), leading to bone resorption and further decrease in mechanical stability.
- Proximal pole fractures are particularly at risk for nonunion for both mechanical (long distal lever arm and a small proximal contact area) and vascular reasons.
- Infection is rarely a cause of scaphoid nonunion but should not be forgotten in the workup and treatment.

NATURAL HISTORY
- Although progression is variable, patients often develop a dorsal intercalated segment instability (DISI) deformity (as described for scapholunate ligament injuries) and advance through stages of degeneration (scaphoid nonunion advanced collapse [SNAC] wrist arthritis) over decades.
- SNAC wrist stage I: affects only radial styloid; stage II: arthritis at radioscapoid joint; stage III: involvement of the scaphocapitate and capitolunate joints; stage IV: pancarpal arthritis with preservation of the radiolunate joint

PATIENT HISTORY AND PHYSICAL FINDINGS
- In established nonunions, patients present with wrist pain and in many cases are unaware of their original injury many years before.
- Findings on examination typically include radial-sided wrist tenderness on palpation and decreased range of motion, particularly extension (secondary to the DISI deformity of the carpus).
- Other than information regarding previous operative and nonoperative treatments, the additional information for evaluation and treatment decisions comes more from imaging.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- CT scan with 1-mm slices in the plane of the scaphoid can help delineate bony anatomy in established nonunions and can determine if there is any evidence of healing in early nonunions.
- MR with intravenous contrast will help determine proximal pole vascularity.
- The time and equipment required for vascularized bone grafting are more substantial than those needed for simple open reduction and internal fixation (ORIF) of the scaphoid with nonvascularized bone graft.

DIFFERENTIAL DIAGNOSIS
- Bone cyst
- Infection
- Acute fracture
- Pressier disease (scaphoid avascular necrosis [AVN])

NONOPERATIVE MANAGEMENT
- If a nonunion has not previously been given a trial of conservative care and if there is no significant resorption, casting and a bone stimulator could be attempted prior to surgical fixation.

SURGICAL MANAGEMENT
- Surgical treatment must solve three obstacles:
  - Re-establishment of local perfusion
  - Replacement of necrotic tissue with an osteoconductive and osteoinductive matrix
  - Stable fixation
- Not all proximal pole nonunions with AVN require a vascularized graft.
- If the distal scaphoid is well perfused and good fixation can be achieved, healing can proceed via creeping substitution.
- Guidewire placement and reaming for screw fixation helps re-establish vascular channels.
- Palmar flexion of the distal fragment and DISI position of the carpus must be corrected at the time of surgery.
- The surgical technique described in this chapter is appropriate to repair grade I to III scaphoid nonunions.
- If a grade IV nonunion lacks significant flexion deformity and has an intact fibrous shell to contain bone graft, one may consider treatment of these fractures using the minimally invasive method reviewed in this chapter.
- Grade V and VI nonunions are characterized by substantial bone loss, synovial nonunion, and significant flexion deformity. They are therefore not suitable for percutaneous treatment.

Preoperative Planning
- Advanced degenerative changes secondary to scaphoid nonunion are a relative contraindication to repair of a nonunion.

</table>

- Advanced imaging, as discussed earlier, is crucial for appropriate preoperative planning.

**Positioning**
- The patient is placed supine.
- Traction for arthroscopy can be performed with either a traction tower or a simple horizontal pulley traction system.

**Approach**
- A dorsal approach is used for proximal pole fractures to provide the most secure fixation (as a basic principle, think of securing the island to the mainland).
- Waist fractures can be treated either dorsally or volarly.
  - The dorsal approach is preferred.
- Nonunion of a distal pole scaphoid fracture, although rare, is best approached volarly.

### PLACEMENT OF THE TARGETING GUIDEWIRES

- A fluoroscopic survey is undertaken to evaluate the fracture, scaphoid alignment, and fragment mobility.
  - Other occult carpal fractures are sought.
  - The wrist is ulnarly deviated to extend the distal fragment.
  - A smooth 0.062-inch dorsal-to-volar targeting Kirschner wire is placed in the distal fragment in the center position.
  - A smooth 0.062-inch lateral targeting wire is placed in the center of the distal fragment from radial to ulnar.
  - These Kirschner wires form a “crosshair” target to guide placement of the central axis guidewire (TECH FIG 1).

**PLACEMENT OF THE DISTAL CENTRAL AXIS DEROTATION WIRE**

- Placement of the first central axis wire in the distal fragment is undertaken.
  - Place a 19-gauge needle into the fracture site and confirm position fluoroscopically.
  - Use the position of the needle to introduce a double-cut 0.045-inch Kirschner wire into the fracture site and down the medullary canal of the distal fragment, using the distal crossed targeting Kirschner wires as guides.
  - Exit at the base of the thumb in an area devoid of neurovascular structures and withdraw it until the proximal tip is at the fracture site.
  - This first Kirschner wire will be used only to maintain a reduction and serve as a derotation wire, so perfect central axis placement is not necessary.
FRACTURE REDUCTION

- From dorsal to volar drive a 0.062-inch Kirschner wire into the proximal fragment to serve as the proximal joystick.
- Flex the distal dorsal-to-volar targeting Kirschner wire toward the proximal fragment joystick wire to correct the flexion deformity of the distal fragment (TECH FIG 2A,B).
- Sometimes a percutaneous snap may need to be introduced for additional leverage or to correct translational deformities.
- Confirm fragment position fluoroscopically while holding the reduction.
- Drive the distal fragment wire that is at the base of the thumb retrograde into the proximal fragment to secure the reduction (TECH FIG 2C).
- Again, perfect placement in the proximal pole is not necessary, as this wire is used only temporarily.

PLACEMENT OF THE PROXIMAL CENTRAL AXIS GUIDEWIRE

- With the wrist partially flexed and under fluoroscopy, impale a 19-gauge needle into the proximal ulnar corner of the proximal pole (TECH FIG 3A,B).
- Drive a 0.045-inch Kirschner wire toward the thumb base, correcting its direction based on the external crossed-wire targeting guide.
- A successfully placed central axis scaphoid wire will hit the crossing wires in the distal scaphoid.
- The guidewire is driven volarly past this intersection, through the trapezium, and exits at the thumb base in a zone devoid of neurovascular structures.
The guidewire is withdrawn until the trailing edge crosses the radiocarpal joint and the wrist can be safely extended without bending the wire. There are now two intramedullary Kirschner wires down the length of the scaphoid, one used to capture the initial reduction and the other placed down the long axis to be used as a guide for eventual screw insertion (TECH FIG 3C). The use of two Kirschner wires limits bending forces and acts as an antirotation construct during scaphoid reaming and screw placement.

**ARTHROSCOPIC EVALUATION AND REAMING**

- The arm is exsanguinated and the extremity is placed in a traction tower with 12 pounds distributed between four finger traps.
- Fluoroscopy can be used with 19-gauge needles to identify the radiocarpal and midcarpal portals. This maneuver limits iatrogenic injury to the joint, which can result from multiple attempts to introduce a blunt trocar blindly.
- A small hemostat is used to separate the soft tissue and enter the wrist joint. A blunt trocar is placed at the radial midcarpal portal and a small joint angled arthroscope is introduced.
- Additional 19-gauge needles are inserted to establish outflow.
- A probe is introduced at the ulnar midcarpal portal, and the competency of the carpal ligaments is evaluated by directly stressing their attachments to detect partial and complete tears.
- Any scapholunate interosseous ligament (SLIL) injury detected is graded using the Geissler grading system. Grade I and II ligament injuries are treated with débridement and shrinkage alone. Grade III injuries are treated with débridement and, after fracture repair, carpal pinning for 6 weeks. Grade IV instability requires open repair of the dorsal SLIL ligament with or without capsulodesis.
- Tears of the triangular fibrocartilage complex are classified using the Palmer classification and are treated based on established guidelines.
- Fracture reduction is thoroughly evaluated arthroscopically.
- It is important to determine the presence of a fibrous capsule around the nonunion site. If there is no fibrous capsule, percutaneous bone graft is contraindicated as it will dissipate into the surrounding synovial fluid.
- If vascularity of the proximal fragment is in question, flex the wrist in the traction tower.
- Drive the central axis guidewire retrograde through the proximal fragment, ream over the wire to the level of the nonunion site.
- Withdraw the central axis wire to the fracture site (while keeping the derotation Kirschner wire in place to maintain reduction) and introduce the scope into the proximal fragment through the previously reamed tract.
- Stop the inflow and let down the tourniquet. Inspect the cancellous bone of the proximal pole with the scope for the appearance of punctate bleeding (TECH FIG 4).
- Keep the wrist in a flexed position and retrograde the central axis wire so it is equally exposed dorsally and volarly.
- Hand ream, under fluoroscopy, to within 2 mm of the distal cortex. Then withdraw the central axis wire volarly back to the level of the fracture site.

**TECH FIG 4** - Inspect the cancellous bone of the proximal pole with the scope for the appearance of punctate bleeding. A. Devascularized proximal pole with no punctate bleeding. B. Vascularized proximal pole.

**DÉBRIDEMENT OF THE NONUNION SITE AND BONE GRAFTING**

- A grade I scaphoid nonunion (delayed presentation) typically does not require débridement or bone grafting.
- For grade II or III nonunions, insert a small curved curette through the path that was just reamed and débride the nonunion site (TECH FIG 5A).
- Avoid disrupting the peripheral fibrous shell so there is a contained cavity within which to pack bone graft.
- Using an 8-gauge bone biopsy needle, harvest cores of cancellous bone from either the distal radius or iliac crest. Introduce the bone biopsy cannula into the reamed proximal pole tract.
- Pack plugs of bone graft through the cannula into the nonunion site until the radiolucent image of the nonunion site becomes radiopaque (TECH FIG 5B).
The wrist is flexed and the central axis scaphoid guidewire at the base of the thumb is driven dorsally.

- The wire is adjusted until the trailing end is in the subchondral bone of the distal scaphoid pole.

- A second wire of equal length is placed percutaneously against the proximal scaphoid pole, next to and parallel with the guidewire.

- The difference in length between the trailing end of each wire represents the scaphoid length. The screw length selected should be 4 mm less than the scaphoid length.

- This permits 2 mm of clearance of the screw at each end of the scaphoid, thus ensuring complete implantation without screw prominence.

- The most common reported complication of percutaneous screw stabilization for scaphoid fractures is implantation of a screw that is too long.1

- Advance the central axis wire so it is exposed equally volar and dorsal.

- Re-ream the entire path of the screw to within 2 mm of the opposite cortex. This creates a path through the bone graft for the screw and prevents exploding the graft through the cortical shell with a blunt screw.

- The scaphoid should never be reamed to the opposite bone cortex (overdrilling). This reduces fracture compression and increases the risk of motion at the fracture site.

- Place the headless cannulated screw. If the screw is advanced to the distal cortex, attempts to advance the screw further will force the fracture fragments to gap and separate.

- A standard-size Acutrak screw will best resist flexion moments.4

- In unstable nonunions, as the screw is advanced it is advisable to use the joysticks to maintain a counterforce compression at the fracture site.

- If screw fixation provides only modest stability, additional fixation is advantageous.

- In proximal pole nonunions the bending forces of the long lever arm of the distal scaphoid can be neutralized with a Kirschner wire or screw from the distal scaphoid into the capitate (TECH FIG 6A).

- Micromotion can be decreased with a Kirschner wire down the second or third web space locking the capitolunate articulation.

- With the wrist partially flexed the radiolunate joint can be secured with a Kirschner wire, preventing the tendency of DISI position (TECH FIG 6B).
**PEARLS AND PITFALLS**

<td>Decrease micromotion</td>
<td>Add supplemental fixation as needed between the scaphocapitate, capitolunate, or radiolunate articulations.</td>
</tr>
</tbody>
</table>

**POSTOPERATIVE CARE**

- A short-arm volar splint and bulky dressing are applied in the operating room and the patient returns in 1 week for suture removal.
- If fixation is secure (as in a waist nonunion), then additional immobilization is not necessary.
- Proximal pole nonunions, especially those with AVN, or other unstable patterns are protected with a short-arm cast until bridging bone is visible on CT scan.
- Early finger motion and gentle hand strengthening are encouraged to reduce swelling and promote axial loading, encouraging fracture healing.
- Serial CT scans can be performed every 6 weeks to assess healing.
- Plain radiographs are not reliable for assessing healing.
- Clinical symptoms are also not a reliable indicator of healing. Rigid fixation alone may provide a painless wrist after surgery before actual bridging bone has occurred.
- Contact sports and heavy labor are restricted until healing is confirmed on CT.

**OUTCOMES**

- Many grade I to IV nonunions have been successfully treated with this technique (data not yet published).
- As more case series are reported, we will be better able to define the functional outcomes, indications, contraindications, and rate of union of percutaneous treatment of these injuries.

**COMPLICATIONS**

- Complications are often related to screw placement.
- Screws placed outside the central axis have less stable fixation and therefore an increased risk of nonunion.
- A screw that is too long risks wear of the radioscaphoid joint.
- Infection and scar tenderness are reported complications but are uncommon.

**REFERENCES**

DEFINITION

- The scaphoid is the most commonly fractured carpal bone in the wrist. Scaphoid fractures that fail to heal after 6 months of treatment are categorized as nonunions and represent about 5% to 10% of all scaphoid fractures.
- Untreated nonunions have been reported to lead to progressive arthrosis and wrist pain.6
- Volar wedge bone grafting is an effective surgical technique in the treatment of certain scaphoid nonunions based on:
  - Location of the fracture
  - Degree of the deformity
  - Vascularity of the scaphoid
- This general technique can also be adapted to increase its versatility.

ANATOMY

- Nearly 80% of the scaphoid’s surface is covered by articular cartilage.6
- Through ligamentous connections, the scaphoid serves as the bridge or link between the proximal and distal rows. Due to these strong tethers proximally and distally, it is highly susceptible to an acute fracture after a fall on an outstretched hand (FIG 1).18
- Other key factors that influence scaphoid fracture healing are its tenuous vascular supply and its unique bony architecture.
  - The vulnerable vascularity of the scaphoid, especially the proximal pole, is well described in the literature.8,14,15,16,20
  - This is due to the fact that the scaphoid has a retrograde blood supply, with 70% of the vascular supply through the dorsal ridge vessel and 30% provided through branches to the scaphoid tubercle (at the level of the radiocarpal joint via superficial palmar branch perforators off the radial artery).
  - The complex geometry of the bone makes it difficult to anatomically reduce the bone fragments.

PATHOGENESIS

- Although there may be a variety of reasons for the development of a scaphoid nonunion, a fractured scaphoid usually fails to heal for three primary reasons:
  - The fracture is either undetected or untreated within the first 4 weeks after the injury.
  - The location of the fracture is proximal, resulting in poor vascularity of the most proximal fragment.
  - The fracture is displaced more than 1 mm.

NATURAL HISTORY

- Scaphoid nonunion advanced collapse (SNAC), described in the literature, is a predictable sequence of changes that occurs as a result of scaphoid nonunion leading to wrist arthrosis, often associated with pain and limitation of motion.1,5
- In studying patients with painful wrists over a 15-year period to determine who will develop symptoms, it is evident that the incidence of symptomatic wrist pathology requiring reconstruction is significantly higher for scaphoid nonunions that have gone untreated.1
- Techniques used to detect an acute scaphoid fracture and its susceptibility to nonunion, wrist pain, and corresponding arthrosis have been discussed in great detail in the literature.14,15,20

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient who presents with a scaphoid nonunion is usually a man between the ages of 18 and 25.
- Unrecognized injuries in adolescence may present with pain related to early SNAC wrist arthrosis in the middle-aged adult.
- Patients generally complain of wrist pain that limits range of motion or hinders activities such as pushups, weightlifting, and opening a door. Moderate to heavy pinch and grip pain have also been described.
- A specific event resulting in the original scaphoid fracture years before is rarely cited by the patient on presentation.
- Consistent physical examination findings include subtle tenderness in the region of the scaphoid tubercle or the anatomic snuffbox, limited wrist extension compared to the contralateral side, and localized pain on the radial side along the radiolunate or scaphoid with loaded wrist extension.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard radiographs include posteroanterior (PA), lateral, and scaphoid oblique 45- and 60-degree pronated views (FIG 2). Such views:
  - Confirm the diagnosis
  - Provide information regarding displacement, angulation, shortening, and the presence of a “humpback deformity”
Nonoperative management may be appropriate for minimally symptomatic scaphoid nonunions. All factors should be taken into consideration when determining the most appropriate treatment: scaphoid nonunion alone is not an absolute reason for surgery.12

**SURGICAL MANAGEMENT**

Volar wedge bone grafting is the preferred surgical technique for treatment of a scaphoid nonunion without osteonecrosis but with shortening, an increased intrascaphoid angle causing a “humpback deformity,” and concomitant carpal collapse. Although many scaphoid nonunions without deformity can be effectively treated with the described procedure, other approaches and grafting techniques that are less invasive may be an option, especially for proximal pole nonunions.2

Determining which bone graft is necessary depends on how much shortening is anticipated.3

- The benefits of distal radius bone grafting include its location within the same surgical site and the fact that it is not limited in size and can be harvested as a vascularized or nonvascularized graft. One important disadvantage is the creation of a relatively large defect and stress riser within the distal radius. Also, the surgical incision is more extensile and it is not possible to get a bicortical or tricortical piece of bone for a more structural bone graft.

- Iliac crest bone graft may be harvested in large quantities and as a bicortical or tricortical piece of bone. It is relatively simple to procure and has a long history of success in such cases, a standard by which all others are currently measured. The disadvantages of this type of bone graft include a separate incision with associated morbidity, as well as a reported risk of cutaneous nerve injuries. Also, it cannot be converted to a vascularized pedicle bone graft.

- When an MRI reveals the presence of osteonecrosis, a vascularized procedure should be considered (see Chap. HA-20).14,15,20

**Preoperative Planning**

After assessing all diagnostic studies, including plain films, MRI and CT scans, the type of bone graft is determined.

- Two types of fixation screws can be used.
  - One type of screw has a smooth shank and two threaded heads. This screw is strong and creates high compression but may not be appropriate for all nonunions. The scaphoid nonunion fragments must be large enough to ensure that no threads of the screw cross into the bone graft site.
  - The other type of compression screw uses a deferential pitch between the proximal and distal portion of the screw. This screw may be more versatile, although it lacks compression strength compared to the above-mentioned screw.

- If compression screws are not deemed appropriate for the type of nonunion that exists, multiple Kirschner wires can be used.

- A regional anesthetic block is used for most patients and is helpful for alleviating postoperative pain. When iliac crest grafting is chosen, additional general anesthesia is needed.

- All radiographic studies are reviewed and brought to the operating room for re-evaluation during the case.

**DIFFERENTIAL DIAGNOSIS**

- De Quervain’s tendinitis
- Scaphotrapeziotrapezoidal arthritis
- Scaphoid lunate instability, static and dynamic
- Radial styloid fracture
- Trapezial ridge fracture

**NONOPERATIVE MANAGEMENT**

Surgery is generally indicated for established scaphoid nonunions that are displaced and symptomatic because of the strong likelihood that radiocarpal arthrosis may develop with this type of persistent nonunion.18,20

- Nonoperative management may be appropriate for minimally symptomatic scaphoid nonunions. All factors should be taken into consideration when determining the most appropriate treatment: scaphoid nonunion alone is not an absolute reason for surgery.12

**SURGICAL MANAGEMENT**

Volar wedge bone grafting is the preferred surgical technique for treatment of a scaphoid nonunion without osteonecrosis but with shortening, an increased intrascaphoid angle causing a “humpback deformity,” and concomitant carpal collapse. Although many scaphoid nonunions without deformity can be effectively treated with the described procedure, other approaches and grafting techniques that are less invasive may be an option, especially for proximal pole nonunions.2

Determining which bone graft is necessary depends on how much shortening is anticipated.3

- The benefits of distal radius bone grafting include its location within the same surgical site and the fact that it is not limited in size and can be harvested as a vascularized or nonvascularized graft. One important disadvantage is the creation of a relatively large defect and stress riser within the distal radius. Also, the surgical incision is more extensile and it is not possible to get a bicortical or tricortical piece of bone for a more structural bone graft.

- Iliac crest bone graft may be harvested in large quantities and as a bicortical or tricortical piece of bone. It is relatively simple to procure and has a long history of success in such cases, a standard by which all others are currently measured. The disadvantages of this type of bone graft include a separate incision with associated morbidity, as well as a reported risk of cutaneous nerve injuries. Also, it cannot be converted to a vascularized pedicle bone graft.

- When an MRI reveals the presence of osteonecrosis, a vascularized procedure should be considered (see Chap. HA-20).14,15,20

**Preoperative Planning**

After assessing all diagnostic studies, including plain films, MRI and CT scans, the type of bone graft is determined.

- Two types of fixation screws can be used.
  - One type of screw has a smooth shank and two threaded heads. This screw is strong and creates high compression but may not be appropriate for all nonunions. The scaphoid nonunion fragments must be large enough to ensure that no threads of the screw cross into the bone graft site.
  - The other type of compression screw uses a deferential pitch between the proximal and distal portion of the screw. This screw may be more versatile, although it lacks compression strength compared to the above-mentioned screw.

- If compression screws are not deemed appropriate for the type of nonunion that exists, multiple Kirschner wires can be used.

- A regional anesthetic block is used for most patients and is helpful for alleviating postoperative pain. When iliac crest grafting is chosen, additional general anesthesia is needed.

- All radiographic studies are reviewed and brought to the operating room for re-evaluation during the case.
Positioning
- The patient is placed in the supine position with the upper extremity positioned on a hand table.
- If an ipsilateral iliac crest bone graft is used, the hip on the same side as the affected hand is prepared and draped. A small bump is placed under the hip for patients with significant adipose tissue.
- A tourniquet is applied to the proximal arm.

Approach
- The location of the scaphoid nonunion helps determine the surgical approach. Wedge bone grafting of a waist nonunion is performed using a standard volar approach.
- For proximal pole fractures with evidence of osteonecrosis, a dorsal approach with possibly a vascularized bone graft would be a more amenable surgical approach.13,19

VOLAR WEDGE BONE GRAFTING USING DISTAL RADIUS BONE GRAFT AND INTRAOSSEOUS COMPRESSION SCREW FIXATION

Incision and Initial Dissection
- An incision is drawn over the flexor carpi radialis (FCR) tendon and extended distally between the glabrous skin of the thenar eminence, angled across the wrist flexion crease (TECH FIG 1A).
- After exsanguination the skin is incised and the FCR tendon is identified. Distally in the wound a volar branch of the radial artery is often sacrificed to gain exposure (TECH FIG 1B).
- The floor of the FCR tendon is sharply incised over the entire course of the incision and the digital flexors and median nerve are swept ulnarly. They are carefully protected throughout the case. A blunt Wheatlander is used to maintain visualization of this interval between the radial artery and the FCR tendon.
- The volar extrinsic ligaments, the radioscaphocapitate (RSC) and long radiolunate (LRL), are identified and precisely incised. Much of the LRL and a portion of the RSC are left intact, helping to stabilize the proximal pole (TECH FIG 1C).
- This stability facilitates the reduction of the distal fragment to the proximal fragment.
- Preserving this ligamentous support also helps maintain fracture reduction during the placement of an intraosseous compression screw by counteracting the torque created during screw insertion.
- Deep dissection proceeds to the scaphotrapezial joint. This interval is exposed using a transverse capsular incision for later insertion of the intraosseous screw.
- The articulation between the scaphoid and capitate is carefully exposed. This visualization will be important during reduction of the scaphoid fragments.
- During exposure it is critical to avoid dissection over the distal dorsoradial scaphoid to avoid interrupting the contribution by the dorsal ridge vessel.

Nonunion Exposure and Preparation
- A no. 64 Beaver blade and Freer elevator are used to define the location of the nonunion and the borders of the scaphoid itself. Time spent here makes reduction and bone graft placement simpler later (TECH FIG 2A,B).
- Two joystick K-wires are placed, one angled proximally in the proximal fragment and one angled distally in the distal fragment (TECH FIG 2C).
Chapter 19  
VOLAR WEDGE BONE GRAFTING AND INTERNAL FIXATION OF SCAPHOID NONUNIONS  

**TECHNIQUES**

**K-wire joysticks**

Fractured scaphoid

**TECH FIG 2** • A, B. A Freer elevator identifies the nonunion site. C. K-wires are used as joysticks to control the scaphoid proximal and distal fragments. D. Manipulation of the K-wires allows for access to the nonunion site for débridement and then graft placement.

- These K-wires facilitate manipulation of the fragments and therefore access to the nonunion site for débridement (TECH FIG 2D).
- The proximal and distal poles are examined carefully for osteolysis and sclerosis. A small curette or rongeur is used for débridement and removal of intervening fibrous tissue. Débridement is complete once good punctate bleeding is noted. In some situations deflating the tourniquet temporarily can be of value in assessing viability of the fragments.

**Fracture Reduction and Preliminary Stabilization**

- A retrograde K-wire may be inserted along the longitudinal axis of the scaphoid to temporarily hold the reduction.
- If placed in an appropriately eccentric position this K-wire may serve effectively as the derotation K-wire (used later to avoid fragment rotation during screw insertion) and yet remain out of the path of the screw.
- Restoration of scaphoid length and anatomic reduction of the fragments are best assessed by direct visualization and fluoroscopy.
- Lateral images will reveal correction of the DISI deformity.
- PA images document proper length of the scaphoid and determine if the Gilula lines are re-established.9
- The size of the volar wedge graft needed to maintain the reduction is now determined based on the volar defect noted after the reduction is accomplished.

By bringing the joystick/crossed K-wires into a more parallel position (relative to one another) and rotating the distal K-wire into slight supination, initial fracture reduction is often accomplished by removing the humpback (TECH FIG 3).
TECH FIG 3 • The scaphoid joysticks are used to reduce the fracture, and the length is estimated to determine the size of the volar wedge graft.

Distal Radius Graft Harvest
- A two-fingerbreadths incision is made more proximally than initially described. This provides the necessary access to the distal radius.
- The pronator quadratus is elevated using cautery, and the distal radius is perforated using K-wires to outline the size of the graft needed to fill the volar defect.
  - Great care is taken to avoid destabilizing the radial cortex of the radius.
- A curved osteotome introduced on three sides allows harvest of the corticocancellous wedge.
- A curette is then used to harvest as much cancellous bone as necessary.

Graft Contouring and Insertion
- The volar cortical defect in the reduced scaphoid is "regularized" using a small water-cooled sagittal saw or a fine rongeur.
  - Very little bone is removed from the fracture fragments to create a standard-shaped trough.
  - Creating such a "regular" defect makes insertion of the wedge graft easier and more secure.
- The same saw or rongeur is used to shape the corticocancellous graft to match the "regularized" defect.
- The prepared proximal and distal fragments are packed with cancellous bone and the corticocancellous graft is tapped into place (TECH FIG 4A).
- Before graft insertion, the longitudinal K-wire, whether it is the K-wire placed to maintain reduction or the K-wire over which the cannulated compression screw is to be placed, is withdrawn into the distal pole and then reinserted after placement of the graft into the trough.

Cannulated Intraosseous Compression Screw Fixation
- At the level of the scaphotrapezial joint a small rongeur is used to remove a portion of the trapezial lip. This facilitates the placement of the K-wire and screw down the longitudinal access of the scaphoid, helping secure center placement of the screw within the bone. A center screw position has been demonstrated to lead to increased healing rates.
- A K-wire from the compression screw system is then inserted in a retrograde direction (distal to proximal) into the center of the scaphoid, perpendicular to the fracture line.
  - If the K-wire is not perpendicular to the fracture, compression generated from the screw may malreduce the fragments.
- Once the K-wire is in perfect position, as judged fluoroscopically, and is fixed in the far (proximal) cortex of the scaphoid, the length is measured.
  - Factors such as cartilage thickness and distance between the fracture fragments is taken into account. It is critical that the screw not be too long and enter the radiocarpal joint.
- While some surgeons advocate advancing the K-wire into the distal radius after the measurement is taken so that the wire remains in position during drilling, that practice is dangerous. It is preferable to leave the K-wire in the scaphoid.
  - Advancing the K-wire can result in cutting the guidewire during drilling or screw placement (particularly with a second-generation compression screw that has cutting flutes at the distal end).
  - If not already present, an eccentric K-wire is placed to maintain the reduction during screw insertion.
  - Under fluoroscopic guidance, a cannulated drill is used followed, in some cases, by a cannulated bone tap. The screw is then placed over the K-wire and the guidewire is removed.
  - Especially during drilling, the surgeon must be careful to remain parallel with the wire.
  - The corticocancellous bone graft must be visualized at all times during these procedures to make certain position is maintained. Maintaining finger pressure over the graft during screw insertion is helpful.
- Imaging confirms proper screw location, fracture reduction, and construct stability. The K-wire is removed from the cannulated screw and the eccentric K-wire is removed (TECH FIG 4B,C).
- The wound is then irrigated and the volar extrinsic ligaments are repaired precisely with permanent suture. The remainder of the joint capsule may be closed with an absorbable suture.
  - Bone filler, preferably cadaver dried cancellous bone chips, can be inserted into the distal radius harvest site with a small tamp to compress and fill the defect. This potentially decreases the risk of hematoma formation. The periosteal sleeve is then closed over the distal radius with absorbable suture.
  - Skin is closed using nylon suture, and the tourniquet is then deflated after placement of a thumb spica splint.
If compression screw fixation is not feasible, then retrograde, nonthreaded K-wires are recommended and placed in the same manner as described above for the bone screw.
- The wires should be left under the skin and removed once the bone has healed.
- K-wires provide adequate stability and may be a better fixation choice with large bone grafts.

**Iliac Crest Graft Harvest**

- Rather than obtaining bone graft from the distal radius, a standard technique of harvesting bone from the iliac crest may be used.16,20
- A 2- to 3-cm incision is made just inferior to the superior border of the iliac crest just posterior to the anterior superior iliac spine (ASIS).
- The incision is kept below the belt line to minimize postoperative incisional tenderness.
- The incision is posterior to the ASIS to avoid iatrogenic nerve injury and subsequent numbness and pain over the proximal lateral thigh.
- Dissection is accomplished using cautery through the deep fascia down to the crest. The superior crest is exposed and muscles are released from a portion of the outer table using cautery and an elevator.
- A water-cooled sagittal saw and a curved osteotome are used to harvest a bicortical segment of corticocancellous graft.
- The graft is slightly larger than the measured defect in the scaphoid.
- The inner table is left intact.
- The harvested outer table will be volar when the graft is placed in the scaphoid and the superior crest will be radial.
- A curette is used to harvest cancellous bone graft.
- The wound is copiously irrigated and temporarily packed with thrombin-soaked Gelfoam while attention is redirected to the scaphoid.
- After the scaphoid is reconstructed, the Gelfoam is removed and the wound again irrigated.
- If indicated, a small suction drain is placed below the fascia.
- The wound is closed in layers with a running locking stitch used for the fascia.
- A local anesthetic with epinephrine may be injected before harvest of the graft or after closure.

**K-WIRE FIXATION**

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>When MRI reveals osteonecrosis in a scaphoid nonunion</th>
<th>Volar wedge bone grafting and internal fixation is the treatment option that is most effective when applied to scaphoid waist fractures, distal-third fractures of the scaphoid without osteonecrosis, or scaphoid waist fractures with concomitant carpal collapse and a nondissociated DISI pattern. When osteonecrosis is present, a vascularized procedure is preferable.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Surgeon prefers an adaptable graft should physical findings during the procedure reveal osteonecrosis not revealed on MRI</td>
<td>The advantage of harvesting from the distal radius rather than the iliac crest exists when the MRI is inconsistent with physical examination findings during the procedure. Harvesting from the distal radius allows the surgeon to use a modified pedicle technique using the pronator quadratus and the periosteum of the distal radius and place it into the volar defect as a vascularized bone graft if necessary.20</td>
</tr>
<tr>
<td>Fixation for greatest chance of bone healing</td>
<td>While either compression bone screws or K-wires can be used as effective fixation in this procedure, compression screws are believed to improve chances of overall bone healing.7,11,18</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE
- When a screw is placed for internal fixation, a thumb spica splint is applied after the procedure.
- The patient returns for a follow-up visit 10 days after surgery. During this visit, the hand is examined for swelling and sutures may be removed.
- A thumb spica, short-arm cast is applied, leaving the interphalangeal joint free. The patient is followed radiographically at intervals of 3 to 4 weeks.
- CT scans are the most predictable way to determine if the scaphoid has healed. This evaluation is recommended before allowing the patient to resume vigorous activities.

OUTCOMES
- Symptomatic scaphoid nonunions with shortening respond well to volar wedge bone grafting with internal fixation, particularly when scaphoid length is restored and when any bony union is achieved.
- A higher rate of bone healing is achieved when a compression bone screw is used as the internal fixation. Reported results show that internal fixation leads to better functional results than standard techniques of bone grafting.7,11,16–18
- Bones failing to heal after the procedure have been shown to respond well to vascularized grafts. Other options for failure to heal include partial scaphoid excision, complete scaphoid excision with four-corner fusion, proximal row carpectomy, radial styloidectomy, and complete wrist fusion.

COMPLICATIONS
- Radiographic findings may not match the findings at surgery. This affects the outcome to varying degrees, depending on the type of graft harvested.
- Persistent nonunion and osteonecrosis resulting in wrist arthritis
- Scarring associated with repair of the capsule, causing some postoperative stiffness

REFERENCES
DEFINITION
- Scaphoid fractures account for 60% of carpal bone fractures.
- Nonunions occur in up to 15% of scaphoid fractures and often result from delayed treatment, inadequate immobilization, displacement of the fracture, or proximal pole involvement or in the setting of avascular necrosis (AVN).

ANATOMY
- The blood supply to the scaphoid travels in a distal to proximal direction and emanates from the radial artery. Intraosseous vessels traverse the scaphoid to supply the proximal pole.
  - In about 30% of scaphoids, there is either a single or no vascular channel found reaching the proximal pole.
  - Studies of vascularity of the distal radius have identified several sources of vascularized bone graft available for nonunion treatment.
  - Animal studies of vascularized bone grafts have documented a significant increase in blood flow present when compared to nonvascularized grafts.

PATHOGENESIS
- Without adequate blood flow, the normal bone healing response cannot be completed. The scaphoid fracture site fills with fibrous connective tissue and motion persists at the site of the fracture.
  - In some cases, the bone undergoes changes of AVN with cellular death, edema, and the eventual loss of trabecular architecture.
  - Studies have shown that in cases in which the trabecular bone pattern has been lost, union may be difficult if not impossible to achieve.

NATURAL HISTORY
- Nonunion of the scaphoid severely alters the normal carpal biomechanics and subjects the cartilage to shear forces detrimental to its survival.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Often patients recall injuring their wrists several years before developing pain severe enough to seek medical attention.
- Patients usually complain of limited range of wrist motion and pain, often with grip or weight bearing. The patients have often significantly reduced their activity level due to persistent pain.
- In most cases the patient will experience tenderness to palpation at the anatomic snuffbox (FIG 1A), the radial styloid–scaphoid joint (FIG 1B), or the distal pole of the scaphoid (FIG 1C), which is palpable on the palmar side of the wrist.
- Wrists with established scaphoid nonunions have an arc of motion that is significantly reduced from the uninvolved side, primarily in extension.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard radiographic studies include posteroanterior (PA), lateral, and scaphoid (ulnar deviation) views (FIG 2).
  - Classic radiographic findings begin at the radial styloid-distal pole of scaphoid interface and proceed to involve the entire scaphoid fossa, the midcarpal joint, and eventually the entire radiocarpal articulation.
  - CT is essential for determining union as well as for identifying patients in whom the normal trabecular bone pattern has been lost.
  - MRI is useful in evaluating the scaphoid for vascularity, although definitive determination of avascularity may be difficult.

FIG 1 • A. Tenderness at the anatomic snuffbox is a classic finding of scaphoid nonunion. B. The radial styloid–scaphoid interface is the earliest site of degenerative change in scaphoid nonunions, and patients will often display tenderness at that location. C. The distal pole of the scaphoid is palpable at the base of the thumb on the palmar aspect of the wrist. Tenderness at this region is usually found in cases of scaphoid nonunion.
Conflicting reports regarding the usefulness of gadolinium enhancement have been published over the past several years.

**DIFFERENTIAL DIAGNOSIS**
- Ligamentous injury to the wrist
- Wrist synovitis
- Intraosseous ganglia
- Primary AVN of the scaphoid

**NONOPERATIVE MANAGEMENT**
- Nonoperative treatment is limited for established non-unions.
- Investigators have attempted the use of bone stimulators, which use either electrical stimulation or ultrasound.
  - There is little evidence in the literature supporting the use of these units for treatment of established scaphoid nonunions.

**SURGICAL MANAGEMENT**
- A vascularized distal radial bone graft is indicated for scaphoid nonunions with and without evidence of avascularity.
- Correction of a “humpback deformity” requires extensive mobilization of the pedicle when attempting the use of a dorsally sourced graft, and a palmar vascularized graft may be more appropriate.
- For significant collapse, a nonvascular iliac crest graft may be required to create a compression-resistant construct.
- When early degenerative changes are present, a radial styloidectomy should accompany the use of a vascularized distal radial graft.
- The presence of more advanced degenerative joint disease or carpal malalignment is a contraindication to performing surgery to obtain bony union.

**Preoperative Planning**
- Radiographs must be evaluated to rule out degenerative joint changes or carpal instability patterns, which are often found in established nonunions.

**Positioning**
- The patient is placed supine on the operating table with the arm placed on an armboard.
- Surgery is performed under tourniquet control.

**Approach**
- Vascularized grafting is carried out through a dorsal approach. Anatomic studies have shown that the dorsal irrigating vessels are of greater diameter and are further from the articular surface than irrigating vessels on the palmar surface of the radius.

**TECHNIQUES**

**VASCULARIZED DISTAL RADIUS BONE GRAFTING USING THE 1,2-INTERCOMPARTMENTAL SUPRARETINACULAR ARTERY**

**Exposure**
- A curvilinear incision is made over the dorsoradial aspect of the wrist, centered between the first and second extensor compartments (TECH FIG 1A).
- The 1,2-intercompartmental supraretinacular artery (1,2 IC SRA) lies on the surface of the retinaculum between the first and second compartments (TECH FIG 1B).
  - The irrigating branch enters the distal radius and supplies bone distal and dorsal to the brachioradialis insertion.
  - Avoidance of exsanguination before tourniquet inflation facilitates its identification.
- The first and second compartments are unroofed on their radial and ulnar aspects, respectively, to avoid damage to this irrigating vessel.

**Graft Harvest**
- The periosteum is scored with a scalpel to outline the graft shape, which measures 1.5 cm in the longitudinal dimension and 0.5 to 0.75 cm in the transverse dimensions (TECH FIG 2A). The distal graft margin extends to a point 0.5 to 1 cm from the articular surface.
- Osteotomes are used to elevate the cortical cancellous graft.
The soft tissue envelope containing the vessel is elevated from the radial periosteum distal to the site of graft harvest (TECH FIG 2B). This can usually be accomplished with a scalpel or Freer elevator.

- The 1,2 IC SRA is not dissected free; rather, it is left as part of the retinacular septum.
- The tourniquet is deflated and perfusion of the vascularized bone graft is ensured (TECH FIG 2C).

**Graft Placement**

- The joint capsule is incised in the distal portion of the incision and the scaphoid nonunion is identified.
- A radial styloidectomy greatly increases the exposure of the scaphoid and eliminates the possibility of bone graft impingement.
- Intervening fibrous tissue and sclerotic bone are removed from the nonunion site using rongeurs and curettes to prepare the scaphoid for graft placement.
- Cancellous bone graft from the distal radius is packed proximally and distally to fill voids created by débriding sclerotic bone.
- The carefully contoured vascularized graft is then rotated into the nonunion site and pressfit into position, taking care to avoid torsion of the vascular pedicle (TECH FIG 3A).
- Kirschner wires are advanced from the distal pole of the scaphoid to the proximal pole to secure the graft in place (TECH FIG 3B).
- The radial capsule is closed loosely with absorbable suture and the skin is closed in a routine fashion.
- The pedicle must not be compressed.
- The patient is placed in a short-arm thumb spica splint.
**POSTOPERATIVE CARE**
- Kirschner wires are removed when healing is observed, usually 4 to 6 weeks after surgery.
- CT scanning may be required to document complete healing before the patient resumes risky activities.
- MRI may be useful in evaluating the scaphoid for vascularity and may be done after Kirschner wire removal.

**OUTCOMES**
- A recent meta-analysis\(^2\) found a scaphoid union rate of 88% with the use of a vascularized bone graft. Individual series report union rates ranging from 60% to 100%.
- Previous reports have shown that patients with MRI evidence of AVN or loss of trabecular bone pattern noted on CT have a decreased level of success with reconstructive surgery. Treatment is rarely successful when both findings are present.
- A recent study\(^1\) has identified risk fractures for failure: proximal pole AVN, radiographic degenerative changes, loss of carpal alignment, inadequate fracture fixation, tobacco use, advanced age, and female gender.

**COMPLICATIONS**
- Failure to gain union
- Progressive degenerative changes
- Impingement of bone on radial styloid
- Infection

**REFERENCES**
DEFINITION
- The scaphoid is the most frequently fractured bone in the carpus. In acute fractures, appropriate treatment yields union rates greater than 90%.1 However, without proper diagnosis and treatment scaphoid fractures frequently result in nonunion. Initial treatment for a scaphoid nonunion is typically open reduction and internal fixation (ORIF) with bone graft, vascularized or unvascularized. Despite appropriate internal fixation and bone grafting, failure rates of 15% have been documented.4 If internal fixation and bone grafting fails, the surgeon is then left with difficult choices:
  - Revision ORIF with bone grafting (failure rate of 50%)2
  - A salvage procedure with lower morbidity and a higher rate of satisfactory results
  - Currently, there are no acceptable prostheses available to replace the scaphoid.
  - When the index treatment or procedure has failed and the patient has persistent pain caused by a chronic scaphoid nonunion (FIG 1) with posttraumatic arthritis limited to the distal pole of the scaphoid and radius, partial scaphoid excision (distal fragment) provides a reasonable, low-morbidity alternative treatment option.3–5

ANATOMY
- The carpus is divided into proximal (scaphoid, lunate, triquetrum, pisiform) and distal (trapezium, trapezoid, capitate, hamate) rows.
- The scaphoid bone represents the bridge between these two rows. Largely covered by articular cartilage, it has important intrinsic and extrinsic ligamentous attachments (radioscaphocapitate, long radiolunate, scapholunate, and scaphotrapezial-trapezoid). In its precarious position as an intercalated rod between the proximal and distal carpal row, the scaphoid is at mechanical risk for fracture when an abnormal stress is applied (eg, forced dorsiflexion).
- After a fracture of the scaphoid, the vascular anatomy specific to this bone contributes to problems in bone healing.7 Taleisnik and Kelly describe three groups of vessels responsible for scaphoid blood supply: laterovolar, dorsal, and distal vessels (FIG 2). The laterovolar vessels are the main contributors to the intraosseous blood supply.

![FIG 1](image1.png) Failed open reduction and internal fixation of a scaphoid nonunion (PA and lateral views).

![FIG 2](image2.png) A. Volar intraosseous blood supply to the scaphoid with laterovolar and distal vessels visualized. B. Dorsal intraosseous blood supply to the scaphoid.
Variations exist in the exact number and locations of the volar vessels entering the scaphoid, but in all studies the most significant vessels enter the scaphoid distal to its waist.

The proximal pole is at risk secondary to its tenuous blood supply.\(^7\)

**PATHOGENESIS**

- Based on its retrograde pattern of blood supply, a more proximal fracture of the scaphoid will have an increased potential to form a nonunion.
- Patients with scaphoid fractures who present with delays in both diagnosis and treatment can develop a nonunion. In addition, patients with comminution, displacement, or improper immobilization of the scaphoid fracture can develop nonunions.

**NATURAL HISTORY**

- A scaphoid nonunion leads to the development of posttraumatic arthritis in the region of the radioscaphoid joint. How quickly this arthritis develops and progresses varies, but most patients will show radiographic evidence of degenerative changes within 5 to 10 years of their nonunion.
- Arthritis first develops between the distal pole of the scaphoid and the radial styloid (scaphoid nonunion advanced collapse [SNAC] wrist stage I; **FIG 3A**).
- The degenerative changes occur at this location due to the abnormal motion between the ununited distal scaphoid fragment and the radial styloid.
- Left untreated, stage I SNAC will progress to involve the entire radioscaphoid articulation (SNAC stage II) and eventually diffuse arthritis of the wrist (SNAC stages III and IV) (**FIG 3B–D**).

**FIG 3** • **A.** Arthritis observed between the distal pole of the scaphoid and the radial styloid (scaphoid nonunion advanced collapse [SNAC] grade I).

**B–D.** Stage I SNAC can progress to involve the entire radioscaphoid articulation (SNAC grade II) with eventual diffuse arthritis of the wrist (SNAC grade III and IV).
Patients sometimes do not seek medical care until pain and decreased range of motion in the wrist become increasingly severe. In these cases, initial radiographic studies reveal a scaphoid nonunion and associated arthritis.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Most patients are young to middle-aged men who sustained a dorsiflexion injury to their involved wrist. Some patients will present with no previous treatment and a chronic nonunion (FIG 4), and some will have failed to respond to either operative or nonoperative therapy.
- Pain aggravated by motion and use, loss of motion, and loss of grip strength, all slowly worsening over the preceding years, are consistent presenting complaints.

- It is critical to know the patient’s smoking history, occupation, and previous operations, as these will dictate future interventions.
- The examiner should palpate the anatomic snuffbox, which lies on the dorsum of the wrist between the extensor pollicis longus and extensor pollicis brevis tendons. Pain in this region is indicative of a fracture.
- Measurements of grip strength and range of motion (ROM) need to be ascertained.
  - Strength is often decreased by as much as 30% to 40% if the patient is experiencing pain.
  - There will often be a decrease in extension and radial deviation of the wrist relative to the contralateral unaffected side.
  - Limited active ROM of the wrist can indicate carpal pathology.
  - Decreased grip strength in association with physical findings can indicate carpal pathology.
- During palmar flexion the examiner may notice both a fullness and a hard bone excrescence on the dorsal radial aspect of the wrist. This fullness is secondary to synovitis and the hard excrescence is the result of the hypertrophic distal pole of the scaphoid.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- We routinely order true posteroanterior (PA), lateral, and ulnar and radial deviation views of the wrist. These views assist in determining whether a partial scaphoid excision is indicated.
  - The lateral plain radiograph allows one to determine the degree of dorsal intercalated segment instability (DISI) (FIG 5A).
  - If the radiographs reveal intercarpal arthritis (FIG 5B) or a small avascular proximal pole, partial scaphoid excision may be contraindicated.
  - If no radioscaphoid arthritis is observed, another procedure (eg, vascularized bone graft) to salvage the scaphoid might be considered.
- MRI is helpful in evaluating the joint surfaces and the blood supply of the proximal scaphoid fragment.
• However, MRIs rarely change the decision to perform a distal pole excision, as plain radiographs most often give adequate and accurate information.
• From a radiographic perspective, the ideal candidate for distal pole excision of the scaphoid has a nonunion of the scaphoid fracture in the midwaist or distal pole with concomitant degenerative joint disease between the distal radius and distal pole only.

**DIFFERENTIAL DIAGNOSIS**

• Scaphoid fracture
• Scaphoid nonunion
• Radioscaphoid arthritis
• Midcarpal arthritis
• Carpometacarpal arthritis

**NONOPERATIVE MANAGEMENT**

• Nonoperative management of chronic wrist pain should be considered before any surgical intervention. Chronic wrist pain is never an emergency and simple noninvasive techniques can be used to control pain.
• The treatment of any painful joint begins with intermittent immobilization (wrist splinting), activity modification, and nonsteroidal anti-inflammatory medications (NSAIDs).
• If immobilization and NSAIDs are ineffective, temporary pain relief can almost always be gained with a steroid injection. These temporizing treatments also put the pain in perspective for the patient. The patient may conclude that medication and splinting is all that is necessary.
• During the nonoperative management period, the surgeon gains a perspective on the degree of patient discomfort and simultaneously gauges the patient’s expectations.
• The operation will work better and the patient will be more satisfied if the patient’s expectations and surgeon’s expectations are similar.

**SURGICAL MANAGEMENT**

• Surgical options to treat persistent pain resulting in compromised function in a patient with a scaphoid nonunion and arthritis limited to the area between the distal fragment of the scaphoid and the radial styloid (stage I SNAC wrist arthritis) include:
  • Open reduction and internal fixation (ORIF) combined with radial styloidectomy
  • Resection of the distal scaphoid fragment
  • A patient with an untreated scaphoid nonunion and no arthritis most often has ORIF of the scaphoid with bone grafting as the initial procedure. In a patient with SNAC wrist grade II, it is too late for distal pole excision; this patient may require a proximal row carpectomy or scaphoid excision with intercarpal fusion.
  • Most patients requiring excision of the distal pole have undergone prior treatment that has failed and both the surgeon and the patient are searching for a reliable procedure with low morbidity to help alleviate the patient’s pain and augment function.
  • Distal scaphoid excision requires that the robust and taut radioscapoid and long radiolunate ligaments exist to support the remaining proximal carpus and prevent collapse (dorsal intercalated segment instability [DISI] of the wrist).
• Contraindications to distal pole excision include:
  • Pre-existing significant DISI deformity. The DISI deformity may indeed get worse with distal pole excision in an individual with poor ligamentous support.
  • Proximal pole that is less than half the entire size of the scaphoid. If the distal fragment is greater than 50% of the size of the scaphoid, resultant collapse of the carpus may occur with severe morbidity.

**Preoperative Planning**

• Before deciding if distal pole excision of the scaphoid is a reasonable choice, radiographs or other images (eg, CT or MRI) must be carefully reviewed.
• If the distal pole is to be excised, there must be enough proximal pole left to support the capitate and the remainder of the carpus. At least one third of the scaphoid must remain. If only a very small (and possibly an avascular) proximal pole remains, the carpus is likely to collapse, resulting in failure of the procedure.

**Positioning**

• The patient is placed in the supine position with application of a pneumatic tourniquet.

**Approach**

• The distal pole of the scaphoid can be excised through either a dorsal or palmar approach. The approach may be dictated by existing scars.
• The palmar approach is the preferred method due to the relatively accessible palmar position of the distal fragment.
• An advantage of the dorsal approach is the ease of excision of the posterior interosseous nerve for wrist denervation.
• A radial styloidectomy can be performed through either approach.

**VOLAR APPROACH TO DISTAL POLE OF SCAPHOID EXCISION**

**Incision and Scaphoid Excision**

• An incision is made directly over the flexor carpi radialis (FCR) tendon, incorporating any previous incisions (TECH FIG 1A,B).
• The tendon is retracted ulnarly and the subsheath of the tendon incised longitudinally (TECH FIG 1C).
• The radiocarpal joint capsule is opened longitudinally and the distal pole of the scaphoid is excised with osteotomies and rongeurs (TECH FIG 1D–G).

**Radial Styloidectomy**

• If indicated, a radial styloidectomy can be performed at this point using an osteotome.

• In this situation, the distal pole may be too large to excise and a radial styloidectomy can accomplish the same purpose.
• The styloidectomy should be large enough so that the arthritic distal pole no longer touches the radius in radial deviation.

**Wound Closure**

• The capsule and volar extrinsic ligaments are closed with interrupted absorbable 4-0 sutures.
• The skin is closed with interrupted nonabsorbable 4-0 sutures.
TECH FIG 1 • A. Chronic scaphoid non-union with scaphoid nonunion advanced collapse (SNAC). The patient had no previous treatment. B. An incision is made directly over the flexor carpi radialis (FCR) tendon. C. The tendon is retracted and its subsheath opened longitudinally. D. The radiocarpal joint is opened longitudinally and the scaphoid is visualized. E,F. The distal pole of the scaphoid is excised with osteotomies and rongeurs. If indicated, a radial styloidectomy can be performed at this point. G. Excised distal pole of the scaphoid.

DORSAL APPROACH TO DISTAL POLE OF SCAPHOID EXCISION

- An incision is made over the radial aspect of the carpus, incorporating any old incisions (TECH FIG 2).
- The radial sensory nerve is identified and retracted.
- The interval between the extensor pollicis longus and the radial wrist extensors is entered.
- The radial artery and its branches are retracted and protected, and then the joint capsule is incised.
- The distal scaphoid fragment will be deep and is best removed using rongeurs after defining its borders with a No. 15 blade.
- A radial styloidectomy can be performed if necessary as mentioned above.
- The capsule is closed with absorbable 4-0 suture.
- The skin is closed with interrupted nonabsorbable 4-0 sutures.
- The patient is placed in a well-padded forearm-based splint, leaving the finger metacarpophalangeal joints and thumb interphalangeal joint free. This volar splint is placed after either the volar or dorsal approach.

TECH FIG 2 • An incision over the dorsoradial aspect of the wrist may be used when prior surgery has been performed.
POSTOPERATIVE CARE

- Patients are immobilized for 2 weeks in a well-padded volar splint.
- The splint and sutures are removed 2 weeks after the procedure.
- A removable orthosis is applied and the patient is instructed on active and passive ROM exercises.
- Once active and passive ROM has been achieved, strength exercises are started (usually at 4 weeks postoperatively).
- Regaining full ROM and strength typically takes about 3 months.
- Pain relief is noticeable within 2 to 4 weeks of surgery.

OUTCOMES

- Review of outcomes in the literature suggest that both ROM and grip strength improve postoperatively.
- Pain relief can be expected if the proper indications for surgery are followed.
- All patients have some degree of DISI preoperatively, and this pattern of deformity may worsen after excision of the distal pole of the scaphoid. DISI deformities that are severe can result in both loss of motion and pain. This problem is not well documented in the literature but certainly exists.
- In the patient undergoing multiple procedures, outcomes of distal pole excision are better than attempting another bone graft and internal fixation, where the failure rate can approach 50%.

COMPLICATIONS

- The presence of midcarpal arthritis undiagnosed before distal pole excision can lead to persistent pain.
- Resection of too large a distal pole (more than two thirds) can result in collapse of the scaphoid.
- If the procedure is performed in a very loose-jointed individual, the DISI pattern may significantly worsen, leading to persistent pain.

REFERENCES

DEFINITION
- These injuries include fractures of the lunate, triquetrum, pisiform, hamate body or hook, capitate, trapezoid, and trapezial body or ridge.
- Any fracture involving the carpal bones should raise suspicion of associated carpal instability.

ANATOMY
- Certain anatomic features of the carpal bones make them more susceptible to injury. These include the unique osteologic regions of some of the carpal bones, such as the hook of the hamate, the ridge or tubercle of the trapezium, and the neck of the capitate.
- The slender shape and projection of the hamate hook make it an obvious injury target for direct trauma to the palmar-ulnar surface of the wrist (Fig 1A). The hook can be identified before incision by placing the interphalangeal joint of the surgeon’s thumb on the pisiform and flexing the thumb toward the first web space. The surgeon’s thumb tip will land directly on top of the hook.
- The trapezial ridge may be considered a radial-sided analogue to the hamate hook in that it is a relatively prominent volar projection, further accentuated by the deep groove for the flexor carpi radialis tendon that runs along its ulnar side (Fig 1B).
- The strong, inelastic transverse carpal ligament attaches to the hamate hook ulnarily and the trapezial tubercle radially.
- These facts make the ridge of the trapezium more susceptible to fracture after direct trauma to the thenar region of the hand.
- The constricted neck portion of the capitate lies between the dense head proximally and the body distally. The body, which accounts for the distal half of the capitate, is rigidly constrained by its associations with the index, middle, and ring finger metacarpal bases, the trapezoid, and the hamate. As a result the capitate neck is a biomechanically vulnerable area.
- Transverse plane fractures through the capitate neck are reported as being the most common.
- Fractures across the neck place the head at risk for avascular necrosis because the blood supply to the capitate flows retrograde toward the head proximally.

PATHOGENESIS
- Traumatic fractures of the carpal bones may occur via direct or indirect mechanisms.
- Direct mechanisms include crush injuries, which should alert the physician to the possible development of compartment syndrome of the hand. Compressive trauma to the hand in the anteroposterior plane will flatten the palmarly directed concave longitudinal and horizontal arches of the carpus and should raise suspicion for potential carpal body fractures and axial disruptions.
- The presence of a seemingly unusual carpal bone fracture may be a herald of a globally destructive injury to the hand and other associated injuries, such as carpometacarpal (CMC) fracture-dislocations, longitudinal fractures of the metacarpals, severe thumb damage, and significant soft tissue injuries. This constellation of pathologies has been referred to as the “exploded hand” (Fig 2).
- More focused direct trauma to individual carpal bones may also cause a fracture. Examples of this include direct blows to the dorsum of the hand, causing capitate fractures, or direct injury from a racquet or club, causing a hamate hook fracture.

**FIG 1** • A. CT scan showing hamate hook. B. CT scan showing trapezial ridge.

![Fig 2](image2.png)

**FIG 2** • “Exploded hand” is a constellation of injuries that can include carpometacarpal fracture-dislocations, longitudinal fractures of the metacarpals, severe thumb damage, and significant soft tissue damage. (Reprinted from Graham TJ. The exploded hand syndrome: logical evaluation and comprehensive treatment of the severely crushed hand. J Hand Surg Am 2006;31A: 1012–1023; copyright 2006, with permission from Elsevier.)
Indirect trauma includes the progressive perilunate instability patterns that are well described and may lead to fractures of the lunate, capitate, triquetrum, or other carpal bones.

Scaphocapitate syndrome involves a dorsiflexion and radial deviation mechanism by which the scaphoid bone fractures and is followed by a fracture of the capitate through the neck in the coronal plane. The capitate head may rotate up to 180 degrees from its anatomic position.

A progressive perilunate instability pattern can produce a similar coronal fracture through the capitate neck but normally without such a severe degree of capitate head rotation.

More minor indirect trauma mechanisms can cause isolated carpal bone fractures.

The commonly seen avulsion fractures from the dorsum of the triquetrum may occur when a fall onto the palmar-flexed wrist causes the dorsal radiotriquetral (also known as dorsal radiocarpal) ligament to avulse a portion of the dorsal cortex.

An impaction type of fracture of the triquetrum may be seen more often in patients with an elongated ulnar styloid.

**NATURAL HISTORY**

The natural history of carpal bone fractures depends both on the specific bone in question as well as associated impairment of other structures.

All of the carpal bones have at least three articular surfaces, except the pisiform, which articulates only with the triquetrum. Anatomic reduction of articular facets is a primary surgical goal in an effort to decrease the incidence and severity of post-traumatic arthritis.

Avascular necrosis can have a profoundly negative impact on final outcome after carpal bone fracture.

Concerns of vascular disruption arise when lunate and capitate fractures occur, although generally fractures of the lunate are not associated with avascularity.

The potential for nonunion is most often seen with hamate hook fractures, capitate neck fractures, and trapezial ridge fractures, especially Palmer type II fractures that involve the tip and not the base of the ridge.

Barring nonunion, the related instabilities and involvement of other hand components are the most troublesome and will most significantly affect patient outcome.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

Ascertaining the mechanism of injury is the most important component of the patient history.

Neurovascular symptoms should be explored, especially when a severe crush or high-energy mechanism is involved, or in cases of hamate hook or pisiform fractures, with special attention to the ulnar neurovascular structures within the canal of Guyon.

A complete evaluation of the median, radial, ulnar, and digital nerves is warranted. Assessment of capillary refill, color, temperature, and Doppler signal determines the vascular status.

The examiner should observe the patient’s hand and wrist for swelling, deformity, and skin and soft tissue injuries, including possible open fractures or fracture-dislocations.

Swelling and soft tissue damage give an indication as to the severity of the injury. The presence of deformity alerts the examiner to possible carpal dislocations that require emergent reduction. Open fractures and fracture-dislocations will guide surgical management.

The examiner should ask the patient where the pain is most significant. The examination should start away from and progress toward this point. The hand, forearm, and elbow should also be palpated to assess for possible associated injuries.

The most obvious area of pain and tenderness is usually the most structurally significant. However, it may mask other more subtle injuries that should be detected by a more thorough global examination.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Routine AP, lateral, and oblique views of the wrist and hand are obtained (FIG 3A).
- Radiographs of the elbow and forearm are ordered if indicated.
- Fluoroscopic images, including dynamic stress and distraction views, help to rule out carpal instability.
- Special views, often best performed with fluoroscopy, help to profile difficult-to-see structures.
- The hook of the hamate is evaluated with the carpal tunnel view and supinated and oblique lateral view with the wrist in radial deviation and the thumb abducted, as if the patient was holding a cup (referred to as the papillon view) (FIG 3B).
- The trapezial ridge is visualized on the carpal tunnel view (FIG 3C).
- The pisotriquetral joint is best seen on a 45-degree supinated lateral view of the wrist.
- CT scans effectively assess osseous detail and will often detect more subtle associated carpal fractures that may be missed on routine radiographs.
- CT is considered the imaging modality of choice for confirming a hamate hook fracture if plain films are nondiagnostic.

**NONOPERATIVE MANAGEMENT**

Isolated carpal bone fractures without associated carpal instability, significant displacement, or intra-articular stepoff may be managed nonoperatively.

- This usually includes use of a cast or brace for several weeks (usually 4 to 6 weeks) until symptoms have improved, tenderness is resolving, and radiographs are stable.
- Short-arm thumb spica casts or splints have been recommended for isolated trapezium and capitate fractures. The digits should be left free.
- A specific fracture of note is the hamate hook.

- These fractures can be treated with cast immobilization if nondisplaced and acute (less than 1 month).
- There is a relatively high rate of symptomatic nonunion, and surgical intervention may eventually be necessary.
- Similar to the treatment of the hamate hook, trapezial ridge fractures may be initially immobilized and later excised if symptomatic nonunion develops.

**SURGICAL MANAGEMENT Indications**

- Indications for surgical management of these fractures include those that significantly involve an articular surface or are structurally destabilizing to the remainder of the carpus, such as a displaced or unstable capitate body fracture.
- Other operative indications include those that are true for most fractures, such as open injuries and those requiring nerve, vessel, tendon, ligament, or soft tissue repair.
If stable and near-anatomic reduction of carpal fractures is not possible, primary limited arthrodesis or carpectomy may be indicated.

Because of the unique nature of each carpal bone, more specific indications will be considered for each fracture.

Late reconstructive options include partial or total wrist arthrodesis or proximal row carpectomy for symptomatic arthritic changes.

Trapezial excision with thumb metacarpal suspension-plasty may be used for posttraumatic arthritis after trapezial body fractures.

Total or hemi-wrist arthroplasty for select cases may become a more popular option as techniques improve.

**Lunate Fractures**

In general, fractures that are of sufficient size and displacement should be reduced and internally fixed.

Fractures that involve the palmar surface of the lunate where stout volar extrinsic wrist ligaments (long and short radiolunate) and vascular conduits (radioscapholunate ligament of Testut) attach should be stabilized.

If the capitate is subluxated volarly relative to the lunate and radius, such as when there is a lunate palmar lip fracture, this must be corrected with reduction and fixation of the lunate palmar fragment.

These fractures are routinely approached palmarly as described in Techniques.

Alternatively, a standard 3–4 interval dorsal exposure (described under capitate fractures) can be used if the fracture pattern dictates a dorsal approach and fixation.

**Triquetral Fractures**

In general, displaced fractures of the triquetral body that are of sufficient size are best treated by open reduction and internal fixation (ORIF).

This can be accomplished through use of pins or screws into the triquetrum alone or in combination with pinning to the lunate or to the hamate as dictated by the fracture.

The triquetrum may be removed in its entirety if it is not amenable to repair.

An apparently isolated fracture of the triquetrum may in fact be part of a reverse perilunate instability pattern (in which the portal of energy entry is at the ulnar wrist) and may be associated with other fractures and ligament disruptions.

**Pisiform Fractures**

The pisiform, similar to another sesamoid bone, the patella, most often fractures in a transverse pattern via an indirect avulsion mechanism through the flexor carpi ulnaris (FCU) or in a pattern of comminution from a direct blow.

Virtually all pisiform fractures are treated nonoperatively initially and then excised late if immobilization of the fracture fails to relieve symptoms after 2 or 3 months.

Fractures that are of sufficient size and displacement can be reduced and internally fixed, although this is rarely indicated.

The approach described in Techniques can be used for fixation or excision of the pisiform.

The pisiform is the last carpal bone to ossify, usually by age 12, and may have a nonpathologic fragmented appearance before complete ossification.

**Hook of Hamate Fractures**

Like pisiform fractures, most acute hamate fractures are treated nonoperatively initially. If the fracture remains persistently symptomatic or nonunited, excision is indicated, even for base fractures (FIG 4A).

ORIF is associated with relatively high complication rates and provides little or no advantage over simple fragment excision.

If ORIF is desired, the hamulus is exposed as described in Techniques and standard internal screw fixation principles are used.

**Hamate Body Fractures**

Fractures of the hamate body are often associated with fourth or fifth CMC dislocations (FIG 4B,C). ORIF is recommended to reduce the articular surfaces and stabilize the CMC joints.

These injuries most often result from a dorsal shear mechanism with fracture of the hamate body in the frontal plane. The metacarpals displace dorsally and proximally with the dorsal hamate fracture fragment.
Capitate Fractures
- Capitate fractures are by and large associated with significant trauma to the wrist.
  - In addition to fractures associated with progressive perilunate instability patterns and the scaphocapitate syndrome, capitate fractures may also occur due to axial loading along the middle finger ray or via direct trauma.
  - If caused by axially directed forces, the fracture line is often in the frontal plane, similar to the hamate dorsal shear fractures described earlier. The capitate may be essentially divided in half in this frontal plane.
  - In these cases, ORIF is performed through a dorsal approach.
  - Truly isolated capitate fractures with minimal displacement heal by immobilization, but this often takes time.

Trapezoid Fractures
- The trapezoid is believed to be the least frequently fractured carpal bone.
  - As with the other bones of the distal carpal row, assessment of the associated index CMC joint is necessary to rule out a fracture-dislocation.
  - Frontal plane dorsal shear fractures of the trapezoid can destabilize the index CMC.
  - These fractures and fracture-dislocations can often be treated by closed reduction and pinning.
  - If an open approach is required to reduce the articular surface and CMC joint, a standard 3–4 dorsal approach may be used. Fixation can be accomplished with pins or screws.
  - A limited exposure (as described below) is an alternative.

Trapezium Fractures
- Fractures of the body of the trapezium nearly always involve one of its four articular facets and frequently lead to subluxation of the thumb CMC joint (FIG 5).
  - If internal fixation is not possible, trapezial excision and palmar oblique ligament reconstruction, or an alternative procedure used for routine thumb CMC osteoarthritis, is performed.

Preoperative Planning
- Examination under anesthesia, possibly with concomitant fluoroscopic imaging, helps confirm whether carpal instability coexists.
  - The surgeon should ensure that all needed fixation implants and systems are available before bringing the patient to the operating room.
  - A hand table, a well-padded upper arm tourniquet, and a mobile mini-fluoroscopy unit are used.
  - Anesthesia and analgesia may be obtained through regional or general methods.

Approach
- Carpal fractures may be approached dorsally, palmarly, radially, or ulnarily depending on the reduction needs, implants used, and fracture location and characteristics.
  - Some surgeons use wrist or small joint arthroscopy as an aid to fracture reduction and management.
ORIF OF LUNATE FRACTURES

Incision and Dissection
- An extended carpal tunnel approach is used for palmar exposure.
- The incision begins in the palm, just ulnar to the thenar crease and in line with the radial border of the ring finger. If the surgeon is comfortable with the deep anatomy, especially the possible anatomic variations involving the thenar motor branch, the incision in the palm may also be along the thenar crease itself.
- It is extended proximally until the distal volar wrist crease is reached.
- A curved or zigzag continuation of the incision is made at the crease so as to avoid crossing perpendicular to the wrist crease, which might cause excessive scarring and a flexion contracture.
- The incision may be continued into the distal forearm, staying ulnar to the palmaris longus so as to avoid damage to the palmar cutaneous branch of the median nerve (TECH FIG 1A).
- It is deepened distally until the palmar fascia is encountered (TECH FIG 1B). This fascia is incised in line with the skin incision.

Reduction and Fixation
- The palmar lip fracture of the lunate is identified, cleaned, and anatomically reduced.
- The fracture may be fixed with small interfragment screws or buried Kirschner wires (TECH FIG 2).
- Screws are favored if at all possible to minimize chances of hardware migration into the carpal tunnel.

**TECH FIG 1** • Fixation of lunate palmar lip fractures. 
A. Carpal tunnel approach. The incision can be continued into the distal forearm, staying ulnar to the palmaris longus to avoid damage to the palmar cutaneous branch of the median nerve. 
B. Palmar fascia and antebrachial fascia exposed. 
C. Transverse carpal ligament released from hamate hook. 
D. Volar wrist capsule exposed.
Chapter 22  SURGICAL TREATMENT OF CARPAL BONE FRACTURES, EXCLUDING THE SCAPHOID 2289

Techniques

Fluoroscopic images are necessary to confirm that the volar carpal subluxation has been corrected with fixation of the lunate fracture.

The volar wrist capsule is repaired with permanent suture and the median nerve and digital flexors are allowed to return to their normal resting position.

The transverse carpal ligament may be repaired in a lengthened fashion or left divided (our preference).

Subcutaneous tissue and skin closure is performed according to the surgeon’s routine.

Access to the triquetrum is usually achieved through the standard dorsal approach to the wrist that is described for capitate fractures.

If there is truly isolated triquetral pathology, a more limited dorsal approach between the fifth and sixth extensor compartments is used.

This incision is centered distal to that which would be used for distal radioulnar joint (DRUJ) exposure.

The fifth compartment (extensor digiti minimi [EDM]) is retracted radially while the sixth compartment (extensor carpi ulnaris [ECU]) is retracted ulnarly.

The carpal capsule is incised longitudinally or obliquely depending on the fracture and the integrity of the dorsal radiotriquetral ligament.

The triquetral fracture may now be cleaned, reduced, and fixed with mini-screws or Kirschner wires as the fracture pattern prescribes.

Supplemental pinning to the lunate or hamate is performed as needed.

The capsule is closed with nonabsorbable suture, followed by routine subcutaneous tissue and skin closure.

ORIF OF TRIQUETRAL FRACTURES

The risk for hardware migration, penetration into the pisotriquetral joint, and other complications in the region of the ulnar neurovascular bundle must be weighed against the good results expected with simple excision.

The split FCU is closed with a nonabsorbable suture and the subcutaneous tissue and skin are sutured in routine fashion.

Hook of hamate excision

Once the level of the hook is reached distally, the ulnar neurovascular bundle is gently retracted ulnarly.

Soft tissue attachments to the tip of the hook are incised longitudinally, including the transverse carpal ligament radially and the pisohamate ligament ulnarly and proximally.

The deep motor branch of the ulnar nerve should be identified as it passes distally around the base of the hamate hook in an ulnar-to-radial direction and must be protected during excision (TECH FIG 3E).

At this point the pisiform can be excised or internally fixed with mini-fragment screws or Kirschner wires.

The risk for hardware migration, penetration into the pisotriquetral joint, and other complications in the region of the ulnar neurovascular bundle must be weighed against the good results expected with simple excision.

The split FCU is closed with a nonabsorbable suture and the subcutaneous tissue and skin are sutured in routine fashion.

Hook of hamate excision

The hook can be identified before incision by placing the interphalangeal joint of the surgeon’s thumb on the pisiform and flexing the thumb toward the first web space. The surgeon’s thumb tip will land directly on top of the hook.

The hamate hook can be approached through a volar incision (preferred) or directly ulnar, proceeding palmar to the small finger metacarpal and dorsal to the abductor digiti minimi.

A longitudinal or curvilinear skin incision is made, centered over the hook (TECH FIG 3A).

The ulnar nerve and artery are identified proximally first and then traced distally, ulnar and superficial to the hamate hook (TECH FIG 3B–D).

A curvilinear incision is made with special care not to cross the distal volar wrist crease perpendicularly. The incision is made centered on or just radial to the pisiform.

The ulnar neurovascular bundle is identified proximally and traced distally just past the pisiform body.

The pisohamate ligament is divided.

The flexor carpi ulnaris (FCU) tendon insertion, if intact, is divided longitudinally and subperiosteally elevated from the radial and ulnar margins of the pisiform.

At this point the pisiform can be excised or internally fixed with mini-fragment screws or Kirschner wires.

The risk for hardware migration, penetration into the pisotriquetral joint, and other complications in the region of the ulnar neurovascular bundle must be weighed against the good results expected with simple excision.

The split FCU is closed with a nonabsorbable suture and the subcutaneous tissue and skin are sutured in routine fashion.

Hook of hamate excision

Once the level of the hook is reached distally, the ulnar neurovascular bundle is gently retracted ulnarly.

Soft tissue attachments to the tip of the hook are incised longitudinally, including the transverse carpal ligament radially and the pisohamate ligament ulnarly and proximally.

The deep motor branch of the ulnar nerve should be identified as it passes distally around the base of the hamate hook in an ulnar-to-radial direction and must be protected during excision (TECH FIG 3E).

The digital flexors within the carpal canal are identified. The ring and small finger flexors, especially the profundus tendons, are inspected to ensure integrity and should be débrided or repaired as needed (TECH FIG 3F).

The tendons are then gently retracted radially.
TECH FIG 3 • Excision of hamate hook fractures. A. The cardinal line of Kaplan, drawn from the apex of the first web space to the ulnar border of the hand, intersects a second line drawn along the ulnar margin of the ring digit at the hamate hook (circle). A 3-cm incision is centered over the hamate hook, gently curving with the radial border of the hypothenar eminence. B. The ulnar nerve and artery can be found proximally first and then traced distally, ulnar and superficial to the hamate hook. C. The ulnar artery is encountered first, volar and radial to the ulnar nerve. D. With the artery retracted ulnarly, the common digital nerve to the fourth web space and the small digit ulnar sensory nerve are visualized. The deep motor branch and the hypothenar motor branch have already been given off. E. The hamate hook is subperiosteally exposed and its margins are palpated with an elevator. The deep motor branch curves radially, closely associated with the distal surface of the hook. F. Care is also taken to protect the flexor tendons during exposure and resection, seen here on the radial margin of the hook.
The hook is cleared of all soft tissue attachments down to the level of the fracture site.
- A no. 69 Beaver blade helps make this exposure precise.
- Using a rongeur or similar tool, the fractured hook is removed piecemeal, again with care to protect the deep ulnar motor branch and other structures.
- Once the fragment is removed, the remaining base is inspected and smoothed with a rongeur, curette, or similar tool until there are no sharp bony prominences.
- The surrounding periosteum is closed if possible.
- Subcutaneous tissue and skin closure is performed in a routine manner.

**HAMATE BODY FRACTURES**

- A dorsal longitudinal or curvilinear incision is made centered over the ring or small finger CMC joints (TECH FIG 4A).
- The ring and small finger extensor tendons are retracted radially or ulnarily together or individually as needed.
  - There can be significant variation in the anatomic appearance and interconnections of the extensor digitorum communis tendons to the ring and small fingers as well as the EDM (TECH FIG 4B). These variations usually dictate which direction to retract the tendons and whether to retract them together or individually to give the best access to the CMC joints.
- The CMC joint capsule and dorsal CMC ligaments are incised longitudinally. The CMC joint is cleared of any hematoma and bone fragments (TECH FIG 4C).
- The fracture site is cleared of hematoma and reduced while directly visualizing the distal articular surface.
  - A dental pick is useful to reduce small fragments.
  - The fracture is temporarily stabilized with Kirschner wires and fluoroscopic images are taken to confirm reduction (TECH FIG 4D,E).
- If there is a large dorsal fragment, two or more dorsal-to-volar lag screws (usually 2.0-mm screws or smaller) are placed perpendicular to the fracture line into the hamate body (TECH FIG 4F,G).
- If there are several small fragments, individual screws may be used for each piece, or a dorsal plate may be more effective (TECH FIG 4H).
  - Fluoroscopic images are necessary to confirm that the screws do not protrude outside of the hamate hook, potentially damaging ulnar neurovascular structures or flexor tendons.
  - The dorsal capsuloligamentous sleeve is closed if possible, thus providing a smooth gliding surface between the extensor tendons and the CMC joint and hardware.
  - The CMC joints may be pinned temporarily if still unstable.
  - In the acute setting, if the dorsal hamate fracture is of sufficient size and securely stabilized and the joint capsule is closed, this is usually not necessary.
  - Soft tissues and skin are closed in a routine manner.

**CAPITATE FRACTURES**

- Often a standard approach to the dorsal carpus is required and is carried out through the routine 3-4 extensor compartment interval.
- A dorsal midline longitudinal or curvilinear skin incision is made, in line with the middle finger ray and centered on the capitate.
- Full-thickness skin flaps are elevated radially and ulnarily.
- The extensor pollicis longus (EPL) is identified, released from its third extensor compartment, and transposed radially.
- The plane between the extensor tendons and the wrist capsule is developed by elevating the second and fourth compartments radially and ulnarily, respectively.
- The joint capsule and dorsal intercarpal ligament are usually divided longitudinally for access to the capitate body.
  - Alternatively, the capsule can be opened longitudinally distal to the dorsal intercarpal ligament (TECH FIG 5).
  - The capsule can be incised transversely distal to the ligament and in line with its fibers, provided that exposure of the capitate is adequate for reduction and fixation of the fracture.
- The fracture site is explored, cleaned as necessary, and stabilized with mini-screws, plates, or pins as indicated.
- The EPL tendon is left transposed, superficial to the extensor retinaculum.
- The retinaculum is closed over the second and fourth compartments, followed by routine closure of subcutaneous tissue and skin.

**TECH FIG 4 • (continued)** E. Temporary Kirschner wire. F,G. Screw fixation. H. Plate fixation.

**TECH FIG 5 • Dorsal intercarpal ligament anatomy.**
TRAPEZIOD FRACTURES

- The trapezoid is approached through a limited dorsal longitudinal or curvilinear incision centered over the index CMC.
- Care must be exercised to identify and protect dorsal radial sensory nerve branches.
- The EPL tendon is identified, released, and transposed radially if needed.
- In the case of limited exposure of the trapezoid, simple retraction of the EPL distal to the extensor retinaculum is effective.

A longitudinal interval is developed between the extensor carpi radialis longus (ECRL) and brevis (ECRB) tendons with radial and ulnar retraction, respectively.
- It is important to stay ulnar to the ECRL to avoid inadvertent damage to the dorsal branch of the radial artery.
- The capsule is divided longitudinally, exposing the trapezoid and the index CMC joint.
- Fracture fixation is carried out with mini-screws or pins, the capsule is closed, and routine subcutaneous tissue and skin closure is performed.

TRAPEZIUM FRACTURES

- Fractures of sufficient size and significant displacement are internally fixed (TECH FIG 6).
- Excision rather than internal fixation may be warranted based on preoperative and intraoperative considerations.
- Unless the fracture planes dictate a specific approach for fixation, the surgeon has the option of using whichever approach he or she is most comfortable with for routine surgical treatment of thumb CMC arthritis (see Chap. HA-102).
- The Wagner approach (described below) is one such approach frequently used for surgical reconstruction of thumb CMC arthritis and is an effective exposure for internal fixation of body fractures.
- Isolated trapezial ridge fractures and nonunions are best approached using the flexor carpi radialis (FCR) approach centered on the scaphotrapezial joint, with retraction of the FCR ulnarly or radially out of its trapezial groove to gain access to the ridge. The Wagner approach is also effective.
- For the Wagner approach, an incision is made along the radial border of the thumb metacarpal at the glabrous skin border.
- At the distal volar wrist crease, the incision is continued ulnarily to the level of the FCR tendon.
- Superficial radial sensory nerve and lateral antebrachial cutaneous nerve branches may be encountered and should be carefully preserved.
- The thenar musculature is elevated in a radial-to-ulnar direction off the thumb metacarpal base.
- Once the FCR tendon sheath is reached, it is incised longitudinally and the tendon is retracted ulnarily if necessary.
- The capsule overlying the trapeziometacarpal and scaphotrapezial joints is opened and the joints are visualized.
- The entire length of the trapezium may be exposed if needed, but it is critical to avoid subperiosteal dissection where not necessary for accurate fracture reduction.
- Extensive exposure may result in delayed union or nonunion.
- At this point, internal fixation is performed if technically feasible, usually using lag screw fixation.
- The capsule is carefully reapproximated and the subcutaneous tissues and skin are closed.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Carpal instability</th>
<th>Be aware of the carpal instability patterns that can accompany these fractures and treat accordingly.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Failure to recognize an associated carpal instability pattern can lead to progressive carpal collapse and degeneration.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Fracture identification</th>
<th>Preoperative imaging is critical so that all fractures that require stabilization are identified; consider CT scanning if plain radiographs are insufficient.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Failing to identify all unstable fractures before or during surgery can necessitate a return to the operating room.</td>
</tr>
</tbody>
</table>
We recommend hamate hook excision as opposed to fixation due to the minimal, if any, added benefit with fixation and the concern for significant nerve and tendon injuries with internal fixation.

<table>
<thead>
<tr>
<th>Screw size</th>
<th>Use small interfragmentary screws or even small plates for fracture fixation whenever possible to decrease chances for hardware migration and to increase stability and possibly allow earlier range of motion.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Excision versus fixation</td>
<td>We recommend hamate hook excision as opposed to fixation due to the minimal, if any, added benefit with fixation and the concern for significant nerve and tendon injuries with internal fixation.</td>
</tr>
<tr>
<td>Future surgery</td>
<td>Be sure the patient is aware of the possible need for further surgery in the future, such as for hamate hook excision, addressing capitate avascular necrosis, excisional arthroplasty or arthrodesis for post-traumatic articular degeneration of any joints involved with the initial trauma, and so forth.</td>
</tr>
</tbody>
</table>

**POSTOPERATIVE CARE**

- Patients are placed in a well-padded volar plaster wrist splint postoperatively.
  - The digits, including the metacarpophalangeal (MCP) joints, are left free unless there is some contraindication, like a dorsal hamate fracture with CMC dislocation, which may require inclusion of MCP joints.
  - This allows early digital range of motion and elevation.
  - Following ORIF of a trapezial fracture, a short-arm thumb spica splint is applied.
  - Two weeks postoperatively the patient is placed in a custom fabricated splint (assuming there is no associated carpal instability).
  - If pins were used and are left outside of the skin, pin care is initiated at this time. Pins are usually removed 4 to 8 weeks postoperatively.
  - In the case of a CMC joint fracture in which relatively large fracture fragments are anatomically stabilized with rigid internal fixation, near-immediate postoperative range of motion is initiated.
  - For most other fractures, a total of about 6 weeks of wrist immobilization is followed by progressive range of motion.

**OUTCOMES**

- Most isolated carpal bone body fractures unite, and it is generally thought that these patients do quite well with regard to symptomatic and functional recovery.
  - The potentially symptomatic exceptions involving the hamate hook and trapezial ridge are easily treated by excision. Posttraumatic symptoms from other fractures, such as of the pisiform, trapezium, or triquetrum, may usually be addressed with isolated carpal bone excision with or without reconstruction, depending on the bone in question and other soft tissue and ligamentous considerations. For those carpal bones that cannot typically be simply excised, such as the hamate body and capitate, symptomatic posttraumatic changes may require partial or total wrist arthrodesis or other reconstructive options.
  - Associated injuries are often the most problematic, and patients must understand the guarded prognosis for severe destabilizing carpal injuries.

**COMPLICATIONS**

- Those complications common to all surgical procedures may occur, including but not limited to bleeding, infection, damage to structures, failure of surgery, potential need for more surgery, and untoward effects of anesthesia.
  - Patients must also understand the relative severity of their injuries and risk for pain, stiffness, and loss of function.
  - Capitate neck fractures are sometimes associated with nonunion or delayed union (up to 50% or more of isolated fractures) and may be analogous to scaphoid proximal pole fractures.
  - Treatment of such nonunions is similar for both entities.
  - Although rare, avascular necrosis of the capitate head may follow a capitate neck fracture that disrupts the vascular supply.
  - The capitate head may be excised with or without interpositional arthroplasty if attaining union is not likely because of avascularity or other issues.
  - Intra-articular fractures of the carpal bones are often complicated by posttraumatic arthritis. When symptomatic, treatment with traditional arthritis remedies, such as activity modification, anti-inflammatory medications, immobilization, or steroid injection, can be tried. If these fail to relieve the patient’s symptoms to his or her satisfaction, the patient may elect to proceed with partial or total wrist arthrodesis, partial carpectomy, whether of the proximal row or otherwise, or selective arthroplasties as indicated.

**REFERENCES**

DEFINITION
- Kienböck disease is a disorder of undetermined etiology that results in avascular necrosis (AVN) of the lunate.\(^5\)

ANATOMY
Lunate Vascularity
- The extraosseous blood supply of the lunate is extensive: branches of the radial and anterior interosseous arteries form a dorsal lunate plexus and branches of the radial, ulnar, and anterior interosseous arteries as well as the recurrent deep palmar arch form a volar plexus.
- The intraosseous blood supply is variable. Because the lunate is covered by cartilage proximally and distally, vessels can enter the bone only at its dorsal and volar poles.\(^1,13\)
- Three studies have identified “lunates at risk” from a vascular standpoint. The vulnerable lunate is one that has large areas of bone dependent on a single intraosseous vessel, which occurs in 7% to 20%. In addition, 31% of lunates have no internal arterial branching.\(^6,7,16\) These internal vascular arrangements may render the lunate more vulnerable to AVN, as injury to the single vessel could not be compensated for by collateral flow.

Ulnar Variance
- The standard posteroanterior (PA) wrist radiograph is taken with the shoulder and elbow at 90 degrees and the forearm in neutral rotation.
- In this view, the length of the distal ulna with respect to the distal radius is called ulnar variance (FIG 1).
- When the ulna is the same length as the radius, it is said to have neutral ulnar variance. When the ulna is shorter than the radius, it is referred to as negative ulnar variance, and when the ulna is longer than the radius it is referred to as positive ulnar variance.
- Theoretically, a negative ulna variance increases shear forces on the lunate.
  - The triangular fibrocartilage complex (TFCC) is thicker in these patients and the difference in compliance between it and the ulnar edge of the radius is accentuated, leading to greater shear force.
  - In addition, loads across the radiocarpal joint are borne disproportionately by the radius.\(^5\)
  - In the North American population, Kienböck disease is associated with an ulnar negative variance.
  - This relationship does not hold true in the Japanese literature.\(^1\)
  - Other authors have noted a tendency toward smaller lunates in patients with Kienböck disease.\(^3\)

PATHOGENESIS
- The cause of Kienböck disease is incompletely understood. Current thinking is that acute or repetitive trauma causes excessive shear forces on a lunate at risk, interrupting its intraosseous vascularity and leading to AVN.\(^1,2\)
- While a history of injury is elicited in over 50% of cases, the absence of a single traumatic event is still very common.
- Fracture of the lunate has been reported in up to 82% of lunates with Kienböck disease.\(^3\) However, it remains unclear whether these fractures are the cause or the result of AVN.
- Kienböck disease is not seen after lunate or perilunate dislocations.\(^5,13\)
- Although transient ischemia may be seen after carpal fracture-dislocations, this spontaneously resolves after 5 to 32 months and should be treated expectantly.\(^1,2\)
- The key feature of transient ischemia is that no progressive radiographic collapse occurs, as opposed to Kienböck disease, where radiographic changes and collapse are predictable.
- It has been suggested that Kienböck disease may be due to venous outflow obstruction with intraosseous vascular congestion, rather than arterial insufficiency. Increased intraosseous pressure has been shown in lunates with Kienböck disease, as well as in femoral heads with AVN.
The most common complaints are dorsal central wrist pain, rarely bilateral.3,21

The male–female ratio is approximately 3:1 to 7:1. It is patients between 20 to 40 years of age.

Most patients with Kienböck disease are young, active patients between 20 to 40 years of age.

This has led to significant concerns about the long-term effects of this disorder.

The male–female ratio is approximately 3:1 to 7:1. It is rarely bilateral.3,21

Regardless of gender, more than 95% of patients are engaged in heavy manual labor.21

The most common complaints are dorsal central wrist pain, stiffness, and significant weakness of grip, which is often reduced to 50% of the opposite hand.1,5,13

There may be a long history of symptoms before presentation.

The pain may vary in intensity from mild discomfort to constant, debilitating pain. It is often activity-related and improves with rest and immobilization.

A history of trauma is variable.1,5

The wrist is typically mildly swollen dorsally, consistent with synovitis, and is tender over the lunate.

Flexion and extension are predictably diminished.

Wrist flexion is more likely to be limited than extension because the volar pole of the lunate often extrudes so that it impinges against the volar rim of the distal radius.

Forearm rotation is not affected.13

While Kienböck disease has been reported in association with steroid use, septic emboli, sickle cell disease, gout, carpal coalition, and cerebral palsy, there is no well-defined correlation with any systemic or neuromuscular process that warrants screening when considering the diagnosis.3

IMAGING AND OTHER DIAGNOSTIC STUDIES

Radiographic Classification

Kienböck disease is diagnosed radiographically,12 and staging is based on plain radiographs.

In 1977, Lichtman and Degnan12 modified Stahle’s original radiographic classification in an attempt to help guide treatment decisions (FIG 2).

Stage I

Radiographs are normal, although a linear fracture without sclerosis or lunate collapse is occasionally present.

MRI shows the characteristic changes of AVN (FIG 3A).5,21

Stage II

The lunate becomes sclerotic and radiodense, similar to the radiologic appearance of other bones with AVN (FIG 3B). A coronal fracture splitting the lunate into dorsal and volar fragments may be noted.

Late in stage II, some loss of lunate height on the radial side may be evident.

The lunate retains its overall shape, and its anatomic relationship to the other carpal bones is not significantly altered.12,21

Stage III

The lunate collapses in the coronal plane and elongates in the sagittal plane. The carpal architecture is altered and the capitate begins to migrate proximally.

Stage IIIA

Lunate collapse has occurred, but carpal height is relatively unchanged and carpal collapse has not yet led to proximal migration of the capitate or scaphoid flexion. Therefore, the carpal kinematics have not yet been significantly altered.12,21

Stage IIIB

The carpal collapse with proximal capitate migration has led to fixed scaphoid flexion, which may be noted on the AP radiograph as the “cortical ring sign.”3,12,21

Stage IV

Arthritis of the radiocarpal or midcarpal joint has resulted from the collapse, fractures, and altered carpal kinematics, leading to joint space narrowing, osteophyte formation, subchondral sclerosis, and degenerative cysts.3,21

MRI and CT

MRI is extremely sensitive in detecting changes in marrow fat that are consistent with, but not diagnostic of, AVN.

Decreased signal on T1 sequences represents replacement of the normal fatty marrow by dead bone or fibrous tissue.21
Because MRI detects only the loss of marrow fat and not AVN specifically, to consider an MRI diagnostic for Kienböck disease over 50% of the lunate should be hypointense on T1 because the changes of Kienböck disease are diffuse, as opposed to other conditions such as ulnocarpal impaction, fractures, and intraosseous tumors, which cause more focal MRI changes.\(^4,20,22\)

- It is possible that a large enchondroma, interosseous ganglion, or other marrow-replacing lesion could lead to MRI changes in over 50% of the lunate. Thus, there is currently no truly pathognomonic imaging sign for Kienböck disease.\(^4\)

- T2 images typically show low signal intensity, which represents replacement of the normal fatty marrow by fibrosis.\(^21\)
- An increased T2 signal may occur if intramedullary edema is present or if revascularization is occurring.\(^3,4,20\)

Thus, when the T2 images show normal or increased signal intensity, an earlier stage of disease with a better prognosis can be inferred.\(^20,21\)

- Although it cannot diagnose AVN directly, MRI is still the optimal imaging modality and gold standard for diagnosing Kienböck disease, especially before trabecular bone has been destroyed.
- Gadolinium-enhanced MRI may provide a more sensitive means of evaluating lunate vascularity.
- CT may upstage the disease compared with radiographs in 89% of those originally considered to have stage I, 71% with apparent stage II, and 9% with apparent stage III disease on radiographs.\(^3\)
- Once lunate collapse has occurred, CT best reveals the extent of necrosis and trabecular destruction.\(^3\)
Differential Diagnosis

- Unnocarpal impaction
- Rheumatoid arthritis
- Radial-sided triangular fibrocartilage tears
- Posttraumatic arthritis
- Acute fracture
- Carpal instability
- Lunate fracture
- Enchondroma
- Osteoid osteoma
- Bone island
- Occult or intraosseous ganglion
- Intraosseous cyst
- Transient ischemia
- “Bone bruise”
- Paget disease
- Gaucher disease

Nonoperative Management

- A trial of 2 weeks to 3 months of immobilization may be attempted for patients with stage I Kienböck disease, especially young patients with hyperintense lunates on T2 MR images.
- The theory behind the use of immobilization is that by decreasing the forces across the carpus, the lunate may be able to revascularize.12
- Most series report poor results with immobilization, and progressive collapse is common.
- There is no study of immobilization consisting of patients with only stage I Kienböck disease. Consequently, the efficacy of immobilization in patients with stage I disease is anecdotal.
- Immobilization does not decrease compressive forces across the lunate, which are imparted by the capitae. The capitae may still force any fracture fragments apart, leading to collapse and displacement.
- Immobilization leads to stiffness.
- The earlier the lunate is unloaded, the less collapse is anticipated. For this reason, early surgical decompression may be considered rather than immobilization, and many clinicians treat stage I disease surgically.13
- In Trumble and Irving’s series of 22 patients with various stages of Kienböck disease treated with immobilization, 17 showed disease progression with continued collapse of the lunate and 5 showed no improvement.22
- In Lichtman et al’s series, 19 of 22 had unsatisfactory results.2,3
- When immobilization fails to reverse the avascular changes, the process will almost always advance to stage II, where surgical management is strongly recommended.2,3
- In a series of patients with stage II or more advanced disease treated with immobilization, 76% (19/25) had either undergone total wrist arthrodesis or experienced daily problems with their wrists at mean 8 (1–11) year follow-up.15
- A study of 18 patients with stage II or III disease treated nonoperatively were compared with those treated by radius shortening.
- Patients treated surgically had less pain and better grip strength.
- In some patients with stage III disease treated nonoperatively there was rapid deterioration to carpal collapse.
- Although radius shortening did not reverse or prevent carpal collapse, it slowed the process.18

Surgical Management

- There is no agreement on the optimal way to treat Kienböck disease.5 Multiple options for surgical management exist and the results do not vary significantly between the different procedures.
- The mainstays of treatment are radius-shortening osteotomy and proximal row carpectomy.5
- Two major radiographic features influence treatment choice: the stage of the disease and ulnar variance.12
- Radius-shortening osteotomy is currently the benchmark against which other treatments are judged.13
- For stages I to IIIB, radius-shortening osteotomy is a very popular option in patients who are ulnar negative. While the use of radius shortening in stage IIB is controversial, because lunate height and normal carpal kinematics will not be re-established, potentially leading to progressive degenerative changes, very good results have been demonstrated in these patients with this procedure.2,24,25 Radius shortening is contraindicated for stage IV disease unless symptoms are severe and salvage procedures are not desired.24
- Radius shortening decreases joint compression forces at the radiolunate joint by redistributing them to the radiocapitate and ulnolunate joints. In addition, it relatively lengthens the tendons crossing the wrist, diminishing overall joint compressive forces.17
- As opposed to ulnar lengthening, no intercalary bone graft is required and only one interface needs to heal, instead of two.
- In addition, radial shortening leads to a relative lengthening of the musculotenonidus units crossing the wrist, resulting in less force transmission across the carpus. Ulnar lengthening does not provide this particular advantage.24
- After radial shortening, the ulnar head and TFCC support more of the wrist’s compressive load through the triquetrum and the ulnar aspect of the lunate. The TFCC is thicker in patients with ulna-minus variance, which provides a compliant pad to support the ulnar carpus.
- Because radial-shortening osteotomy is an extra-articular procedure, it does not alter normal carpal joints or interfere with intracarpal relationships. It “burns no bridges,” and intracarpal procedures can always be undertaken at a later date if the radial shortening is ineffective and disease progression occurs.24
- In patients who are ulnar-neutral or ulnar-positive, a radial closing wedge osteotomy (FIG 4) or capitae shortening with or without capitohamate fusion can be performed.
- While radius shortening in patients with neutral or positive ulnar variance is not advised, good results have been reported even in these patients.1,24
- For stages I to IIIA, revascularization using a vascularized pedicle or bone graft may be performed and may be combined with radius shortening or another unloading procedure (see Chap. HA-24).
- In patients with stage IIIB disease, proximal row carpectomy, scaphotrapeziotrapezoid fusion, or scaphocapitate fusion may be performed with or without lunate excision and soft tissue interposition.
- For stage IV disease, proximal row carpectomy or total wrist fusion may be indicated. A study of arthroscopic débridement for stage III or IV disease showed some pain relief at 19 months of follow-up.14
Based on the hypothesis that Kienböck disease is due to venous obstruction, “metaphyseal core decompression” of the distal radius has also been reported with good results.8

- Wrist denervation may also be considered and can be used as an adjunct at any stage.3

- Lateral closing wedge osteotomies increase lunate coverage (joint contact area) in proportion to the decrease in radial inclination.
  - This transfers the compressive forces of the capitate from the lunate to the scaphoid, decreasing pressure at the radiolunate joint.17,23
  - To keep the wrist straight in relation to the forearm, the patient is forced to ulnarily deviate the wrist, extending the scaphoid, which may further transfer forces from the capitate to the scaphoid and decrease forces on the lunate.19

Preoperative Planning

- Good-quality, standard preoperative PA radiographs should be taken with the shoulder and elbow flexed 90 degrees and the forearm in neutral rotation.
- While many authors have recommended removing sufficient bone during radial shortening to result in an ulnar-neutral to 1-mm-positive variance,3 90% of the strain reduction occurs within the first 2 mm of shortening.1,5

Positioning

- The patient is positioned supine with the arm on a radiolucent armboard.

Approach

- A volar approach to the radius is performed.

**VOLAR APPROACH**

- A longitudinal incision is made over the flexor carpi radialis (FCR) tendon, ending distally at the distal volar wrist crease (TECH FIG 1A).
- The approach is continued through the FCR sheath (TECH FIG 1B), with the FCR tendon retracted ulnarly to protect the palmar cutaneous branch of the median nerve (TECH FIG 1C).
- The plane between the FCR and deep muscles of the radius (pronator quadratus and FCR) is bluntly dissected (TECH FIG 1D).
- The distal border of the pronator quadratus and the radial insertions of the pronator quadratus and flexor pollicis longus muscles are incised with Bovie electrocautery, with care taken to retract and protect the radial artery, which does not need to be formally identified.
- The volar surface of the radius is then subperiosteally exposed in a radial to ulnar direction (TECH FIG 1E).
- Circumferential subperiosteal dissection should be avoided to preserve maximal blood supply to the osteotomy.
Part 6  HAND, WRIST, AND FOREARM  •  Section III  CARPAL FRACTURES AND AVASCULAR NECROSIS

**RADIUS-SHORTENING OSTEOTOMY**

**Initial Plate Application**
- Traditionally, a seven-hole 3.5-mm dynamic compression plate is placed as far distally as possible without riding up the volar lip of the distal radius.\(^2\)
- However, the newer fixed-angle volar plates used for fixation of distal radius fractures work very well and allow the osteotomy to be placed in metaphyseal bone.
- To decrease the risk of nonunion, the osteotomy should be performed as distal as possible to be through metaphyseal cancellous bone, staying proximal to the DRUJ.
- The plate is placed over the distal radius so that its distal fixation will be within 2 to 3 mm of the subchondral bone, without intra-articular penetration. The plate is provisionally fixed with Kirschner wires (TECH FIG 2).
- Following fluoroscopic confirmation of appropriate placement, four fixed-angle screws are placed distally.

**Radius Osteotomy**
- The osteotomy is marked proximal to the distal fixation and proximal to the DRUJ (TECH FIG 3A).
- The plate is removed and the osteotomy is made at a 45-degree angle, from distal volar to proximal dorsal (TECH FIG 3B).
- An oblique osteotomy has less potential for nonunion than a transverse osteotomy\(^1\) and allows placement of an interfragmentary compression screw for additional fixation.

---

**TECH FIG 1** • A. Incision. B. Dissection proceeds through the flexor carpi radialis (FCR) sheath. C. The FCR is retracted ulnarly to protect the palmar cutaneous branch of the median nerve. D. The pronator quadratus is exposed. E. The volar distal radius is subperiosteally exposed.

**TECH FIG 2** • A, B. The volar locking plate is placed so that its distal fixation (represented radiographically by a Kirschner wire) travels just proximal to the subchondral surface. Distal locking screw fixation is placed but not fully tightened.
The 2 to 3 mm to be taken is measured out and marked and the full amount of bone to be taken is removed from volar to dorsal so that the dorsal cortex remains intact to stabilize the bone during bone removal (TECH FIG 3C).

The dorsal cortex is then removed last (TECH FIG 3D).

During the osteotomy, constant cool irrigant is used to avoid thermal osteonecrosis.

While a slight (1 mm) concave bend in the plate over the osteotomy site may occasionally be needed to achieve compression of the dorsal osteotomy surface, this is not usually necessary.

A longitudinal line may be marked across the osteotomy site to allow rotational assessment. However, the flat surface of the volar cortex allows for easy assessment of rotation.

An elevator can be placed on the dorsal surface of the osteotomy to protect the extensor tendons from the saw.

Two to 3 mm of shortening may be appropriate regardless of the amount of negative ulnar variance present.

For the reasons noted above, I prefer to shorten the radius by only 2 to 3 mm.

Excellent results have been reported with osteotomies that do not fully correct the radius length to neutral variance.²⁴,²⁵

The 2 to 3 mm to be taken is measured out and marked and the full amount of bone to be taken is removed from volar to dorsal so that the dorsal cortex remains intact to stabilize the bone during bone removal (TECH FIG 3C).

The dorsal cortex is then removed last (TECH FIG 3D).

Final Plate Application and Osteotomy Fixation

The plate and its distal fixation are then replaced.

Approximation of the two bone ends may also be facilitated by radial deviation of the wrist²⁴ and use of a Verbrugge clamp.

A bicortical screw is placed 1 cm proximal to (not through) the plate (TECH FIG 4A).
The hooked end of the Verbrugge is placed in the plate’s most proximal screw hole and the bifid end is placed around the screw proximal to the plate (TECH FIG 4B).

The Verbrugge clamp is closed manually, imparting tremendous mechanical advantage to compress the osteotomy.

The first screw is placed in a compression mode eccentrically in the plate hole just proximal to the osteotomy (TECH FIG 4C).

Reduction of the osteotomy and fixation are evaluated fluoroscopically.

Adjustments are made as necessary and the remaining screws are placed (TECH FIG 4D).

A lag screw is placed obliquely across the osteotomy through the most distal of the proximal plate holes for additional fixation (TECH FIG 4E–H).

After irrigation, osteoperiosteal shingling may be performed with allograft or bone substitute placed over the shingled cortex to facilitate healing (TECH FIG 4I).
Forearm rotation should be checked to ensure that it is full.
- If forearm rotation is limited after osteotomy, the radius should be translated radially or a lateral closing wedge component added.\textsuperscript{17}
- Radiographs often show some mild residual gap at the osteotomy site even with full compression under direct vision.\textsuperscript{24}

Intraoperative radiographs may not demonstrate the eventual ulnar variance (amount of radial shortening) because of soft tissue restraints at the DRUJ. In these cases, postoperative radiographs will demonstrate the anticipated correction.\textsuperscript{17}

**RADIUS CLOSING WEDGE OSTEOTOMY**

A 15-degree radial closing wedge osteotomy is performed 4 to 5 cm proximal to the tip of the radial styloid and proximal to the DRUJ.\textsuperscript{23}

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Radial shortening</th>
<th>Two to 3 mm of shortening is all that is needed in the vast majority of cases. Shortening the radius by only 2 to 3 mm makes compression of the osteotomy easier.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>In cases of significant DRUJ obliquity, shortening the radius greater than 2 mm may lead to DRUJ problems.</td>
</tr>
<tr>
<td>Fragment handling</td>
<td>If rotation is not full or the DRUJ is compromised after osteotomy, radial translation of the distal fragment should be considered.</td>
</tr>
<tr>
<td>Verbrugge clamp</td>
<td>Use of a Verbrugge clamp compressing against a screw proximal to the plate gives the surgeon a tremendous mechanical advantage in shortening the osteotomy.</td>
</tr>
</tbody>
</table>

**POSTOPERATIVE CARE**

- The extra-articular nature of this procedure combined with stable internal fixation allows for quick postoperative rehabilitation.
- The wrist is splinted for 2 weeks, after which a removable splint may be used and gentle motion started.
- The osteotomy usually heals in 2 to 3 months, although 4 or 5 months is occasionally required.

**OUTCOMES**

A review of the reported series by Weiss\textsuperscript{24} in 1993 included 121 patients treated with radius shortening, with about 85% good or excellent results at just over 4 years of follow-up.

- One study reviewed 30 wrists after radial shortening osteotomy for stages I to IIIB Kienböck disease at mean 3.8 years of follow-up.\textsuperscript{25}
  - Pain decreased in 87% and grip strength improved in 49%. However, the radiographic appearance of the lunate changed little if at all.
  - The authors noted that good results could be obtained by shortening less than that required to attain neutral ulnar variance.
  - The exact amount of radius shortening may not be as important as the relative unloading of the lunate resulting from the shortening of the radius. The amount of shortening needed to be effective may be only about 2 mm. Radial shortening may therefore be used in ulnar-neutral wrists.
  - In addition, excellent results were realized in patients with stage IIIA and IIIB disease. There was one nonunion. Only 10 of 30 wrists had evidence of possible lunate revascularization, as indicated by decreased sclerosis and a more normal trabecular pattern.
- Clinical improvement after radius shortening or radial wedge osteotomy does not necessarily correlate with the radiographic results.\textsuperscript{1,5,19} It appears that the lunate “stands still in time” after radius shortening, with no significant further deterioration or improvement in the lunate architecture or height.\textsuperscript{24}
- Another study reviewed 68 radius-shortening osteotomies at a mean of 52 months of follow-up.\textsuperscript{17}
  - Pain was diminished in 93%, grip strength was improved in 74%, and motion was improved in 52% and worsened in 19%.
  - Twenty-five patients had undergone one or more additional procedures concurrently, which did not lead to a significant difference in clinical outcomes.
  - Complications were uncommon; there were no nonunions, but ulnocarpal impaction developed in two patients.
  - Lunate density was improved in 40%, unchanged in 46%, and increased (worsened) in 14%.
  - Fifty-five percent of wrists that underwent concurrent vascularized bone grafting of the lunate had an improved radiographic appearance, compared to only 20% that underwent isolated radius shortening.
- It has been suggested that prognosis is improved in younger patients due to increased remodeling potential.\textsuperscript{12}
  - Teenage patients (aged 11 to 19 years) were treated by radius shortening or lateral closing wedge osteotomy.\textsuperscript{9} Two had neutral or positive ulnar variance. At a mean 30 months of follow-up, 10 of 11 were pain-free. Five of six with stage IIIB disease had excellent outcomes.
The other patient had moderate wrist pain during strenuous activity, leading to only a fair result after lateral closing wedge osteotomy for stage IIIB disease.

Radiographic improvement, indicating possible lunate revascularization, was seen in 8 of 11 patients.

There were no complications of radial overgrowth or growth abnormalities in these patients.

Twenty-five patients were followed for a minimum of 10 years (mean 14.5 years) after radial osteotomy. 23

Nonunion has been reported in up to 6% of cases. 5

COMPLICATIONS

Nonunion has been reported in up to 6% of cases. 5

If the fixation remains stable, treatment should consist of autogenous cancellous bone grafting if healing has not occurred by 5 or 6 months.

A second operation may occasionally be necessary for plate removal, but this is uncommon.

Care must be taken not to overshorten the radius, or DRUJ incongruity or ulnocarpal impaction may occur. 24

REFERENCES

DEFINITION
- Lunate revascularization for Kienböck disease involves transfer of either a vessel or a pedicled bone graft to the lunate in an attempt to reverse avascular necrosis.
- Vascularized bone grafts from the pisiform, volar and dorsal radius metaphysis, second metacarpal head, and iliac crest (via free microvascular graft) have all been reported.
- Unloading procedures, like a capitate shortening osteotomy, are often combined with a revascularization procedure to protect the graft and to alter forces through the lunate.

ANATOMY
Vascular Anatomy of the Dorsal Distal Radius
- The dorsal distal radius is primarily supplied by the branches of the radial artery and the posterior division of the anterior interosseous artery (pAIA) (Fig 1).
- The 2, 3 intercompartmental, supraretinacular artery (2, 3 ICSRA) is superficial to the extensor retinaculum and passes between the second and third extensor compartments (Fig 1).
- The fourth extensor compartment artery (ECA) is located deep to the extensor retinaculum in the fourth extensor compartment (Fig 1).
  - It lies directly adjacent to the posterior interosseous nerve on the radial floor of that compartment.
  - It originates from the pAIA or the fifth ECA.
  - It anastomoses with the dorsal intercarpal arch and the dorsal radiocarpal arch.
  - The fourth ECA is a source of numerous small nutrient arteries to the dorsal radius at the level of the fourth extensor compartment that penetrate deeply into cancellous bone.
  - The fifth ECA is located deep to the extensor retinaculum in the fifth extensor compartment or within the septum between the fourth and fifth extensor compartments (Fig 1).
  - It is the largest of the four dorsal vessels.
  - It originates from the pAIA and anastomoses distally with the fourth ECA, the dorsal intercarpal arch, the radiocarpal arch, the 2, 3 ICSRA, and/or the oblique dorsal artery of the distal ulna.
  - The fourth and fifth ECA pedicle is ideal for use in grafting the lunate because of the large diameter of the fifth ECA, the length of combined pedicle, the ulnar location of the fifth ECA (away from necessary incisions), and the multiple anastomoses, which provide retrograde flow.
  - The fifth ECA by itself seldom provides direct nutrient branches to the radius.
  - A 2, 3 ICSRA graft based on antegrade flow through the fifth ECA can be used if the fourth ECA is damaged or not present.

Vascular Anatomy of the Dorsal Hand
- The blood supply to the hand consists of a series of anastomotic arches over the carpus that form the dorsal carpal arch, usually with contributions from both the radial and ulnar arteries (Fig 1).3,8
- The dorsal carpal arch lies distal and deep to the extensor retinaculum.
- The dorsal metacarpal arteries lie just deep to the fascia overlying the interossei muscles.
- The second, third, and fourth dorsal metacarpal arteries arise from the dorsal carpal arch. They terminate by dividing into digital arteries.
The digital arteries are also supplied by perforating branches from the deep palmar arch.
- The first and fifth dorsal metacarpal arteries are direct branches from the radial and ulnar arteries respectively.
- The second dorsal metacarpal artery is the preferred vascular source for vessel implantation due to its size and predictable presence.
  - If this vessel is damaged or cannot be found, the third dorsal metacarpal artery may be used.

SURGICAL MANAGEMENT
- Treatment of Kienböck disease is based on the following factors:
  - Lichtman stage
  - Ulna variance
  - Presence of arthritic changes
  - Integrity of the lunate’s cartilaginous shell (FIG 2)
  - Patient symptoms and other patient-specific factors
- Nonsmokers with Stage I to IIIA Kienböck disease, an intact lunate cartilaginous shell (as determined using sagittal images and at surgery), and limited arthritic changes are suitable candidates for treatment using a vascularized grafting procedure (FIG 3).
- Relative contraindications to vascularized grafting include:
  - Previous surgery with exposure of the dorsal aspect of the hand and wrist
  - Age more than 60 years
  - History of peripheral vascular diseases or poorly controlled diabetes
  - Vascular grafting is accompanied by a lunate unloading procedure.
  - Unloading has been shown to improve symptoms related to Kienböck disease (see Chap. HA-23).
  - Altering force distribution through the lunate serves to protect the vascular grafts and to encourage revascularization.

FIG 2 • A. At the time of surgery the articular surfaces are carefully evaluated. B. T2-weighted MRI sagittal image of the lunate revealing a coronal plane fracture line, separation of volar and dorsal fragments, and interruption in the cartilaginous envelope. (Copyright Thomas R. Hunt, III, MD.)

FIG 3 • A, B. AP and lateral radiographs showing stage II–III Kienböck disease with sclerosis and subtle, early collapse. There is no evidence of a coronal plane fracture line. C. T1-weighted MRI coronal image showing loss of marrow signal of the lunate. (Copyright Thomas R. Hunt, III, MD.)
Unloading procedures commonly used in conjunction with a vascular procedure include:

- Capitate shortening osteotomy is our preferred choice in patients with positive or neutral ulna variance. This procedure is completed before inserting the vascular graft or vessel.
- Scaphocapitate pinning or external fixation (4 to 6 weeks) is used when ulna variance is positive and a contraindication to capitate shortening osteotomy exists.
- Radius shortening and angular osteotomy is used when ulna variance is negative (see Chap. HA-23).
- Intercarpal arthrodesis (see Chap. HA-88).

Preoperative Planning

- The surgeon should review all imaging studies to determine the stage of the disease, ulna variance, and the status of the lunate’s articular shell.

Positioning

- The patient is positioned supine with the arm on a radiolucent armboard.
- A proximal arm tourniquet is applied. Gravity exsanguination of the limb before tourniquet inflation allows visualization of the vessels.

Approach

- The surgeon should consider arthroscopic assessment before the open approach if the status of the lunate articular shell is in question.
- The 4-5 portal and ulnar midcarpal portal should be avoided as they may damage 4+5 ECA.
- Dorsal approaches to the hand and the wrist are used.
- Specific incision placement varies based on the graft choice and associated lunate unloading procedure.

**VASCULARIZED BONE GRAFTING**

Exposure and Identification of the Fourth and Fifth Extensor Compartment Arteries

- Make a 5- to 6-cm longitudinal skin incision between fourth and fifth extensor compartments, ending distally between the third and fourth metacarpal bases.
- Incise the fifth extensor compartment.
- Identify the fifth ECA and its venae comitantes on the radial aspect of the compartment lying adjacent to or partially within the septum and separating the fourth and fifth extensor compartments (TECH FIG 1).
- Trace the fifth ECA proximally to its origin from the posterior division of the anterior interosseous artery as it emerges from the interosseous membrane.
- Identify the fourth ECA arising from the same feeding vessel.
- Trace the fourth ECA distally and identify the area of greatest vascular penetration into bone, typically 1 cm proximal to the radiocarpal joint.

Lunate Preparation

- Elevate the extensor retinaculum as a radial-based flap from the fifth through the second extensor compartments to allow joint capsulotomy.
- Carefully protect the dorsal carpal arch.

**TECH FIG 1** • A. The fifth extensor compartment artery is identified and carefully traced proximally to its origin from the posterior division of the anterior interosseous artery. B. Matching clinical photograph showing fourth and fifth extensor compartment arteries. (B: Copyright Thomas R. Hunt, III, MD.)
Perform a ligament-splitting capsulotomy and protect the scapholunate and lunotriquetral ligaments.

Inspect the lunate, its cartilage shell, and surrounding articular surfaces.

Consider vascularized bone grafting only if the shell is not compromised, the bone is not fragmented, and the joint is not arthritic.

Enter the noncartilaginous portion of the dorsal lunate cortex using a small curette or a 2- to 3-mm round burr.

Through this dorsal cortical window and under direct visualization and fluoroscopic guidance, carefully remove necrotic bone from the lunate by hand with curved and straight curettes.

Leave a shell of intact subchondral bone.

If the lunate is collapsed, expand it gently using a small blunt-ended lamina spreader.

The amount of expansion obtained is highly variable.

Use of a lamina spreader in this manner is not suggested in cases with bone fragmentation.

Determine the graft size required by measuring the dorsal excavated area of the lunate.

**Elevation of the Vascularized Bone Graft**

Using a smooth 0.045-inch Kirschner wire, outline the area of the distal radius most infiltrated by nutrient vessels from the fourth ECA.

The size of the graft is influenced by the nutrient vessels and the earlier measurement.

Ligate the posterior division of the anterior interosseous artery proximal to the fourth and fifth ECA branches (TECH FIG 2).

Sharply elevate the vascular pedicle from the bone while protecting the nutrient vessels at the graft site.

Complete elevation of the corticocancellous graft using sharp osteotomes, with judicious handling of the vascularized pedicle (Tech Fig 2).

Deflate the tourniquet to verify blood flow to the graft.

Protect the pedicle graft in a moist sponge.

**Placement of the Vascularized Bone Graft into the Lunate**

Obtain cancellous bone graft from the donor site in the distal radius and pack this graft into the lunate cavity using fluoroscopic images for guidance.

Using small, precise rongeurs, contour the corticocancellous pedicle graft to the size needed.

Insert the vascularized bone graft with the cortical surface arranged in a proximal–distal orientation and without tension on the vascular leash (TECH FIG 3).

This allows the graft to serve as a strut to help maintain lunate height during revascularization.

No internal fixation is necessary to secure the graft in the lunate.

**Closure**

Repair the capsule using absorbable suture, taking great care to avoid pressure on the vascular pedicle.

Close the extensor retinaculum with absorbable suture and the skin with Prolene.

Apply a nonocclusive dressing and a volar, below-elbow splint.
Incision and Approach

- Make an extensive dorsoradial incision extending from the second metacarpophalangeal joint to a point about 4 cm proximal to the wrist, which gently slopes ulnarly around the tubercle of Lister.
  - Visualize and protect the dorsal sensory branch of the radial nerve.
- Incise the extensor retinaculum over the third compartment and transpose the extensor pollicis longus into a subcutaneous position.
- Retract the contents of the fourth extensor compartment ulnarly and the second extensor compartment radially.
- Use fluoroscopy to confirm the lunate's location.
- Perform a standard ligament-splitting capsulotomy.
  - Take care to avoid injury to the transverse basal dorsosal metacarpal arch from which the vascular pedicle arises.
- Inspect the lunate and surrounding joints. Perform a synovectomy as required.

Elevation of the Second Dorsal Metacarpal Vascular Pedicle

- In the interval between the second and third metacarpals, incise the interosseous muscle fascia from proximal to distal.
  - The vessels lie underneath the aponeurosis that covers the interosseous muscles.
- Elevate the artery and venae comitantes along with a thin layer of surrounding perivascular areolar tissue from the second dorsal web space to the dorsal carpal arch (TECH FIG 4A).
  - Identify and coagulate all branches off this main metacarpal artery.
  - Ligate the vessel at its most distal location.
  - This should provide a 5- to 6-cm vessel of adequate length to reach the dorsal lunate.

Lunate Preparation and Implantation of the Vascular Bundle

- Curette and expand the lunate as discussed earlier.
- Pack autogenous cancellous bone graft into the lunate.
- Use a 2.7-mm bit and drill from dorsal to volar through the body of the lunate.
- Sew a 5-0 monofilament suture to the end of the mobilized vessel, then place the suture ends through the eye of a straight needle.
- Feed the vessel into the avascular portion of the lunate by passing the needle from dorsal to volar through the previously drilled hole, exiting the palmar skin just ulnar to the flexor carpi radialis tendon (TECH FIG 4B).
  - Make a small skin incision over the needle and tie the suture over the palmar antebrachial fascia.
  - Release the tourniquet to assess vessel patency.
  - Achieve hemostasis and close the capsule, retinaculum, and skin in the manner described earlier.
  - Apply a nonocclusive dressing and a volar, below-elbow splint.
If this trial reduction reveals that the proximal hamate is prominent in the midcarpal joint or the hamate–lunate articulation is incongruous, perform a hamate osteotomy in the same manner and at the same level as the capitate osteotomy.

**Capitate Osteotomy**

- After the capsular-sparing incision is performed for the vascular procedure but before the graft or vessel is inset into the lunate, identify the waist of the capitate and confirm the osteotomy site with fluoroscopic imaging.
  - The osteotomy should correspond to the level of the scaphotrapeziotrapezoidal joints (TECH FIG 5A).
- Use a sharp osteotome, a fine water-cooled saw, or both to resect a 2.0-mm wafer bone from the capitate (TECH FIG 5B).
- Complete the proximal cut before the distal cut.
- Perform a trial reduction using a Freer elevator in the midcarpal joint to control and compress the proximal capitate fragment.

**Osteotomy Fixation**

- Compress the two cut surfaces of the capitate manually as discussed earlier in preparation for placement of a cannulated, headless compression screw.
- Place the guidewire across the osteotomy site of the capitate from proximal to distal.
- Wrist flexion helps present the capitate head into the field. Be careful to avoid distraction of the osteotomy with this maneuver.
Confirm the placement of the guidewire with fluoroscopy.

- Insert the headless compression screw over the guidewire and achieve compression across the osteotomy site (TECH FIG 6A).

- Complete the vascular procedure as indicated and close the wrist capsule, the extensor retinaculum, and the skin (TECH FIG 6B).

- Apply a bulky hand dressing with a volar splint.

**POSTOPERATIVE CARE**

- Remove the dressing 10 to 14 days postoperatively and apply a below-elbow cast for 3 weeks.

- Remove the cast 4 to 5 weeks after surgery and initiate supervised therapy emphasizing active wrist motion. Over the next 4 weeks the patient can progress to active assisted and then passive range-of-motion exercises.

- A removable splint is used for 3 to 4 weeks.

- Evaluate the progress of healing using serial radiographs.

- Strengthening is initiated at 3 months after surgery and slowly progressed.

- Patients undergoing revascularization of the lunate are followed for 1 to 3 years.

**OUTCOMES**

- Lunate revascularization techniques have demonstrated promising clinical results for Kienböck disease.1,7

- Mazur et al4 described the results of nine reverse-flow pedicle grafts obtained from the radius metaphysis in patients with stage IIIA Kienböck disease.

- Grip strength was improved by 25%, ultimately measuring 60% to 100% of the opposite side.

- Range of motion of the wrist joint was not significantly different from the preoperative status.

- Radiographic measurements demonstrated no change in the modified carpal height ratio, lunate index, or scapholunate angle.

- MRI data demonstrated progressive signs of revascularization over time. Normalization of T2 values was seen initially by 18 months, followed by normalization of T1 values by 36 months.

- Moran et al5 retrospectively reviewed the results of 24 patients treated with vascularized bone graft using 4+5 extensor compartment artery (4+5 ECA).

- Grip strength improved from 50% to 89% of the unaffected side.

- Ninety-two percent of the patients had significant improvement in their pain.

- Seventy-seven percent of patients showed no further collapse on postsurgical radiographs.
Seventy-one percent of the patients showed evidence of revascularization with improvement in the T2 signal, T1 signal, or both.

Waitayawinyu et al9 described the results of 14 patients who had capitate shortening osteotomy with vascularized bone grafting for Kienböck disease; all had positive ulna variance.

Grip strength was improved from 58% to 78% of the normal side.

Average time to osteotomy healing was 48 days.

COMPLICATIONS

Failure of revascularization of the lunate or progression of disease may necessitate a second procedure such as intercarpal arthrodesis, proximal row carpectomy, total wrist arthrodesis, or wrist denervation.

Continued inflammation or disease progression may cause persistent pain, which may require brief periods of splinting during symptomatic flares.

REFERENCES

DEFINITION
- Thumb carpometacarpal (CMC) joint instability can occur as a result of ligament laxity or trauma.
- Regardless of the cause, injury to the stabilizing ligaments surrounding the CMC joint leads to instability and dorsoradial subluxation or dislocation of the thumb metacarpal.

ANATOMY
- The thumb CMC joint is a biconcave-convex joint similar to a horseback rider’s saddle.4
- The base of the thumb metacarpal has a prominent volar styloid process (beak) that articulates with a recess in the volar trapezium when in flexion.
- There are 16 ligaments that provide stability to the thumb CMC joint.1 Of these ligaments, the two that provide the most restraint against dorsoradial subluxation of the thumb metacarpal are the dorsoradial and volar beak ligaments (FIG 1).1,4,12,15
- The volar beak ligament (deep anterior oblique ligament, palmar ligament, ulnar ligament) originates from the volar central apex of the trapezium and inserts onto the volar beak of the thumb metacarpal.1 It lies immediately under a more widely based superficial anterior oblique ligament, which is located immediately deep to the thenar musculature and has a broad insertion across the base of the thumb metacarpal.
- The dorsoradial ligament originates from the dorsoradial tubercle of the trapezium and inserts onto the dorsal base of the thumb metacarpal. It is the thickest, widest, shortest, and strongest of the CMC ligaments.4

PATHOGENESIS
- The biconcave-convex nature of the thumb CMC joint allows for a wide range of thumb motion but is inherently unstable.7 Laxity or incompetence of the supporting ligaments, especially the volar beak or dorsoradial ligaments, will cause instability of the thumb CMC joint.10,12 Especially in middle-aged women, the cause of the laxity is often idiopathic.
- In addition, there is a population of patients who have inherent ligament laxity, such as those with collagen disorders like Ehlers-Danlos syndrome.
- In the setting of trauma, acute thumb CMC joint dislocation occurs with axial loading and flexion of the thumb metacarpal. In all reported cases, the dislocation occurs in a dorsoradial direction.11,12

NATURAL HISTORY
- Ligamentous laxity at the thumb CMC joint may cause degenerative changes to the joint cartilage and lead to arthritis, corresponding to higher stages in the Eaton–Littler staging system.2
- If the ligamentous laxity is symptomatic and causing pain, ligament reconstruction can be successful in reducing pain in over 90% of patients. Ligament reconstruction has also been shown to potentially halt the progression of arthritis.5

FIG 1 • The stabilizing ligaments of the thumb carpometacarpal joint. Of these, the dorsoradial and volar beak ligaments are the most important in preventing dorsoradial subluxation of the thumb metacarpal.
For traumatic dislocations, a stable reduction is important for thumb function. If the thumb CMC joint remains unstable, functions such as key pinch and grasp may be compromised.

Open ligament reconstruction of these unstable thumb CMC joint dislocations may decrease the incidence of recurrent instability and joint degeneration compared to closed reduction and pinning.\textsuperscript{11}

**PATIENT HISTORY AND PHYSICAL FINDINGS**

**Nontraumatic Ligamentous Laxity**

- The history should include questions about ligament laxity involving other joints. Metabolic diseases such as Ehlers-Danlos syndrome are notable.
- Radiographic findings often do not correlate with symptomatology. Therefore, it is important to elicit from the patient the exact symptoms and their severity.
- Any history of previous nonoperative treatments should be noted. If splinting and steroid injections have not been attempted, it may be beneficial to attempt these treatment modalities before discussing surgery.
- The physical examination should determine the degree of subluxation and reducibility of the thumb CMC joint.
- The thumb metacarpophalangeal (MCP) joint should also be examined for possible hyperextension laxity.
- Pinch strength and opposition should be tested and compared to the contralateral side.
- The hand should also be evaluated for concomitant carpal tunnel syndrome, flexor carpi radialis tunnel syndrome, and De Quervain tenosynovitis, as these may also need to be addressed.

**Traumatic Injuries**

- In addition to the evaluation cited for nontraumatic laxity, the history and physical examination should include the following:
  - Time and nature of the injury
  - Status of the thumb before injury
  - Stability of joint reduction: This is of major concern in the physical examination because assessment of stability will determine the treatment path.
  - Associated MCP joint collateral ligament injury and stability
  - Other associated hand injuries are important to note as well.
  - Tests to perform include the ballottement test and the grind test.
  - Tenderness associated with dorsal pressure indicates symptomatic subluxation.
  - Crepitance and pain are positive indicators of CMC pathology.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- A true lateral film of the thumb is one in which the sesamoids volar to the thumb MCP joint overlap each other.
- A 30-degree oblique stress view of the thumb CMC joint is performed by pressing the radial side of the thumb tips together. This maneuver will subluxate the thumb metacarpal base radially, thereby demonstrating the degree of laxity in the radial direction.\textsuperscript{14}

**DIFFERENTIAL DIAGNOSIS**

- De Quervain tenosynovitis
- Flexor carpi radialis tunnel syndrome
- C6 radiculopathy
- Trigger thumb

**NONOPERATIVE MANAGEMENT**

- For symptomatic ligament laxity and stage I or II basal joint disease, conservative management should first be attempted. This includes thumb spica splint immobilization and anti-inflammatory medications.\textsuperscript{6,13}
- If the symptoms do not improve, a steroid injection into the CMC joint can be attempted. The number of injections should be limited to a maximum of three; theoretically more than three injections increases joint morbidity.
- In the scenario of acute trauma, reduction of the CMC joint should be performed by applying axial traction and palmar-directed pressure to the base of the thumb metacarpal, along with pronation of the thumb metacarpal. After reduction, if the joint remains reduced, the injury can be treated with cast immobilization.
- If the joint is unstable at all after an attempt at closed reduction, surgical management is indicated.\textsuperscript{11}

**SURGICAL MANAGEMENT**

- Freedman et al\textsuperscript{5} have demonstrated that ligament reconstruction for symptomatic thumb CMC joint laxity can halt or slow the progression to degenerative arthritis. By providing joint stability, shear forces on the CMC joint and translation of the metacarpal on the trapezium can be minimized.
- In the presence of articular pathology, arthroplasty may be the treatment of choice, depending on the degree of chondromalacia.
- If greater than 20 degrees of MCP hyperextension is present with lateral pinch, MCP capsulodesis or arthrodesis may also need to be considered.\textsuperscript{14}
- If carpal tunnel syndrome or De Quervain tenosynovitis is present, carpal tunnel release or first dorsal compartment release may be needed at the time of surgery.
- For traumatic thumb CMC joint dislocations, Simonian and Trumble have shown that ligament reconstruction was superior to percutaneous pinning of unstable joints.\textsuperscript{11}
- When the injury pattern results in fracture-dislocations such as unstable Bennett and Rolando fractures, percutaneous pinning or open reduction and internal fixation may be the treatment of choice.

**Preoperative Planning**

- Plain films should be reviewed.
- In the case of acute trauma, associated fractures and hand injuries should be addressed.
A preoperative Allen test should be performed since all procedures involving the thumb CMC joint are in close vicinity to the radial artery, and iatrogenic injury may occur.

**Positioning**
- The procedure is performed with the patient supine and the arm on a standard hand table.
- The operating table should be turned away from the anesthesia machines to allow the surgeon and assistant to sit across from each other at the hand table.

**Approach**
- A number of techniques have been described for ligament reconstruction of the thumb CMC joint using a variety of different tendons, including the flexor carpi radialis, palmaris longus, extensor carpi radialis longus, extensor pollicis brevis, and abductor pollicis longus (APL).
- The technique presented here is the classic volar ligament reconstruction described by Eaton and Littler. This method effectively reconstructs both the volar and dorsal ligaments using the flexor carpi radialis.

**MODIFIED WAGNER APPROACH TO THE THUMB CMC JOINT**
- The incision is started longitudinally along the radial side of the thenar mass, at the junction between the glabrous and nonglabrous skin. The distal extent of the incision is near the midpoint of the thumb metacarpal (TECH FIG 1A).
- Proximally at the wrist crease, the incision is brought transversely across the wrist to the ulnar side of the flexor carpi radialis tendon.
- Once through the skin, care should be taken to avoid transection of superficial radial sensory nerve branches that may be crossing the operative field.
- The soft tissue is bluntly dissected until the thenar musculature is identified (TECH FIG 1B). The radial border of the thenar muscle mass is incised and the muscles are elevated extraperiosteally to expose the CMC joint capsule. The capsule is incised and the thumb metacarpal base, the CMC joint, and the trapezium exposed (TECH FIG 1C).
- Blunt dissection is continued dorsally toward the extensor pollicis longus and brevis tendons. The dorsal metacarpal cortex is exposed between these tendons.

**FLEXOR CARPI RADIALIS GRAFT HARVEST**
- The flexor carpi radialis tendon is identified just radial to the palmaris longus tendon at the wrist crease. The tendon sheath is then opened.
- A transverse incision is made proximally in the forearm overlying the flexor carpi radialis musculotendinous junction, about 8 to 10 cm proximal to the wrist crease (TECH FIG 2A,B).
- The soft tissue is bluntly dissected until the tendon sheath is identified and opened. The flexor carpi radialis tendon is then exposed.
- A longitudinal split is made in the midline of the tendon just proximal to its insertion onto the trapezium. A 0 Prolene suture is then passed through the longitudinal split (TECH FIG 2C).
A pediatric feeding tube is now passed from the proximal wound into the distal wound, just under the flexor carpi radialis tendon sheath but superficial to the flexor carpi radialis tendon fibers. The tip of the feeding tube is cut off, and the two ends of the Prolene suture are passed through the end of the feeding tube from distal to proximal. Once the suture is seen in the proximal wound, the feeding tube can be removed, leaving the ends of the Prolene suture in the proximal wound site (TECH FIG 2D–F).

TECH FIG 2 • A. Flexor carpi radialis harvest incision is made 8 to 10 cm proximal to the wrist crease. B. Flexor carpi radialis musculotendinous junction. C. A longitudinal split is made through the flexor carpi radialis distally and a 0 Prolene suture is passed through it. D. A pediatric feeding tube is passed from the proximal to the distal wound. E. The Prolene suture is then passed through the feeding tube from distal to proximal. F. The feeding tube is removed, leaving the Prolene suture ends in the proximal wound. G. The two suture ends are pulled, thereby dividing the flexor carpi radialis tendon in half until the proximal wound is reached. The flexor carpi radialis tendon spirals, so the distal radial half corresponds to the proximal ulnar half of the tendon. H. The split flexor carpi radialis tendon is delivered into the distal wound.
The two suture ends in the proximal wound are now pulled so that the rest of the suture is delivered from the distal to the proximal wound. In so doing, the suture will divide the flexor carpi radialis tendon in half along its course into the proximal wound (TECH FIG 2G).

At this time, the ulnar half of the tendon is transected proximally just after the musculotendinous junction. The fibers of the flexor carpi radialis tendon spiral, so the ulnar half of the tendon will continue to become the radial half of the tendon distally at the wrist. Before transection, traction should be applied to the proximal ulnar half of the tendon to ensure that it corresponds to the distal radial half of the tendon.

The split flexor carpi radialis tendon is finally delivered into the distal wound (TECH FIG 2H).

**METACARPAL TUNNEL PLACEMENT AND FLEXOR CARPI RADIALIS GRAFT PASSAGE AND FIXATION**

- A tunnel is made from dorsal to volar in the thumb metacarpal, 1 cm distal to the articular base. The tunnel should start dorsal to the APL insertion and then course parallel to the articular surface, exiting volarly just distal to the insertion of the volar beak ligament onto the metacarpal base.
  - The tunnel is started by first drilling a 0.045 Kirschner wire from dorsal to volar in the manner described.
  - The tunnel is enlarged by drilling a 0.062 Kirschner wire, followed by a 3.5-mm drill (TECH FIG 3A,B).
  - Once completed, a nylon whipstitch is placed in the end of the flexor carpi radialis graft. The ends of the stitch are passed through the metacarpal tunnel from a volar to dorsal direction. The stitch is pulled dorsally, delivering the flexor carpi radialis graft through the metacarpal tunnel to the dorsum (TECH FIG 3C).
  - As the graft exits the dorsal hole in the metacarpal, the thumb is extended and abducted. The graft is pulled tightly and then allowed to relax 2 to 3 mm to set the appropriate tension.
  - Once the graft tension is set, the graft is sutured to the metacarpal periosteum where it exits the dorsal hole using nonabsorbable 3-0 suture material.
  - The flexor carpi radialis graft is then passed under the APL tendon radially toward the volar side of the wrist. The graft is sutured to the APL with similar nonabsorbable 3-0 suture material as it is passed underneath it.
  - The graft is then passed underneath and around the ulnar portion of the flexor carpi radialis tendon that has remained intact. The graft is also sutured to the flexor carpi radialis tendon as it is looped around it.
  - If there is additional length to the graft, it is brought back dorsally and again passed underneath and sutured to the APL (TECH FIG 3D).
  - A 0.045-inch Kirschner wire is drilled from the radial thumb metacarpal base into the trapezium to immobilize the CMC joint. The wire is removed after 5 weeks once adequate soft tissue healing has occurred (TECH FIG 3E).
TECH FIG 3 • (continued)  D. The flexor carpi radialis graft is passed underneath and sutured to the abductor pollicis longus, the remaining flexor carpi radialis, and back dorsally to the abductor pollicis longus if the graft length permits.  E. A 0.045 Kirschner wire is drilled from the thumb metacarpal into the trapezium to protect the ligament repair.

WOUND CLOSURE

- The thenar muscle mass is reapproximated and sutured using synthetic absorbable 3-0 suture material.
- The proximal and distal skin incisions are closed with 5-0 nylon sutures (TECH FIG 4).
- The hand is then placed in a short-arm thumb spica splint.

TECH FIG 4 • Final wound closure with nylon sutures.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>In the setting of stage I or II basal joint disease and ligament laxity, the status of the articular cartilage must be carefully assessed intraoperatively. If significant cartilage damage is present, arthroplasty may be preferred.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Approach</td>
<td>Care must be taken to identify and preserve the superficial radial sensory nerve and lateral antebrachial cutaneous nerve branches to prevent neuroma formation.</td>
</tr>
</tbody>
</table>
| Flexor carpi radialis graft harvest | The entire insertion of the flexor carpi radialis onto the second metacarpal base must be left intact.  
Transect the proximal portion of the graft near the musculotendinous junction to ensure that adequate graft length will be obtained.  
Once the graft harvest is completed, the graft should occasionally be moistened through the remainder of the procedure to prevent desiccation and tenocyte injury. |
| Metacarpal tunnel placement | Start with a small-diameter tunnel. Gradually increase the diameter of the tunnel until the graft fits snugly through it.  
When creating the tunnel, be careful not to injure the insertion of the APL onto the radial base of the thumb metacarpal. |
| Flexor carpi radialis graft passage and fixation | It is important to set the appropriate graft tension. After placing a few periosteal sutures to hold the graft, make sure that the thumb can still be brought back into a neutral position.  
Before weaving the graft under the APL and around the intact flexor carpi radialis tendons, check an image to ensure that the CMC is adequately reduced.  
Braided synthetic suture such as Ethibond is soft and may be less palpable than stiffer suture such as Prolene. |
POSTOPERATIVE CARE
- AP, lateral, and oblique films or fluoroscopic mini C-arm views are obtained intraoperatively to evaluate CMC joint congruency and Kirschner wire placement.
- The thumb spica splint is left in place for 2 weeks. At 2 weeks of follow-up, the dressings are taken down, sutures are removed, and a new thumb spica splint is applied.
- At 5 weeks of follow-up, the Kirschner wire is removed and a removable thumb splint is used for protection. The splint can be removed for therapy, which can be started at this time.
- Therapy should start with active range-of-motion exercises of the wrist, thumb CMC, MCP, and interphalangeal joints. Thumb abduction, flexion, and opposition are emphasized.
- Strengthening exercises can be started at 2 months after surgery, and full activity without restrictions can begin at 3 months.

OUTCOMES
- When performed for stage I basal joint disease, ligament reconstruction has been shown to improve pain and establish joint stability.
  - In a number of long-term follow-up studies of over 5 years, 87% to 100% of patients demonstrated joint stability against stress testing, 29% to 67% of patients reported no pain, and 83% to 100% reported marked improvement in pain. Interestingly, only 0% to 37% of patients progressed to a higher stage of arthritis.\(^5,8\)
  - Freedman et al\(^5\) reviewed their long-term results of 24 thumbs that underwent ligament reconstruction for stage I or II disease. After a minimum of 10 years of follow-up, 29% of patients reported no pain, 54% reported pain with strenuous activity only, and 17% of patients had pain during activities of daily living. When tested against stress, 87% demonstrated joint stability.
  - Simonian and Trumble\(^11\) found that 89% of patients who underwent ligament reconstruction after traumatic thumb CMC dislocation had no pain with work at 2 years of follow-up. Also, none of the patients in this treatment group had any evidence of joint instability, and no revision procedures were required. This is in contrast to 50% of patients who had residual joint instability and pain after closed reduction and percutaneous pinning. Of this treatment group, 38% required revision surgery and underwent ligament reconstruction. 12% of these patients required CMC arthrodesis.

COMPLICATIONS
- Residual joint instability
- Residual pain, likely due to untreated arthritis involving surrounding joint articulations, such as the scaphotrapezial joint
- Radial artery injury
- Superficial radial nerve or lateral antebrachial cutaneous nerve injury
- Pin tract infection

REFERENCES
DEFINITION
- The first carpometacarpal (CMC) joint comprises the thumb metacarpal base and the trapezium.
- The thumb CMC joint is vital to the function of the hand, and injuries can result in pain, weakness, and loss of grip or pinch strength.
- Two fracture-dislocation patterns commonly result from trauma to the thumb CMC joint: Bennett and Rolando fractures.
  - Bennett fractures are intra-articular fractures in which the metacarpal shaft is radially displaced by the pull of the abductor pollicis longus tendon, leaving an intact ulnar fragment at the base of the thumb metacarpal that is held reduced by the strong volar beak ligament (**FIG 1A**).
  - Rolando fractures are complex intra-articular fractures involving the base of the thumb metacarpal that often have a T- or Y-type pattern. These fractures are classically described as being three-part; however, the name also applies to more comminuted fracture variants (**FIG 1B**).

ANATOMY
- Understanding the deforming forces in these fracture-dislocations is important when deciding on treatment options and determining prognosis.
- The thumb metacarpal serves as the site of attachment for several tendons, including the abductor pollicis longus (APL) at the proximal base, the adductor pollicis (AP) distally, and the thenar muscles volarly.
- The articular surfaces of the thumb metacarpal base and trapezium resemble reciprocally interlocking saddles and allow motion in many planes.
- Joint stability is maintained by five primary ligaments: the anterior-volar (beak), the posterior oblique, the dorsal radial, and the anterior and posterior intermetacarpal ligaments (**FIG 2**).

**FIG 1 • A.** A typical Bennett fracture is a unicodial fracture of the base of the first metacarpal with the fracture fragment consisting of the volar-ulnar corner of the proximal metacarpal.  
**B.** A Rolando fracture is multifragmentary, with the entire articular base of the metacarpal being involved. By definition, no portion of the metacarpal shaft is in continuity with the carpometacarpal joint.

**FIG 2 • A,B.** Anterior and posterior views of the thumb basal joint stabilizing ligamentous structures. The crucial anterior, volar-oblique (beak) ligament is often attached to the displaced Bennett fragment.
Buchler et al\(^2\) described three zones at the base of the thumb metacarpal (FIG 3):
- Zone 2 represents the central portion of the joint that is normally loaded.
- Zone 1 includes the volar aspect of the joint.
- Zone 3 involves the dorsal aspect of the joint.
- The trapezium has several important adjacent articulations. These include the first metacarpal base, the radial aspect of the second metacarpal base, the scaphoid, and the trapezoid (along with the trapezium, these last two make up the STT joint).

PATHOGENESIS
- Bennett fractures occur when the partially flexed thumb metacarpal is axially loaded, resulting in a Bennett articular fragment (the volar-ulnar portion of the metacarpal base) and the remainder of the metacarpal that displaces dorsally, proximally, and radially.
- Rolando fractures result from a similar injury mechanism and may have a variable degree of comminution at the base of the thumb metacarpal.
- In Bennett-type fractures, the thumb metacarpal shaft is displaced dorsally and proximally by the pull of the APL at the metacarpal base, and angulated ulnarly by the AP and the extensor pollicis longus (EPL) tendons, which insert more distally on the digit.\(^{15}\)
- Rolando-type fractures are subject to the same deforming forces, except that the APL can sometimes displace both the shaft and the dorsal-radial basilar articular fragment.
- Due to the deforming forces that act on the fracture fragments, both injury patterns are usually unstable and difficult to reduce and stabilize by closed means.

NATURAL HISTORY
- Injuries to the thumb CMC joint are the most common of all thumb fractures.\(^4,8\)
- Nonoperative treatment is generally reserved for nondisplaced fractures. There is a low likelihood of maintaining reduction using closed means in displaced fractures.
- Residual subluxation of the metacarpal shaft leads to basal joint incongruity and the potential for developing posttraumatic arthrosis.\(^5\) In addition, residual intra-articular step-off greater than 1 mm may predispose to the development of arthrosis, although this has not been found to be true in all studies.\(^5,6,19\)

PATIENT HISTORY AND PHYSICAL FINDINGS
- Most of these fractures occur with direct trauma to the thumb tip, often from a fall or sports-related injury.
- The injury is most common in young males, and two thirds occur in the dominant hand.\(^8,15\)
- The history should reveal whether the patient had pre-existing basal joint arthritis, which is common and will affect treatment options and expected results.
- Common physical examination findings include tenderness and ecchymosis surrounding the thumb CMC joint, crepitus with attempted motion, instability, and a "shelf" deformity resulting from displacement of the metacarpal shaft dorsally (FIG 4).\(^{16}\)
- Metacarpal subluxation or dislocation represents an unstable fracture.
- Range of motion is decreased and may be associated with crepitus. Adjacent joints may also have arthrosis and decreased range of motion.
- It is important to perform a complete neurovascular examination and to search for associated pathology such as wrist ligamentous injuries.
- Neurovascular injuries are uncommon but compartment syndrome should be suspected in higher-energy injuries.
- Tendon function should be examined, specifically the EPL, flexor pollicis longus (FPL), and extensor pollicis brevis (EPB).
IMAGING AND OTHER DIAGNOSTIC STUDIES
- AP, lateral, and oblique images of the hand should be obtained, although the oblique plane of the thumb in relation to the hand may make these images difficult to interpret.
- A true AP view of the thumb CMC joint can be obtained with the forearm maximally pronated with the dorsum of the thumb placed on the cassette (FIG 5A).17
- A true lateral view, advocated by Billing and Gedda,1 is obtained with the hand pronated 20 degrees and the thumb positioned flat on the cassette. The x-ray beam is tilted 10 degrees from vertical in a distal-to-proximal direction (FIG 5B).
- Radiographs of the contralateral, uninjured basal joint are helpful in certain cases as a template for reconstruction.
- Computed tomography may be indicated if a significant amount of articular comminution is present or when plain films inadequately demonstrate the pathology.
- A traction view may be helpful in Rolando-type fractures in which nonoperative treatment is being considered and tomography is not available (FIG 5C).
- Fluoroscopy alone should be used with caution in ensuring anatomic reduction as this has recently been shown to be less accurate than plain x-rays or direct visualization.3

DIFFERENTIAL DIAGNOSIS
- Bennett-type fracture
- Rolando-type fracture
- Basal joint degenerative joint disease
- STT joint arthrosis
- Thumb CMC joint ligamentous injury
- Trapezial body fracture
- De Quervain tenosynovitis

NONOPERATIVE MANAGEMENT
- Nondisplaced, minimally comminuted fractures may be treated with closed reduction and thumb spica casting, but precise molding of the cast and close observation for fracture displacement are necessary.
- In a Bennett fracture, closed treatment may be indicated if there is minimal displacement between the volar ulnar fragment and the metacarpal shaft. Most importantly, a concentric reduction of the metacarpal base in Bennett fractures must be maintained.6
- Several factors make closed treatment of these intra-articular fractures problematic and worsen results:
  - Difficulty in providing accurate three-point molding of the thumb metacarpal
  - Treatment of patients 4 or more days after the initial injury
  - Difficulty assessing the adequacy of reduction with radiographs taken through the cast4,9
- Some studies looking at closed treatment have demonstrated decreased motion, grip strength, and radiographic evidence of degenerative joint disease at long-term follow-up.14
- Development of degenerative changes may occur if there is any residual subluxation of the thumb metacarpal shaft.5,8

SURGICAL MANAGEMENT
- The majority of displaced Bennett fractures and almost all Rolando fractures require percutaneous Kirschner wire fixation or open reduction and internal fixation.
- The goals of surgery are to restore the articular congruity of the thumb CMC joint and to align the first metacarpal base articular surface with the trapezium.
- In thumb CMC joint fractures associated with trapezial body fractures, the trapezial articular surface should first be reduced anatomically before proceeding to the thumb metacarpal fracture.16

**Bennett Fractures**
- Closed reduction and percutaneous pinning is the preferred treatment for most Bennett fractures with displaced fracture fragments representing less than 25% to 30% of the articular surface.16,18

**FIG 5** A. An ideal AP view of the thumb and carpometacarpal joint is taken with the forearm hyperpronated and the dorsum of the thumb on the cassette. B. A true lateral view of the carpometacarpal joint is obtained with the radial aspect of the thumb on the cassette and the other fingers clear of the x-ray beam. C. A fluoroscopic view of a Rolando fracture with traction applied. Distraction at the carpometacarpal joint helps to delineate the fragments at the base of the metacarpal. (Copyright John Capo, MD.)
The metacarpal base often needs to be pinned to the unfractured second metacarpal, trapezoid, or trapezium to lessen the deforming forces on the fracture.

Residual displacement of the joint surface greater than 2 mm after attempted closed reduction and percutaneous pinning or impaction in the force-bearing aspect of the joint surface (Buchler zone 2) necessitates open reduction.15

Rolando Fractures

Closed reduction with longitudinal traction and percutaneous pinning is indicated if successful reduction can be achieved under fluoroscopic guidance; however, this is usually successful only when large T- or Y-type fragments are present.

If the joint cannot be reduced by closed methods, open reduction and internal fixation with a combination of smooth wires, screws, and 1.5- to 2.7-mm L, T, or blade plates is indicated.

Significant comminution may require either external fixation or a combination of external fixation, limited internal fixation with Kirschner wires and small (1.3 or 1.5 mm) screws, and cancellous bone grafting as advocated by Buchler et al.2

An additional option is tension-band wiring with or without external fixation, as described by Howard.11 The external fixator maintains length and alignment, while the tension-band construct provides stability to the fracture fragments.

Preoperative Planning

A thorough history and physical examination are mandatory to choose the appropriate treatment and rule out associated injuries.

True AP, lateral, and oblique radiographs of the thumb should be obtained in all cases. Traction radiographs help assess the effects of ligamentotaxis on fracture reduction.

Surgery may be performed acutely, but if significant soft tissue swelling is present, elevation in a well-padded thumb spica splint for 2 to 5 days may be necessary before undergoing operative fixation.16

Positioning

The patient is placed supine on the operating room table.

A radiolucent hand table is used to allow for intraoperative fluoroscopy.

The patient is moved toward the operative side to center the hand on the table.

A non-sterile tourniquet is placed on the upper arm.

General, regional (axillary or infraclavicular), or local (wrist block with local infiltration) anesthesia can be used, although muscle relaxation is often necessary to obtain proper reduction.16,18

Approach

The Wagner approach can be used for both Bennett and Rolando fractures in which open reduction is necessary.

**CLOSED REDUCTION AND PERCUTANEOUS PINNING OF BENNETT AND ROLANDO FRACTURES**

- Longitudinal traction, abduction, and pronation of the thumb is performed while applying direct manual pressure over the metacarpal base.16

- Traction is maintained and the reduction is held while fluoroscopy is used to verify acceptable fracture reduction and alignment of the articular surface (**TECH FIG 1A,B**).

**TECH FIG 1 • A,B.** Lateral and PA views of a Bennett fracture with intraarticular displacement. C. The metacarpal base is first reduced to the trapezium and then a pin (0.045) is placed across the carpometacarpal joint. Two additional pins are provisionally placed and readied to stabilize the Bennett fracture fragment. D. The two smaller pins (0.035) are then advanced across into the Bennett fragment. (Copyright John Capo, MD.)
Incision and Dissection

- A Wagner approach is used for open reduction of a Bennett fracture (TECH FIG 2A).
- An incision is made on the dorsal-radial aspect of the thumb CMC joint, at the junction of the glabrous and nonglabrous skin, and curved in a volar direction toward the distal wrist crease to the flexor carpi radialis (FCR) tendon sheath (TECH FIG 2B).
- The palmar cutaneous branch of the median nerve, the superficial radial nerve, and distal branches of the lateral antebrachial cutaneous nerve are at risk in this approach and should be carefully protected (TECH FIG 2C).
- The thenar muscles are elevated extraperiosteally from the CMC joint and a longitudinal capsulotomy is made to expose the joint and the fracture fragments.
- An effort should be made to preserve all soft tissue attachments to the fracture fragments.
- The fracture line is exposed and cleaned of all hematoma and early callus.
- Large fragments may be manipulated percutaneously with Kirschner wire "joysticks" and then stabilized.
- The wires are bent and cut outside of the skin, followed by application of a well-padded thumb spica splint with the thumb in abduction and wrist in extension.
- If less than 2 mm of step-off cannot be obtained by closed reduction, the surgeon should consider abandoning this technique for an open reduction and internal fixation.¹⁶,¹⁸
- In rare instances, a similar technique can be used for Rolando fractures, with large T- or Y-type fracture patterns with minimal comminution.

OPEN REDUCTION AND INTERNAL FIXATION OF BENNETT FRACTURES

TECH FIG 2 * A. A preoperative radiograph demonstrating a large (~40%) Bennett fracture with intra-articular displacement. B. The typical incision for open reduction and internal fixation of a Bennett or Rolando fracture. The proximal aspect starts at the flexor carpi radialis tendon sheath. In the case of a Rolando fracture, especially one treated by plate fixation, the distal portion of the incision should extend along the thumb metacarpal. C. Distal nerve branches are seen during the exposure of these fractures. The nerves can usually be retracted dorsally to allow exposure of the carpometacarpal joint. D. The thenar muscles are reflected volarly and the carpometacarpal joint is entered. The volar, oblique fracture is now clearly visualized. Care is taken to maintain soft tissue attachments. (Copyright John Capo, MD.)
Reduction and Fixation

- The displaced thumb metacarpal shaft should be reduced to the volar-ulnar fragment under direct visualization and secured with fine reduction clamps or Kirschner wires (TECH FIG 3A).
- One or two 0.045-inch smooth Kirschner wires are used to provisionally hold the reduction, or in certain fracture patterns they can serve as the definitive means of fixation.
- Alternatively, 1.3- to 2.0-mm screws can be placed in an interfragmentary compression fashion for added stability (TECH FIG 3B).7
- One Kirschner wire is removed at a time and replaced with a screw.
- Generally, the path of the removed Kirschner wire effectively guides the drill in the appropriate direction. Use of a mini-fluoroscopy unit is helpful.

- Care should be exercised to avoid overcompression, which may cause an alteration in the arc of curvature of the articular surface.
- If fixation is tenuous, the metacarpal base can be pinned to the second metacarpal or to the carpus for added stability.
- Anatomic reduction of the articular surface is verified under direct visualization.
- The wound is closed in layers with absorbable suture in the capsule, followed by nylon sutures in the skin. A thumb spica splint is applied.
- The screws should be precisely evaluated fluoroscopically to be certain they are not in the CMC joint or adjacent second metacarpal base (TECH FIG 3C,D).

TECH FIG 3 • A. The fracture is cleared of hematoma and then reduced with a pointed reduction forceps. A provisional Kirschner wire is placed percutaneously from the dorsal metacarpal shaft into the fragment. B. Two screws of 1.3 mm diameter are placed in a lag fashion from the metacarpal shaft into the fracture fragment. C,D. OPEN REDUCTION AND INTERNAL FIXATION OF ROLANDO FRACTURES

Incision and Dissection
- The previously described Wagner approach is used to expose the thumb CMC joint (TECH FIG 4A,B).
- The radial portion of the incision is extended distally to expose the diaphysis of the thumb metacarpal. Branches of the radial sensory nerve must be protected at this stage (TECH FIG 4C).

Reduction and Fixation
- The basilar-articular fragments are then reduced under direct visualization and provisional fixation is performed with Kirschner wires or bone reduction clamps (TECH FIG 5A).
- A lag screw can be placed in a transverse direction by overdrilling the proximal cortex to compress the basilar fragments together, followed by application of a minifragment neutralization plate or by additional Kirschner wires to stabilize the shaft (TECH FIG 5B,C).6,16
- If greater fracture stability is desired, a small (1.5 to 2.7 mm) T, L, or blade plate can be used alone.
  - The palmar radial incision is extended further distally to expose the thumb metacarpal shaft to accommodate the plate.
  - Reduction is obtained using the above techniques, with axial traction to maintain appropriate length and bone reduction forceps or smooth Kirschner wires to provisionally hold the articular reduction.
- Once the fracture fragments are aligned, the plate is secured to the thumb metacarpal, with the transverse portion of the plate placed over the basilar fracture fragments.16
- The most palmar and dorsal proximal holes of the T portion of the plate can be drilled eccentrically to allow for compression at the fracture site between the basilar fragments,7,13 followed by fixation of the plate to the metacarpal shaft with cortical screws (TECH FIG 5D,E).
- Additionally, a lag screw can be placed between the shaft and the basilar fragment either within or outside of the plate. An appropriate bit is used for overdrilling of the shaft fragment, followed by core drilling of the distal basilar fragment. This interfragmentary screw increases the stability of the construct and may allow for earlier functional range of motion (TECH FIG 5F–I).
- The joint surface reduction is visualized directly with distal traction of the thumb and ensured to be anatomic.
- The wound is then irrigated and closed in layers, followed by immobilization in a well-padded thumb spica splint.

TECH FIG 4 • A,B. Preoperative radiographs of a Rolando fracture demonstrating severe intra-articular comminution. C. The thumb thenar muscles have been elevated from the carpometacarpal joint and a capsulotomy has been performed. The fracture fragments are identified and cleared of hematoma. TECH FIG 5 • A. The articular surface is first reduced and provisionally stabilized with multiple small Kirschner wires. B, C. Intraoperative fluoroscopic lateral and AP views demonstrate excellent restoration of the joint surface. Kirschner wires have been placed from the thumb metacarpal into the trapezium and second metacarpal to stabilize the construct. D. The two proximal holes of the T plate are drilled offset for articular fragment reduction. E. The two proximal screws are tightened to compress the proximal fragments. F, G. AP and lateral views of a comminuted, displaced Rolando fracture. (continued)
APPLICATION OF AN EXTERNAL FIXATOR FOR COMMINUTED ROLANDO FRACTURES

- Before this procedure, a radiograph of the contralateral thumb CMC joint is advised for templating and to judge postreduction length.
- A mini-external fixator (2.0- to 2.5-mm pins) is applied to the thumb and index metacarpals using standard technique with a quadrilateral frame configuration.²,¹²
- Exposure and open reduction are then performed as discussed previously.
- Distraction is maintained using the external fixator, and the depressed joint fragments are elevated and aligned using the preoperative radiograph of the opposite side as a guide.
- A sharp dental pick is an excellent tool to manipulate small fragments.
- 0.045-inch smooth Kirschner wires or interfragmentary screws can then be used to secure the fracture fragments.
- The external fixator is loosened to decrease the flexion deformity of the thumb metacarpal shaft, and to ensure the base of the thumb is maintained in the proper position. It should be co-linear with the base of the second metacarpal base.
- At the end of the procedure the thumb should be in 45 degrees of palmar and radial abduction and about 120 degrees of pronation in relation to the plane of the hand (TECH FIG 6).
- The incision is irrigated and closed in layers.
Chapter 26  OPERATIVE TREATMENT OF THUMB CARPOMETACARPAL JOINT FRACTURES

TECHNIQUES

POSTOPERATIVE CARE

Bennett Fractures

- A thumb spica splint is applied in the operating room. Pin sites are inspected at 1 week and a thumb spica cast is applied for 4 to 6 weeks, until fracture union.
- Hand therapy is begun early for thumb IP and MP joint motion and index through small finger range of motion.
- Pins are removed at 4 to 6 weeks and therapy is advanced to the CMC joint along with intermittent immobilization using a removable thumb spica splint.16
- In patients treated with interfragmentary compression screws and therefore more stable fixation, active range-of-motion exercises can be started at 1 to 2 weeks postoperatively with a removable splint for protection.

Rolando Fractures

- Patients treated with closed reduction and percutaneous pinning are placed in a thumb spica splint, which is removed at 1 week for pin inspection. A thumb spica cast is applied for an additional 4 to 5 weeks.
- The pins are removed in the outpatient office at 6 weeks after surgery. A removable splint may be continued for 2 to 4 additional weeks while active range-of-motion exercises are advanced.16
- In patients treated with stable plate fixation, active range-of-motion exercises may be instituted at 1 to 2 weeks after surgery. Patients typically wear a removable splint for 2 to 4 weeks.
- If a severe injury dictated the use of external fixation, the pins and frame should remain in place for about 6 weeks, or until fracture stability is adequate based on interval radiographs. A removable thumb spica splint can then be worn for an additional 4 to 6 weeks.

OUTCOMES

- The majority of patients can expect a successful recovery after operative treatment of Bennett or Rolando fractures (FIG 6).
Superior results are seen in operatively treated fractures in which there is no residual subluxation of the thumb metacarpal shaft and less than 2 mm of intra-articular displacement.\textsuperscript{5,15}

It is generally agreed that if pain and articular incongruity persist after 6 months of observation after closed or open treatment, arthrodesis of the thumb metacarpal to the trapezium or basal joint arthroplasty may be indicated.

- CMC joint fusion is durable, but patients have difficulty with placing their hand on a flat surface and getting the hand into a pants pocket.
- Basal joint arthroplasty for acute fractures should be reserved for older, lower-demand patients.

**COMPLICATIONS**

- Malunion and subsequent arthrosis resulting from inadequate articular reduction
- Pin tract infection
- Injury to the superficial cutaneous nerves during open dissection and percutaneous fixation
- Contracture of the first web space from immobilization or pinning of the thumb in an adducted position

**REFERENCES**

DEFINITION
- Disruption of the restraining structures on the volar surface of the joint between the metacarpal and proximal phalanx of the thumb may result in excessive joint motion and abnormal hyperextension.
- Often painful, this instability frequently causes significant functional deficits because so much of what humans do with their hands depends on having a stable, pain-free thumb to oppose the other digits.
- Acute injuries, including joint dislocations, must be treated correctly and promptly to afford the best chance for successful outcomes.
- Chronic volar instability is seen less often than is collateral ligament incompetence, but it should not be overlooked. It can be treated effectively with a variety of techniques, which will be discussed in this chapter.

ANATOMY
- The thumb metacarpophalangeal (MP) joint has features of both a ginglymus (hinge) joint and a condyloid joint. The joint moves mostly in a flexion–extension mode (ginglymus-style), but there are also elements of rotation and abduction—adduction in the normal joint (condyloid).
- Thumb MP joint motion varies widely from individual to individual because of the spectrum of metacarpal head geometry seen in “normal” hands.
- Some metacarpal heads are more rounded and allow greater flexion, extension, and rotation, while others are flatter and allow relatively less range of motion (ROM).
- The joint derives its stability mostly from soft tissue constraints, not bony architecture (FIG 1).
- The proper collateral ligaments originate from the region of the lateral condyles of the MC and pass palmarly and obliquely to insert on the palmar portion of the proximal phalanx.
- The accessory collateral ligaments originate from the same region but slightly more proximal and traverse distally and palmarly in an oblique fashion to insert on the volar plate and sesamoids.
- The volar plate serves as the floor of the MP joint. The adductor pollicis inserting into the ulnar styloid sesamoid at the distal edge of the volar plate and the insertions of the flexor pollicis brevis and abductor pollicis brevis into the radial sesamoid at the radial-distal edge of the volar plate provide additional volar support.
- Those muscles also contribute fibers to the extensor mechanism by way of the adductor and abductor aponeuroses and thus provide a modicum of lateral joint stability.
Dorsally, the extensor pollicis brevis inserts onto the base of the thumb proximal phalanx and the extensor pollicis longus inserts at the base of the thumb distal phalanx; both traverse the MP joint and add to the stabilizing forces surrounding the joint.
- The MP joint capsule itself surrounds the joint and contributes slightly to stability.

**PATHOGENESIS**
- Dorsal dislocations of the thumb MP joint are much more common than are volar dislocations.4,5
- The typical mechanism is a hyperextension force strong enough to rupture the volar plate and joint capsule.
  - For example, when a ball strikes a player’s thumb or when there is a direct blow or fall that drives the phalanx into sudden hyperextension
- Occasionally the radial or ulnar collateral ligaments (or both) of the MP joint are ruptured along with the volar plate. Their treatment is addressed in other chapters.
- Sometimes the instability occurs in the setting of a patient with generalized ligamentous laxity such as Ehlers-Danlos syndrome (or other collagen disorders), but in those situations symptoms are less common and patients typically learn to compensate for the joint laxity.

**NATURAL HISTORY**
- Posttraumatic instability left untreated may result in weakness of pinch and grip and progress to painful arthrosis due to the abnormal biomechanics of the damaged joint.

**HISTORY AND PHYSICAL EXAMINATION**
- In traumatic cases it is important to inquire about the mechanism of injury.

If patients recall which way the thumb was “pointing” at the time of injury, it helps the examiner determine which structures were likely injured.
- Was the joint dislocated and did it reduce spontaneously or with assistance from a coach, trainer, or the patient?
- How difficult was the reduction?
- Physical examination should include an assessment of ROM and grip and pinch strength, particularly in comparison with the contralateral thumb. Focal areas of tenderness should be ascertained. Residual tenderness along the volar plate may persist long after the injury.
- The examiner should observe the resting joint posture; dislocated joints exhibit obvious deformity.
- The examiner should check for open wounds and assess vascular status. Open wounds or vascular compromise mandate emergent treatment.
- Limited or absent interphalangeal joint ROM suggests flexor pollicis longus tendon entrapment.
- Dislocated or painful MP joints will have limited ROM.
- Volar plate stability is assessed, since instability must be recognized and treated appropriately to maximize outcomes.
- Severe collateral ligament injury is uncommon in conjunction with volar plate instability but must be recognized and treated where indicated.
- An acute dislocation is rarely subtle, but when patients present with chronic instability symptoms, there may be guarding against full joint extension and soft tissue thickening in areas of chronic pathology.

**IMAGING AND DIAGNOSTIC STUDIES**
- Plain radiographs of the thumb in three views (AP, lateral, and oblique) are requisite.
- Injury films will reveal the direction of joint dislocation and any associated fractures (FIG 2A–C).

![FIG 2](A) AP and (B) lateral injury films. (continued)
In the chronic setting, films may show evidence of prior fractures or bony injuries as well as the positions of the sesamoid bones relative to the joint space. In cases of chronic volar plate instability, the proximal phalanx may show subtle dorsal subluxation on the metacarpal head (that is more commonly noted when there has been injury to the dorsal capsule in association with collateral ligament damage).

- Arthritic changes at the MP joint seen on the plain films will alter the treatment options. If the chronically unstable joint is already arthritic at the time of presentation, then an arthrodesis will be a better option than a soft tissue reconstruction.
- Fluoroscopic real-time imaging and stress testing may confirm the suspected joint instability (FIG 2D).
- A digital block may be placed to facilitate an adequate examination.
- Ultrasound, MR imaging, and arthrography are advocated by some, but these studies are rarely of additional value in the assessment of thumb MP joint stability.

FIG 2 • (continued) C. Oblique injury film of the thumb (vs. hand) show a dorsal metacarpophalangeal joint dislocation (arrows). D. Fluoroscopic imaging shows joint instability.

DIFFERENTIAL DIAGNOSIS

- Fracture
- Collateral ligament injury
- Ligament laxity, generalized (eg, Ehlers-Danlos syndrome)
- Arthritis
- Locked trigger thumb (stenosing tenosynovitis)

NONOPERATIVE MANAGEMENT

- Most acute thumb MP dislocations can be reduced closed.
- The reduction maneuver for a dorsal dislocation involves very slight hyperextension of the MP joint followed by direct volarly directed pressure on the base of the proximal phalanx to gently slide the phalanx over the metacarpal head and back into proper alignment.
- Subtle, slight rotation (pronation and supination) at the same time may help ease any interposed soft tissue out of the way as the phalanx reduces.
- Longitudinal traction and excessive hyperextension should be avoided because the soft tissue tension generated may cause one or more structures surrounding the joint to slip between the metacarpal head and the proximal phalanx, blocking reduction.
- The volar plate, the flexor pollicis longus, and one or both sesamoid bones have all been described as culprits that have become incarcerated in the joint space, preventing reduction.2,3,5,9
- Once the joint is reduced, the patient should be able to flex and extend the thumb joints and the radiographs should show concentrically reduced and congruent joint surfaces (FIG 3).
- If either of those conditions is not met, it suggests there may be residual soft tissue interposed in the joint, an indication for open reduction.
- After successful closed reduction, the thumb should be splinted in flexion to relax the injured volar structures.
- After a few days, when the acute swelling has dissipated, the splint may be changed to a thumb spica cast, again with the MP joint flexed, for an additional 2 to 3 weeks. Rehabilitation can commence thereafter, emphasizing ROM exercises within a safe zone of motion from full flexion to just short of neutral extension and then increasing gradually to unrestricted ROM and hand use by 6 weeks after injury.
- For patients engaged in activities that risk forced hyperextension of the thumb, taping or splinting may be required during these endeavors for an additional period.
- Failure to recognize or treat the acute instability or overly aggressive progression to full, unlimited hand use may result in chronic volar instability.
Nonoperative management then is limited to providing the patient with a custom-molded splint to prevent hyperextension of the MP joint. A properly trained hand therapist is invaluable in assisting patients who prefer to manage the problem nonoperatively and use a protective splint rather than proceeding with surgical treatment for their chronic instability. Volar dislocation is very rare. There are only a few cases reported in the literature, and all required open reduction. 

Surgical Management

Open reduction is required when attempts at closed manipulation and reduction of acute dislocations fail. Failure is typically the result of soft tissue interposition in the joint that blocks reduction. Tissue interposition may have happened at the time of the original injury or as a result of a well-meaning coach, friend, or medical colleague trying to reduce the dislocation by applying vigorous traction, which can cause the soft tissues to become incarcerated. Chronic instability, which is persistently symptomatic despite nonoperative treatment, is best treated with a soft tissue stabilization technique unless moderate to severe arthrosis is present or the instability is global and exceedingly severe. In those cases, arthrodesis is the treatment of choice.

Preoperative Planning

The physician should review all imaging studies. In most cases, those will be limited to plain radiographs and perhaps spot films from fluoroscopic evaluations. Films should be reviewed for any bony abnormalities, especially nondisplaced fractures. One should avoid fracture displacement during intraoperative manipulation of the thumb. In fracture-dislocations of the MP joint, larger fragments are stabilized using Kirschner wires or screws and smaller avulsion-type fragments are excised and the ligament is secured to the bone. For chronic cases, it is important to review the films and rule out osteoarthrosis, which would warrant different treatment strategies. Examination under anesthesia with the assistance of fluoroscopy can be useful to confirm the degree and direction of joint instability. Spot films obtained before and after surgical stabilization can be helpful visual aids for use in postoperative discussions with the patient and his or her family to explain again the nature of the problem and how it was treated.

Positioning

The patient should be supine on the operating table with a standard hand table attached and projecting out from the operating table to support the operative hand. A tourniquet should be placed on the operative arm and checked for proper function and pressure before initiation of the surgery (typically 250 mm Hg or 100 mm Hg greater than systolic blood pressure).

Approach

Acute, irreducible MP joint dislocations are best approached from the volar side of the joint so that any soft tissues that may be trapped in the joint can be identified and carefully protected, before they are injured by approaching them “blindly” from the dorsal side! That assumes there are no open wounds, which then would alter one’s approach accordingly by incorporating the traumatic wound into the surgical incision.
A lateral approach is also possible, but less often used.

Chronic MP joint volar instability that is amenable to soft tissue stabilization should also be approached from the volar aspect of the joint so the pathology can be visualized and addressed directly.

If chronic MP joint instability has resulted in arthritis, arthrodesis is a better solution. This may be accomplished in a variety of ways using a variety of hardware options, including screws, plates, and wires. All are best placed through a dorsal approach.

**OPEN REDUCTION OF ACUTE MP JOINT DISLOCATIONS**

- Make a zigzag (Bruner-type) incision, centered at the level of the MP joint.
- Gently elevate the skin flaps to expose the underlying soft tissues, which will by definition be displaced from their usual locations (*TECH FIG 1*).
- Identify the neurovascular bundles and mobilize them enough to ensure their protection.
- Small rubber loops can be placed around them if desired both for protection and for easy identification.

Retract the soft tissues enough to identify whatever structure is interposed into the MP joint and reflect it out of the joint.

Most often that is the flexor pollicis longus tendon or the volar plate. The volar plate may have the sesamoids still attached to its distal edge if it has failed proximally.

Reduce the joint and check for smooth, congruent joint motion.

Check the stability of the collateral ligaments. Providing the joint does not gap open more than 25 degrees due to

---

*TECH FIG 1* • Open reduction of dorsal thumb metacarpophalangeal joint dislocation. A. Make a volar surgical approach and carefully identify the neurovascular bundles; tag and protect them with soft rubber loops (*). B. The flexor pollicis longus (*solid arrow*) is interposed and trapped behind the metacarpal head (*open arrow*). C. Umbilical tape (*arrow*) passed around the flexor pollicis longus delivers the tendon safely out of harm’s way, allowing the joint to be reduced. D. Intraoperative fluoroscopy is helpful for verifying anatomic reduction (*arrow*) with congruent joint surfaces and smooth gliding through a safe range of motion.
collateral ligament damage (rare), no further treatment for that component of the joint injury is needed.

- In some cases it may be possible to place sutures through the volar plate at its torn proximal or distal edge and tack that back to its normal insertion point. Otherwise, simply replacing the plate in normal alignment will be adequate when combined with proper rehabilitation (discussed later in the chapter).
- Replace the neurovascular bundles and flexor pollicis longus into their proper locations and close the wound in routine fashion.

### TECHNIQUES

**In some cases it may be possible to place sutures through the volar plate at its torn proximal or distal edge and tack that back to its normal insertion point. Otherwise, simply replacing the plate in normal alignment will be adequate when combined with proper rehabilitation.**

**Replace the neurovascular bundles and flexor pollicis longus into their proper locations and close the wound in routine fashion.**

### CHRONIC VOLAR INSTABILITY

**Volar Plate Advancement and Sesamoid Arthrodesis**

- The Tonkin procedure\(^{11}\) was originally described to treat MP instability resulting secondarily from osteoarthrosis of the thumb carpometacarpal joint or in patients with cerebral palsy, but it is now considered a valuable technique for treating posttraumatic instability of the MP joint.
- Approach the MP joint through a volar or volar-radial incision (TECH FIG 2A).
- Divide the accessory radial collateral ligament at its insertion into the volar plate and mobilize the plate to advance it proximally (TECH FIG 2B).
- Denude the articular surface of the sesamoid bones. A Beaver blade works well.

- Decorticate a trough along the retrocondylar fossa of the metacarpal neck to accept the sesamoids.
- Drill Keith needles through that area of the retrocondylar fossa using a wire driver. The needles should exit the metacarpal dorsally (TECH FIG 2C).
- Advance the sesamoids and volar plate into the prepared trough and secure the sutures dorsally (TECH FIG 2D).
- **Variations:**
  - Schuurman and Bos\(^{10}\): Place sutures through the proximal edge of the volar plate and pass them through the metacarpal via the Keith needles. Reinforce the construct with nonabsorbable sutures to local tissue where possible.

**TECH FIG 2** • Sesamoid arthrodesis in the manner of Tonkin. A,B. Through a volar or radial lateral approach, create a cortical defect in the metacarpal retrocondylar fossa (solid arrow), which will accept the denuded sesamoids while preserving the articular surface of the metacarpal head (dashed arrow). C. Advance and secure the volar construct including the sesamoids into the prepared trough (arrow), using sutures in the volar plate that are brought through the metacarpal neck via Keith needles drilled through the bone. D. The sutures are tensioned and tied over the dorsal metacarpal (*). (continued)
**TECH FIG 2 • (continued) E.** A Kirschner wire is drilled across the metacarpophalangeal joint to keep it flexed 30 degrees, protecting the repaired volar structures during initial healing.

- Eaton and Floyd: Place sutures in the proximal corner of the volar plate and pass them subperiosteally from volar to dorsal around the metacarpal and secure them to advance the volar plate snugly into the prepared retrocondylar fossa.

- Pin the MP joint in about 30 degrees of flexion using a Kirschner wire (TECH FIG 2E).
- Close the wound in routine fashion and apply dressings and a thumb spica splint.
- Remove the sutures at 10 to 14 days as usual and apply a thumb spica cast.
- Remove the Kirschner wire and cast at 4 to 6 weeks and begin active flexion exercises.

**Tendon Graft Tenodesis**

- A procedure used by Littler and cited by Glickel et al has been described whereby a free tendon graft (usually the palmaris longus) is woven through drill holes in the proximal phalanx and metacarpal and secured in place to provide a passive restraint against MP joint hyperextension.
- However, the bulk of soft tissue that results from this procedure and the amount of dissection needed to perform it have caused this operation to fall out of favor.
- Local tissue mobilization in conjunction with suture anchors provides a better solution.

**ARTHRODESIS**

**Cannulated Headless Compression Screw Fixation**

- Make a dorsal longitudinal approach (TECH FIG 3A–D).
- Split the interval between extensor pollicis longus and brevis.
- Split the joint capsule longitudinally.

- Mobilize the joint adequately. That requires releasing the remaining collateral ligaments and recessing the volar plate enough to deliver the metacarpal head fully into view.
- Use a water-cooled oscillating saw to remove the metacarpal head. Angle the cut from dorsal-distal to
TECH FIG 3 • (continued) D. Through a dorsal approach, the interval between the extensor pollicis brevis and longus (arrow) is developed and the joint is entered. E. Remove the metacarpal head with an oscillating saw. F. Prepare the base of the proximal phalanx with a burr. G. The opposing bone surfaces should be flush-cut and angled slightly so the final arthrodesis position is 15 to 20 degrees of flexion. H. The guidewire for the chosen cannulated screw is drilled across from metacarpal into the medullary canal of the proximal phalanx. I. Its position is checked with fluoroscopy. J. After the proper implant length is measured and the leading cortex overdrilled, the screw is inserted over the guidewire. K. Confirm correct final positioning with fluoroscopy. L. The joint capsule is closed and the extensor mechanism reaproximated.
palmar-proximal so that the final positioning will leave the MP joint surface flexed about 15 degrees (TECH FIG 3E).
- All the flexion for the arthrodesis will be accomplished by this cut. Preparation of the proximal phalanx base will be perpendicular to the longitudinal axis of that bone and will not add flexion.
- Use a burr to prepare the base of the proximal phalanx, removing any remaining articular cartilage and eburnated subchondral bone (TECH FIG 3F). Osteophytes and ridges should be trimmed away also to make a flush surface that will oppose the MC surface (TECH FIG 3G).
- Alternatively, carefully protect the underlying flexor pollicis longus and use a water-cooled oscillating saw to remove the needed bone.
- Avoid excessive bone resection that will shorten the thumb. Cup and cone reamers are an alternative to straight bone cuts and may minimize shortening and maximize flexibility in positioning the arthrodesis.
- Reduce the fusion surfaces and drive a guidewire for the selected cannulated screw set from the metacarpal into the medullary cavity of the proximal phalanx (TECH FIG 3H).
- Be certain that the starting point for the guidewire is sufficiently proximal on the dorsal surface of the metacarpal that the screw does not fracture the cortical bridge when inserted.
- Alternatively, the guidewire may be drilled in a retrograde fashion starting at the cut end of the metacarpal head. The fusion surfaces are then reduced and the guidewire is advanced into the phalanx in an antegrade manner.
- Consider placing a second temporary Kirschner wire to increase stability and minimize rotation during screw insertion.
- Confirm that the overall alignment is satisfactory radiographically and clinically (TECH FIG 3I).
- The metacarpal and phalanx should be co-linear in the AP plane and flexed about 15 to 20 degrees in the lateral plane. Rotation should be neutral or slight pronation for pinch.
- Intraoperative fluoroscopy is helpful to confirm correct alignment.
- Adjust the position of the guidewire for the cannulated screw such that its distal tip is just past the narrowest portion of the proximal phalanx. A screw ending at this level will experience excellent purchase and gain maximum stability. Measure the Kirschner wire length, choose the screw (keeping in mind the likelihood of compression at the arthrodesis site), and then advance the guidewire distally into the cortex.
- Drill, tap, and place the selected screw, avoiding any prominence over the dorsal metacarpal. Tighten securely while the reduction is compressed manually (TECH FIG 3J).
- Reconfirm correct alignment in all planes, paying particular attention to rotation. Confirm satisfactory hardware positioning (TECH FIG 3K).
- Morselized bone graft can be harvested from the resected metacarpal head and packed in and around the arthrodesis site if needed.
- Close the joint capsule with absorbable suture to minimize extensor tendon adhesions.
- Approximate the extensor tendon interval with interrupted, inverted permanent suture and close the wound in a routine fashion (TECH FIG 3L).
- Place a forearm-based thumb spica splint.

**Plate and Screw Fixation**

- It may be desirable to use plate and screw fixation rather than cannulated screws in such cases as nonunion after attempted arthrodesis, failure of implant arthroplasty, and traumatic injuries with severe deformity, bone loss, or segmental defects (TECH FIG 4).
- The advantage of plates and screws is that more rigid, secure fixation can be achieved immediately, avoiding the concern for rotation or loosening around a single cannulated screw.
- The disadvantage of that technique is that hardware prominence and tendon irritation and adhesions are more often a subsequent source of trouble.
- If plate and screw fixation is chosen as the desired technique, then the overall approach and bone preparation are similar to that described for the cannulated screw technique.
- With the arthrodesis site reduced and temporarily stabilized with a Kirschner wire, a 2.0-mm, five-hole compression plate is contoured to the dorsal surface of the bones.
- The plate is first secured distally and then applied proximally using compression technique principles.
- It is critical to avoid long screws and irritation of the flexor pollicis longus.
- Closure and postoperative care are similar to that described earlier.

**TECH FIG 4** - Arthrodesis with plate and screw fixation.
**PEARLS AND PITFALLS**

| Initial treatment | - Acute MP joint dislocations should be reduced promptly, but straight traction should be avoided because it can result in soft tissue entrapment and turn a simple dislocation into a complex, irreducible injury requiring open reduction.  
- The joint should be immobilized and protected long enough and rehabilitated carefully enough to avoid chronic volar instability. |
| Treatment indications | - Chronic volar instability without arthritic change can be treated with a variety of capsulodesis procedures.  
- When arthritic changes have developed as a result of chronic instability, MP joint arthrodesis should be done. |
| Hardware problems | - Cannulated screws work well for MP arthrodesis and leave the hardware buried.  
- Plates and screws, Kirschner wire fixation, and transosseous wiring techniques can be effective ways of achieving arthrodesis but are more likely to cause hardware problems requiring subsequent treatment. |

**POSTOPERATIVE CARE**

**Acute Dislocation**
- The MP joint is generally stable once a dislocation is reduced acutely, whether by closed or open methods.  
- The MP joint should be held in about 30 degrees of flexion in a short-arm thumb spica splint or cast for 2 weeks.  
- ROM exercises can begin thereafter, using a removable thumb spica splint for an additional 4 weeks, gradually weaning out of the splint and advancing activities as symptoms allow.  
- Supervised hand therapy is often helpful for patients to guide their recovery of motion and strength and optimize their outcomes.

**Chronic Instability**
- Volar plate advancement procedures and the Tonkin sesamoid arthrodesis procedure should be protected with the thumb MP joint flexed in a cast for 4 to 6 weeks, depending on the surgeon’s assessment of tissue quality and patient compliance. Then supervised ROM can begin, but MP joint hyperextension forces should be avoided for 8 to 12 weeks.  
- MP joint arthrodesis procedures require longer protection so that the fusion site is not stressed or disrupted before final bony union.  
- Generally it is best to use a thumb spica splint (plaster) for the first 10 to 14 days after surgery until the swelling decreases and the sutures are removed.  
- Then a thumb spica cast can be used for an additional 3.5 to 4 weeks, at which time a custom-molded, removable splint can be used to protect the arthrodesis site but allow ROM of the uninvolved adjacent joints of the hand to prevent undue stiffness.  
- By 12 weeks most arthrodeses are healed solidly enough to allow unrestricted hand use.

**OUTCOMES**
- Acute volar instability and dorsal dislocations of the MP joint that are treated appropriately can be expected to have a good prognosis.\(^2\),\(^3\),\(^9\) Whether the dislocation is reduced closed or open reduction is required, once the joint is reduced it is usually stable.  
- Following rehabilitation as outlined above, there well may be some residual joint stiffness. While that may continue to improve for up to 1 year after injury, the lost range of motion is rarely a functional problem.  
- Tonkin et al.\(^11\) reported successful outcomes in 38 of 42 cases (90%) of sesamoid arthrodeses for chronic MP joint volar instability. Those results compare favorably with outcomes following other capsulodesis and volar plate reinforcing procedures. The advantage of all such procedures is that hyperextension is blocked, restoring stability to the joint, while still allowing the MP joint to flex. Mean loss of flexion compared with the preoperative condition was 8 degrees in the series reported by Tonkin et al.\(^11\)  
- Outcomes after arthrodesis for chronic volar instability must be viewed with the proper surgical goal in mind. The goal is to relieve pain (from instability and arthritic change) and provide stability to the thumb ray. Success rates are high, barring any unfortunate complications as discussed next.

**COMPICATIONS**
- Complications following MP joint dislocations are uncommon and mostly limited to the sequelae of concomitant soft tissue injuries.  
- Damage to the adjacent neurovascular structures can result from the initial traumatic injury or careless surgical technique at the time of open reduction.  
- Damage to the flexor pollicis longus tendon may occur when it gets trapped in the joint or again when it is manipulated surgically during an open reduction.  
- A complication encountered more often is persistent, chronic instability of the MP joint that results from failure to recognize the nature of the original injury or rehabilitate it properly.  
- Complications after treatment for chronic MP joint volar instability are likewise uncommon and generally related to failure of the chosen procedure.  
- Volar plate advancement can fail due to stretching out over time or a second trauma that causes acute rupture of the repair or sutures.  
- Nonunion of attempted arthrodesis is always a risk, but fortunately in the small joints of the hand, including thumb MP joints, it is uncommon. Nonunion rates range from 0% to 12% in several reported series.\(^12\)  
- Hardware causing soft tissue irritation is a potential complication. That can be from superficial pin tract infections in cases where Kirschner wires are used to maintain joint reduc-
tion to extensor tendon irritation when fusions are done using plates and screws.

REFERENCES

DEFINITION
- Ulnar collateral ligament (UCL) and radial collateral ligament (RCL) tears of the thumb metacarpophalangeal joint (MCP) are common injuries resulting from disruption of the continuity of these ligaments.
- These disruptions are frequently the result of an athletic injury, a fall, or a motor vehicle accident.

ANATOMY
- The MCP joint of the thumb is transitional between a condyloid and ginglymus joint. The articulating surface of the base of the proximal phalanx is a shallow concavity that provides relatively little intrinsic stability. Hence, most of the joint’s stability is afforded by its ligament and capsular supports.
- The RCL and UCL are both structurally similar, composed of both proper and accessory components, and are the main stabilizers of the thumb MCP joint.
- The proper collateral ligaments, which originate from a fossa in the metacarpal neck dorsal to the axis of rotation, are the primary ligamentous supports. They fan out from their proximal origins to distal insertions on the lateral and volar aspect of the base of proximal phalanx.
- The accessory collateral ligaments act as supplementary supports originating from the palmar aspect of the metacarpal neck fossa and inserting into the volar plate and the sesamoid on respective sides of the joint.
- The collateral ligaments provide not only medial and lateral stability but also stability in the dorsovolar plane by virtue of their dorsal origin and their volar insertion.
- The volar plate is a central fibrocartilaginous structure extending from the neck of the metacarpal proximally to the base of the proximal phalanx distally.
- One difference between the ulnar and radial sides of the MCP joint is related to the aponeurosis. The broad abductor aponeurosis covers the entire radial side of the MCP joint, whereas the much narrower adductor aponeurotic sheath spans the ulnar side of the joint.

PATHOGENESIS
- Acute injury of the UCL usually results from sudden forceful abduction and extension at the thumb MCP joint. This can take place during a fall on an outstretched hand with the thumb abducted, as seen in skiers, or in baseball players when the glove strikes the ground while fielding.
- The extent of the injury and the grade of the injury depend on the loading force at the time of impact. The most common injury of the thumb MCP joint is a partial disruption or sprain of the UCL.
- Tears of the UCL can occur anywhere within the ligament’s substance, although most take place at or near the site of insertion into the proximal phalanx, sometimes with an avulsion fracture (FIG 1A).
- The narrower adductor sheath on the ulnar aspect of the joint allows superficial displacement and entrapment of the torn proximal end of UCL, termed a Stener lesion (FIG 1B). Because of the broader abductor aponeurosis, however, such a lesion is not seen on the radial side.
- RCL injuries are generally caused by sudden abduction and extension of the MCP joint, commonly occurring during athletic injuries. They can also occur by direct blunt impact to the lateral side of the thumb.
- The RCL is more often injured close to its origin on the dorsal radial metacarpal head. It may also be disrupted in its midsubstance.

NATURAL HISTORY
- Untreated UCL injuries are relatively common. Patients are often sent away being told they simply have a “sprain.” If instability is present and not corrected, the patient may experience pinch weakness and eventually chronic pain.
- Untreated RCL tears are even more common and often result in late degenerative arthritis, commonly requiring MCP arthrodesis.
- Less severe avulsions may lead to prominent osteophytes on the dorso radial aspect of the metacarpal neck, suggesting the prior injury.
- Mondry first described the unstable thumb MCP joint in 1940, while Watson-Jones mentioned the importance of the UCL in relation to stability of the MCP joint of the thumb.
- Campbell described gamekeeper’s thumb as a chronic instability of the UCL in Scottish gamekeepers.
- Gerber et al. popularized the term skier’s thumb to refer to acute UCL injuries.
- Stener outlined the ligamentous anatomy of the thumb MCP joint and subsequent pathoanatomy of the lesion now termed the Stener lesion. Stener also described avulsion of the UCL leading to articular fracture of the proximal phalanx, now popularly referred to as a “bony gamekeeper’s thumb.”
- Moberg and Stener reported that UCL disruption is 10 times more common than RCL disruption. This frequency has been widely confirmed.
Frank and Dobyns reported that RCL injuries are somewhat more common than initially thought, with incidences ranging from 23% to 35% of collateral ligament injuries. This has echoed our experiences with the more subtle RCL injuries often being neglected, causing late morbidity.

### PATIENT HISTORY AND PHYSICAL FINDINGS

#### UCL Tears
- Patients with UCL tears present with pain, stiffness, tenderness, and swelling of the MCP joint. The defining symptom, however, may be marked pinch weakness.

- On examination there is discrete tenderness over the ulnar joint line, at the ulnar side of the metacarpal neck, and most classically at the volar ulnar base of the proximal phalanx.
- Physical examination is critical in establishing the need for surgical treatment by distinguishing between a partial and a complete ligament tear.
- A valgus stress examination comparing the stability of the injured versus the uninjured UCL is the best method to detect a complete tear.
- The stress test may be aided by live fluoroscopy and the use of a local anesthetic block.
- The presence of an associated fracture should not deter the examiner from performing a stress test. Nondisplaced avulsion fractures at the insertion site of the proper collateral ligament may coexist with a complete ligament tear.
- The results of the stress test are based on angular instability of the joint and the quality of the “end point.”
- Laxity of more than 30 degrees in extension and 15 degrees in flexion as compared to the contralateral side should be highly suggestive of a complete tear of the UCL.
- The presence of fullness or a palpable mass on the ulnar aspect of the metacarpal head and neck, representing a Stener lesion, is strongly suggestive of a completely disrupted and retracted UCL.
- Volar subluxation of the MCP joint signifies loss of the dorsal volar stabilizing effect of the collateral ligament and is also consistent with a complete tear.

#### RCL Tears
- RCL tears present as localized tenderness over the radial base of the proximal phalanx but more commonly over the metacarpal head.
- The dorsoradial aspect of the metacarpal head may be prominent due to soft tissue swelling.
- Acute RCL injuries are assessed in the same manner as discussed for UCL injuries.
- For the stress test of the RCL in extension and 30 degrees of flexion, laxity of the joint greater than 30 degrees as compared to the uninjured side suggests a complete tear of the RCL.
- The emphasis on distinguishing partial tears from complete tears does not directly affect treatment and therefore is less important than for UCL injuries. Even complete RCL tears are not capable of retracting behind the aponeurosis and therefore may be treated nonoperatively.
- RCL injuries are more common than often thought. Significant radial-sided pain with laxity or subtle radiographic signs of dorsal capsule avulsion necessitate treatment.

#### IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs include posteroanterior, lateral, and oblique views of the thumb. Images of the contralateral thumb are used for comparison and may reveal subtle joint subluxation.
- Stress radiographs of the MCP joint in full extension and in 30 degrees of flexion are rarely required though occasionally
can help distinguish between a partial and complete ligament injury.4,12

- MCP joint arthrography, MRI, and ultrasound have all been used to determine the degree of ligament injury and displacement but are almost never required.
- On MRI, a Stener lesion is characterized by a “yo-yo on a string” sign.

**DIFFERENTIAL DIAGNOSIS**

- Diffuse capsular injury without discrete ligament tear
- Fracture or articular cartilage injury
  - The articular surface is best assessed via arthroscopy or perhaps MRI.
- Arthritis
  - Diffuse soft tissue injury involving a previously asymptomatic but arthritic joint can result in persistent pain.

**NONOPERATIVE MANAGEMENT**

- Treatment depends on the severity of injury, the type of tear,7,14,16,17,20,22 and the presence of an avulsion fracture involving a significant portion of the articular surface or an open physis.
- Partial UCL and partial and complete RCL tears without volar subluxation of the proximal phalanx can be effectively managed by immobilization, then protected mobilization using a removable splint for a total of 4 to 6 weeks.
  - Initial immobilization is traditionally accomplished using a thumb spica cast. Such a cast allowing wrist motion is preferable.
  - Alternatively, a customized thermoplastic splint that immobilizes only the thumb MCP joint and leaves the wrist and interphalangeal joint free can be used for reliable patients with less severe injuries.

**SURGICAL MANAGEMENT**

- Complete UCL disruption, especially if denoted by a Stener lesion or joint subluxation, should be treated surgically. Additionally, a displaced avulsion fracture involving a significant portion of the articular surface should be reduced and stabilized operatively.
- An avulsion fracture of the proximal phalanx can be effectively managed by arthroscopic techniques.3,23,24 Occasionally, it is necessary for an arthroscopic procedure to be converted to an open procedure if reduction of a large or comminuted fracture fragment in the proximal phalanx is not feasible (FIG 3).
- Injuries associated with a Stener lesion warrant open repair.
- Partial tears of RCL are best managed by cast immobilization, whereas complete tears associated with palmer subluxation require open surgical repair of the ligament and dorsal capsule.10
- Arthroscopy can also be a useful adjunct to open procedures as it allows a more thorough débridement and evaluation of concomitant pathology.
- A regional anesthetic combined with light intravenous sedation is generally adequate for the procedures detailed below.
ACUTE UCL DISRUPTIONS

Arthroscopic Treatment of UCL Avulsion Fractures

- Traction is applied using a finger trap placed on the thumb with 5 pounds of counterforce.
  - A traction tower is not used in order to facilitate fluoroscopy.
- Palpate the joint and then inject 1 to 2 mL of lidocaine using an 18-gauge needle.
  - Take care to avoid injuring the articular cartilage.
- Insert a 1.9-mm 30-degree arthroscope via a longitudinal portal stab wound on the radial side of the extensor pollicis longus tendon.
  - This allows the best visualization of the ulnar-sided pathology.
- Insert a 2-mm full-radius shaver in the ulnar portal and evacuate the hematoma and any minute bone fragments that may prevent visualization.
- Perform a synovectomy, with emphasis on the ulnar side. This allows clear delineation of the avulsed fracture fragment (TECH FIG 1A).
- Insert a small probe through the ulnar portal and hook the fragment on its radial side, within the fracture site. Gentle proximal and radial traction on the ulnar fragment typically accomplishes the reduction.
- Preoperative radiographs help to plan the specific maneuver necessary for fracture reduction, but the arthroscopic picture will ultimately determine the direction of fragment derotation required to achieve anatomic reduction of the joint.
  - Reintroduce the shaver as needed for débridement and to assist fracture reduction.
  - Insert a 0.035-inch Kirschner wire percutaneously into the joint just proximal and ulnar to the reduced bony fragment (TECH FIG 1B).
- Arthroscopic visualization aids in placement and orientation of the transfixing Kirschner wire using the wire driver (TECH FIG 1C).
  - Using the wire driver, engage the radial cortex to stabilize the fracture fragment.
  - Use both fluoroscopy and arthroscopy to determine the adequacy of fragment reduction as well as to confirm proper wire placement and fracture stability (TECH FIG 1D,E).
  - Cut the wire just underneath the skin (TECH FIG 1F).
  - Close the skin and apply a bulky thumb spica plaster splint while the thumb is still suspended.
  - Final fluoroscopic pictures are taken and the tourniquet is released.

Open Repair of Complete UCL Disruptions

- Make a curvilinear or a longitudinal lazy-Z incision with the superior or dorsal portion proximal.
- The UCL origin is more dorsal and fans out in volar fashion.

TECH FIG 1 • A. With the arthroscope in the dorsoradial portal and the shaver in the dorsoulnar portal, arthroscopic débridement is performed before reduction of the fragment. B. The fragment is reduced arthroscopically and stabilized with a Kirschner wire. C. Arthroscopic view showing the Kirschner wire and the fracture fragment before reduction. D. This displaced and rotated bony avulsion fracture at the attachment of the UCL is reduced arthroscopically and stabilized. E. Radiograph showing anatomic arthroscopic reduction and pinning. F. The Kirschner wire, fixing the avulsed fragment, is cut beneath the skin.
Dissect the subcutaneous tissues with small tenotomy scissors, taking care to maintain hemostasis using a bipolar cautery.

Identify the dorsal radial sensory nerve branches and gently retract them dorsally.

Take note of the oblique transverse fibers of the adductor aponeurosis. In more severe injuries the aponeurosis my be torn, revealing the underlying UCL.

Divide the adductor aponeurosis longitudinally, allowing the muscular origin of the adductor pollicis to pull back the fascia and facilitate posterior retraction of the aponeurosis.

The torn UCL is seen directly under the incised adductor aponeurosis (TECH FIG 2A).

In the case of a Stener lesion, the retracted and displaced stump of the UCL is visualized just superficial to the proximal edge of the adductor aponeurosis before incision.

Determine the direction of the UCL fibers and incise the joint capsule on the ligament’s dorsal margin.

Inspect the joint, and perform a limited débridement and synovectomy as indicated.

Precisely determine the location and degree of UCL injury.

Less common intrasubstance tears are repaired primarily with 3-0 or 4-0 permanent suture in a mattress or figure of 8 configuration.

Avulsion of the ligament attachment from the base of the proximal phalanx is most frequently encountered and is treated by reattaching the ligament's insertion.

Isolate the anatomic insertion site for the proper collateral ligament on the volar ulnar base of the proximal phalanx and prepare the site for ligament attachment by débriding the remaining soft tissue down to bleeding bone.

Creating a small bony trough at the insertion site helps stimulate bleeding and ligament attachment (TECH FIG 2B).

Prepare the UCL stump by mobilizing it on its margins and freshening the distal end with a no. 15 blade.

Insert a 2-mm or smaller suture anchor into the prepared bony site and verify its position with fluoroscopy.

While the thumb is deviated in an ulnar direction, reattach the ligament stump to the proximal phalanx by placing a horizontal mattress stitch using the suture from the anchor.

Repair the accessory portion of the UCL by placing 3-0 or 4-0 permanent suture from the ligament into the ulnar margin of the volar plate.

Additional permanent sutures may be placed to secure the repaired UCL to surrounding soft tissues.

Close the capsule to the dorsal margin of the ligament using 4-0 absorbable suture.

Precisely reconstruct the adductor aponeurosis with 4-0 inverted interrupted permanent suture and close the skin.

Ensure restoration of stability and maintenance of full MCP joint flexion.

Place a forearm-based thumb spica splint.

Very severe injuries with extensive disruption of soft tissue stabilizers may rarely require augmentation with a temporary Kirschner wire.

ACUTE RCL DISRUPTIONS

Make a dorsoradial curvilinear or a longitudinal lazy-Z incision similar to that used for the repair of UCL disruptions, and dissect the soft tissues as detailed earlier.

Incise the adductor aponeurosis in line with the RCL.

Radial-sided lesions are often coupled with concomitant avulsions of the dorsal capsule. If the capsule is intact, incise it along the dorsal margin of the RCL to inspect the joint.

Isolate the ligament and its point of disruption, and then mobilize the structure to allow for anatomic repair.

Typically, disruptions take place at the proximal origin (TECH FIG 3A).

Débride the bone and ligament stump in the manner detailed for open repair of UCL avulsions.

Remove reactive bone and early osteophytes at the site of ligament or capsule avulsion with a rongeur.

Place a 2.0-mm or smaller suture anchor in the collateral recess, the dorsoradial distal metacarpal.

Ensure proper placement radiographically.

Reattach the ligament to its anatomic point of origin using the suture from the anchor (TECH FIG 3B).

Repair the capsule and further secure the RCL to surrounding soft tissue with 3-0 or 4-0 permanent suture (TECH FIG 3C).
PEARLS AND PITFALLS

- MCP ligamentous lesions require a high index of suspicion.
- The obvious lesions with instability will likely get appropriate repairs with subsequent rehabilitation programs.
- Missing a significant ligament tear may cause few physical problems short term but may become a chronic painful lesion long term.
- This is where arthroscopy may also play a good role. The chronically painful lesions may not demonstrate laxity or even a gross physical problem. Nevertheless, the pain is present and repeat corticosteroid injections are certainly not a solution. Arthroscopic synovectomy or capsular or ligamentous débridement will alter the articular milieu enough to allow for resolution of chronic pain and swelling. All this is coupled with rapid resolution of symptoms and recovery of range of motion.

POSTOPERATIVE MANAGEMENT

- Bony gamekeeper’s thumb
  - A fiberglass thumb spica cast is applied at 1 week postoperatively and the pin is removed under local anesthesia at about 5 weeks postoperatively.
  - A brief course of physical therapy is initiated. The patient is given a hand-based thumb–carpometacarpal type of removable splint to be used during strenuous activities.
  - Therapy is usually short term owing to less swelling and stiffness as compared with open approaches.
  - All unrestricted activities are permitted at 8 weeks.
- UCL and RCL injuries: True ligament-to-bone healing is necessary, so 6 weeks of postoperative thumb spica immobilization is critical to success.

OUTCOMES

- Many contralateral thumbs display a flexion arc of less than 20%; therefore, the normal restoration of full motion is not the goal. Good stability without pain should be the aim.
- RCL injuries of the thumb tend to have a higher tendency to develop posttraumatic arthritis.
- Our long-term experience has shown the need for late arthrodesis on only two occasions. These are cases in which significant volar subluxation is present, and the articular wear at time of surgery was likely predictive of this long-term outcome.
- A chronically painful thumb, with any degenerative changes on radiographs, coupled with volar posturing of the phalanx, should likely be considered straightaway for fusion.
- Thorough counseling of the patient indicating the minimal deficit produced by arthrodesis is helpful.

COMPLICATIONS

- Careful surgical dissection should avoid the most common complication, which would be iatrogenic trauma to the dorsal sensory nerve. Once done, there are minimal complications associated with this area of hand surgery.
- Other complications can include stiffness, as previously discussed, infection, persistent instability, or chronic pain syndromes.
- Recalcitrant pain or instability can simply be managed by arthrodesis, still portending a good functional outcome.

Reconstruction of Chronic Radial and Ulnar Instability of the Thumb Metacarpophalangeal Joint

Steven Z. Glickel and Louis W. Catalano III

DEFINITION
- Chronic instability of the ulnar collateral ligament (UCL) and the radial collateral ligament (RCL) of the metacarpophalangeal (MCP) joint of the thumb usually results from unrecognized or untreated acute tears of the ligament.
- Persistent laxity may cause pain and weakness and, eventually, osteoarthritis resulting from asymmetrical wear of the articular cartilage.

ANATOMY
- The MCP joint of the thumb has characteristics of both a condyloid and a ginglymus joint. The radial condyle is taller in the dorsovolar dimension than the ulnar condyle.
- The dorsoulnar and dorsoradial digital nerves are terminal branches of the superficial sensory branch of the radial nerve and invariably cross the operative field in the plane immediately superficial to the adductor and abductor aponeuroses, respectively.
- They are at risk during reconstruction of the collateral ligaments. During the exposure of the joint, the nerve should be mobilized and gently retracted.
- The adductor aponeurosis is an extension of the tendon of the adductor pollicis muscle, which contributes obliquely oriented fibers to the extensor mechanism distal to the vertical fibers.
- The abductor aponeurosis is wider than the adductor aponeurosis. Hence, a ruptured ligament is separated from its deep insertion by the aponeurosis, preventing ligament healing.
- The abductor aponeurosis is wider than the adductor aponeurosis. When the RCL tears, the ends of the torn ligament remain deep to the abductor aponeurosis. Hence, a Stener type of lesion rarely occurs on the radial side.

PATHOGENESIS
- The UCL of the MCP joint of the thumb is usually torn by forceful abduction and extension of the thumb, as in a fall on the outstretched hand with the thumb abducted. The proximal phalanx deviates radially and, if there is sufficient force, the proximal phalanx avulses from its insertion on the base of the proximal phalanx. As the proximal phalanx deviates radially, the ruptured UCL stump retracts proximal and superficial to the adductor aponeurosis. Hence, the avulsed ligament is separated from its deep insertion by the aponeurosis, preventing ligament healing.
- The abductor aponeurosis is wider than the adductor aponeurosis. When the RCL tears, the ends of the torn ligament remain deep to the abductor aponeurosis. Hence, a Stener type of lesion rarely occurs on the radial side.

NATURAL HISTORY
- Over time, chronic tears of the collateral ligaments of the thumb MCP joints cause weakness of pinch and grip due to lack of stability and pain.
- Incompetence of the UCL diminishes the thumb’s ability to act as a stable post against which to pinch with the index finger. Patients often have difficulty holding large objects that require counterpressure by a stable thumb. Patients with chronic RCL instability often have pain with torsional motions like unscrewing jar tops.

In summary, chronic instability of the thumb MCP joint can cause pain, weakness, and instability. Reconstruction procedures may be necessary to restore function and prevent further injury.

- The proper ulnar and radial collateral ligaments originate from fossae of the condyle of the metacarpal head on the radial and ulnar sides and pass obliquely from dorsal proximal to volar distal to insert on the volar third of the base of the proximal phalanx. The ligament widens as it goes from its metacarpal origin to its proximal phalangeal insertion.
- The proper collateral ligaments are tight in MCP joint flexion and lax in extension.
- The accessory collateral ligaments originate on the metacarpal head contiguous with but just volar to the proper collateral ligament and extend obliquely across the MCP joint, inserting on the sesamoid and volar plate.
- The accessory collateral ligaments are tight in extension and lax in flexion.
- By definition, to have a complete ligament rupture, both the proper and the accessory collateral ligaments must be torn.
- The Stener lesion is a palpable soft tissue mass on the ulnar aspect of the MCP joint. It results from a tear of the UCL caused by forceful radial deviation of the proximal phalanx, angulating the MCP joint 70 degrees or more. The ligament tears distally at or near its insertion on the volar ulnar base of the proximal phalanx. As the proximal phalanx deviates radially, the ruptured UCL stump retracts proximal and superficial to the adductor aponeurosis. Hence, the avulsed ligament is separated from its deep insertion by the aponeurosis, preventing ligament healing.
- Two primary causes of chronic instability of the UCL exist.
  - Inadequate treatment of an acute, complete UCL disruption, with or without an associated Stener lesion
  - Progressive attenuation of the ligament due to repetitive trauma
- Tears of the RCL typically result from forceful ulnar deviation and extension of the MCP joint.
  - Proximal and distal avulsions of the ligament occur with roughly equal frequency.
  - Intrasubstance tears occur infrequently.
- Chronic instability of the radial RCL has three primary causes.
  - Most commonly, chronic laxity is due to lack of recognition of the pathology and therefore inadequate or late treatment.
  - Even when recognized, conservative management may fail.
  - Chronic attenuation due to repetitive trauma is less common.
• Chronic laxity may cause incongruity and asymmetrical wear of the MCP joint, which may progress to posttraumatic osteoarthritis of the joint.
• Arthritis of the joint causes pain, stiffness, and progressive weakness.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

• Obtaining a relevant history from patients with chronic instability of the thumb MCP joint includes eliciting a history of trauma to the thumb in the recent or distant past.
• Patients are questioned about pain in the thumb, particularly if it is exacerbated by forceful pinch and grasp and torsional activities like turning keys in locks, turning doorknobs, or unscrewing jar tops.
• The examine should establish the chronicity of the symptoms and whether they are increasing in severity.
• Assessment of instability of the thumb MCP collateral ligaments is primarily clinical.
• Clinical examination begins with observation.
• The resting posture of the thumb at the MP joint is occasionally indicative of pathology. The joint may be angulated or rotated in its resting posture if the collateral ligament is grossly incompetent and the instability is chronic.
• In thumbs with chronic RCL instability, there is often a dorsal prominence on the radial aspect of the metacarpal head. Such a prominence is generally not present in cases of chronic UCL instability.
• The involved side of the joint is usually tender to palpation.
• Palpation of a fullness or soft tissue mass on the ulnar side of the metacarpal head is strongly suggestive of a Stener lesion.
• Stability of the collateral ligament is tested in extension and 30 degrees of MCP joint flexion (under local anesthesia if needed). There is no consensus in the literature concerning the degree of instability that is diagnostic of a complete tear.
• Valgus stress of the MCP joint in flexion is used to assess the stability of the proper UCL, whereas stress with the joint in extension is used to assess the accessory UCL as well.
• The criteria for diagnosis of a complete ligament disruption that are most accurate were described by Heyman et al and include 30 to 35 degrees of laxity of the ulnar side of the MCP joint when stressed in extension and 15 degrees more laxity than the contralateral thumb when stressed in 30 degrees of flexion.
• Laxity in extension suggests that the accessory and proper collateral ligaments are both torn.
• A more subtle, but often more helpful, finding is the presence or absence of a discrete endpoint to joint opening when stressed. Absence of a solid endpoint is strongly suggestive of a complete ligament tear.
• To test for joint degeneration, the MP joint is passively moved in extension and flexion combined with radial and ulnar deviation. The joint is axially loaded as it is deviated. Crepitus and pain strongly suggest the presence of osteoarthritis, a contraindication to reconstruction of an unstable MCP joint.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

• Radiographic evaluation includes PA, lateral, and oblique radiographs of both thumbs.
• Fractures should be ruled out.
• The lateral view may show volar subluxation of the MCP joint, which is fairly common and may be the result of extension of the collateral ligament tear to involve the dorsal capsule. This may occur with UCL or RCL tears. An isolated tear of the dorsal joint capsule very rarely causes volar subluxation without an associated collateral ligament injury.
• A comparison lateral radiograph of the contralateral thumb is extremely helpful if volar subluxation is suspected.
• Stress views of the MP joint have been recommended to radiographically demonstrate instability.
• Most experienced clinicians rely almost exclusively on physical examination and static plain radiographs to make the diagnosis.
• MRI, ultrasound, and arthrography are rarely indicated to assess completeness of the UCL tear, particularly in the setting of a chronic injury.
• The use of arthroscopy as a diagnostic and treatment modality in the setting of chronic UCL instability remains investigational.

**DIFFERENTIAL DIAGNOSIS**

• Fracture of the metacarpal head or base of the proximal phalanx
• Synovitis of the MCP joint
• Chronic partial tear of the UCL or RCL
• MCP joint arthrosis

**NONOPERATIVE MANAGEMENT**

• Customized hand-based thermoplastic splints, nonsteroidal anti-inflammatory medication, and corticosteroid injections may improve the synovitis and pain resulting from chronic instability and early degenerative arthritis.

**SURGICAL MANAGEMENT**

• The indication for reconstruction of chronic UCL or RCL disruption is failure of conservative treatment, with persistent pain and instability of the MCP joint.
• Instability alone is a soft indication for surgery.
• Theoretically, the asymmetric wear of the articular cartilage resulting from chronic laxity causes degeneration of the articular cartilage. This can be used as an argument for prophylactic reconstruction.
• Most patients without pain are hesitant to consider surgery and the prolonged rehabilitation required after surgery.
• Contraindications to reconstruction of UCL or RCL tears include osteoarthritis, “multidirectional” instability, and fixed subluxation of the joint.
• Mild chondromalacia is a relative contraindication to reconstruction and may be better treated by MCP arthrodesis.
• If an arthritic joint is stabilized, pain is likely to persist and increase over time, necessitating conversion to an arthrodesis.
• Fixed instability of the MCP joint is an uncommon contraindication to ligament reconstruction.
• Reconstruction of the incompetent ligament in this scenario requires an extensive joint release, creating “multidirectional” instability.
• Failure to release the joint adequately results in rapid recurrence of the preoperative deformity and instability.
Reconstruction of chronic instability may involve mobilization of the disrupted ligament, mobilization of local tissues, or ligament replacement using a tendon graft.

- The decision is made at the time of surgery.
- The more chronic the injury and the more dramatic the laxity and deformity, the more likely the need for replacement of the ligament with a graft.

**Preoperative Planning**

- The patient is asked to actively bring all five digits together and simultaneously flex the wrist against resistance. The volar wrist is inspected for the presence of a palmaris longus tendon.
- Examination under anesthesia may show even greater joint laxity than expected.

**Positioning**

- The patient is supine on the operating room table with the arm on a hand table at an angle slightly less than perpendicular to the torso.

**Approach**

- Lazy-S incision centered over the MCP joint
- Midaxial incision
- Chevron-shaped incision centered over the midaxial point of the MCP joint

**RECONSTRUCTION OF CHRONIC UCL DISRUPTIONS USING TENDON GRAFT**

**Exposure**

- Incise the skin over the ulnar joint line (TECH FIG 1A,B).
- Elevate skin flaps and retract them with 4-0 silk sutures.
- Identify and protect the branch of the dorsoulnar digital nerve that invariably crosses the wound (TECH FIG 1C).
- Identify the frequently fibrotic adductor aponeurosis.
  - The proximal stump of the torn UCL may be visualized at the proximal margin of the adductor aponeurosis if a Stener lesion is present.
- Incise the adductor aponeurosis longitudinally, exposing the underlying torn UCL (TECH FIG 1D).
- If the ligament cannot be defined and mobilized sufficiently for direct repair or reinsertion the remnant of the ligament is excised, exposing the ulnar side of the distal metacarpal head, the base of the proximal phalanx, and the MCP joint (TECH FIG 1E).
- The MCP joint is “booked open” to visualize the articular cartilage.
- Significant degenerative disease is a contraindication to reconstruction (TECH FIG 1F).

**TECHNIQUES**

- Incise the skin over the ulnar joint line (TECH FIG 1A,B).
- Elevate skin flaps and retract them with 4-0 silk sutures.
- Identify and protect the branch of the dorsoulnar digital nerve that invariably crosses the wound (TECH FIG 1C).
- Identify the frequently fibrotic adductor aponeurosis.
  - The proximal stump of the torn UCL may be visualized at the proximal margin of the adductor aponeurosis if a Stener lesion is present.
- Incise the adductor aponeurosis longitudinally, exposing the underlying torn UCL (TECH FIG 1D).

**TECH FIG 1**

- **A.** The lazy-S incision used for ulnar collateral ligament reconstruction. The proximal incision is dorsal and the distal incision is midaxial. **B.** A chevron-shaped incision is made centered over the ulnar side of the metacarpophalangeal joint. **C.** A dorsal ulnar sensory nerve branch is identified and protected throughout the surgery. **D.** The adductor aponeurosis is incised longitudinally about 2 mm from the extensor expansion, providing a cuff of tissue dorsally to facilitate an adequate repair at the end of the procedure. (continued)
Bone Preparation

- Make two holes in the ulnar base of the proximal phalanx using hand-held gouges of increasing diameter (TECH FIG 2A).
  - The diameter of the hole required depends on the size of the tendon graft to be used for reconstruction.
  - The preferred donor is the palmaris longus, which is usually fairly thin and can fit in a relatively small hole.
  - The gouge holes must be made far enough apart to preserve a substantial bony bridge between the holes.
  - A bridge that is too narrow can fracture during passage of the tendon graft.
- Place the holes at the 7 and 11 o’clock positions in the base of the proximal phalanx if looking at the right thumb end on. Make the holes at an angle of about 45 degrees to the bone surface and direct them toward each other in order to converge within the medullary canal and create a bone tunnel.
- Prebend a 28-gauge stainless steel wire into the approximate arc of curvature of the bone tunnel to facilitate its passage.
- Pass the wire through the bone tunnel and secure the ends with a hemostat.
- Create a second bone tunnel in the metacarpal neck. Use the gouges beginning at the fossa from which the UCL normally originates and extending slightly obliquely, from distal to proximal, across the metacarpal, exiting radially (TECH FIG 2B,C).
  - Most often the small, medium, and large gouges are used to create one large hole since both ends of the tendon graft are passed through this hole.

TECH FIG 2 • A. The proximal phalangeal holes are made at the 7 and 11 o’clock position; the surgeon must be careful to make a wide bone bridge to avoid fracture. A 28-gauge wire is placed into the bone tunnel to assist with passage of the tendon graft. B. A large gouge is used to create a single hole in the metacarpal head. An incision is made radially over the end of the gouge to allow for fixation of the graft. C. The adductor aponeurosis has been divided and the collateral ligament remnants have been excised. Gouge holes have been made in the base of the proximal metacarpal head.
A second 28-gauge stainless steel wire is placed through this bone tunnel and the ends are secured with another hemostat.

Preset a 0.045-inch Kirschner wire (sharp at both ends) in the metacarpal head for later advancement across the MCP joint.

Radially deviate the proximal phalanx to expose the metacarpal head.

Starting in the center of the metacarpal head and aiming at an angle of about 45 degrees, advance the wire retrograde through the radial cortex of the metacarpal shaft until it is just below the articular surface of the metacarpal head.

**Tendon Graft Harvest and Passage**

Harvest the palmaris longus (PL) for use as a graft.

If the palmaris is absent, use half of the flexor carpi radialis (FCR) tendon or the plantaris tendon.

The obvious advantage of the FCR is its availability without requiring a second surgical site.

Make a short transverse incision over the PL tendon at the distal wrist flexion crease (TECH FIG 3A) and mobilize the tendon distally.

Make a second, proximal incision over the PL musculotendinous junction and mobilize the tendon at this level and under the skin bridge.

Use of a tendon stripper is an alternative method of harvest.

After incising the PL as distal as possible, apply firm traction and withdraw the tendon through the proximal incision, and then divide the tendon at the musculotendinous junction.

Secure the tendon graft to the limb of the stainless steel wire emerging from the more volar of the two proximal phalangeal gouge holes by tying a knot around one end of the tendon graft (TECH FIG 3B) or by using a grasping suture placed through the graft.

Moisten the tendon graft with saline.

Pull the wire to draw the tendon into and through the bone tunnel, emerging from the dorsal hole (TECH FIG 3C).

The tendon is pulled using moderately firm traction and a circular motion of the wire.

Avoid fracturing the bony bridge between the gouge holes by pulling too firmly on the wire with a vector of pull away from the bone.

The wire is removed from the end of the tendon.

Remove this wire and tie the ulnar end of the wire previously placed in the metacarpal bone tunnel around both ends of the tendon graft.

Using the same technique combining lubrication, traction, and rotation of the wire, bring the two ends of the graft together and through the metacarpal gouge hole, exiting radially (TECH FIG 3D,E).

Set the tension of the reconstruction by pulling on both limbs of the graft simultaneously and stressing the joint with radially directed force on the proximal phalanx.

Flexion and extension should not be limited and the joint should open minimally with stress.

When the desired tension is achieved, tie the ends of the graft in a knot (TECH FIG 3F).

Suture the knot to the adjacent periosteum with two mattress sutures stitches of 3-0 braided synthetic suture.

Alternatively, place a bone anchor adjacent to the metacarpal tunnel on the radial side and use the loaded sutures to secure the knot.

Transfix the MCP joint by driving the previously placed Kirschner wire antegrade, across the joint into the proximal phalanx (TECH FIG 3G,H).

Bend and cut the proximal end of the Kirschner wire superficial to the skin.

Suture the tendon graft to the native collateral ligament remnants using 3-0 braided synthetic suture (TECH FIG 3I).

Repair the adductor aponeurosis with 5-0 absorbable PDS suture (TECH FIG 3J).

Reapproximate the skin with either subcuticular 4-0 Prolene or interrupted, absorbable 5-0 suture.

A forearm-based thumb spica splint is applied, leaving the thumb interphalangeal joint free.
**Hand Fractures and Dislocations**

**Reconstruction of Chronic RCL Disruptions Using Tendon Graft**

- The steps used to stabilize the radial MCP joint using a tendon graft are much the same as those detailed for reconstruction of chronic UCL disruptions.

**Exposure**

- Center the skin incision over the radial MCP joint line (**TECH FIG 4A**).

- Identify and protect the branch of the dorsoradial digital nerve (**TECH FIG 4B**).

- Incise the adductor aponeurosis longitudinally, exposing the underlying torn RCL.

- In thumbs with chronic instability the RCL may be densely fibrotic and adherent to the underlying ligament.

**TECH FIG 3** *(continued)*

- E. The graft has been passed through the gouge holes and is secured on the radial side of the thumb metacarpophalangeal joint by tying the ends into a knot; it is further secured with sutures to local tissue. **F.** The graft ends are tied into a knot and secured to the local periosteum with 3-0 nonabsorbable suture. **G,H.** AP and lateral radiographs verify concentric joint reduction and proper placement of the transfixing 0.045-inch Kirschner wire. The Kirschner wire is left in place for 6 weeks. **I.** The tendon graft is sutured to the dorsal and volar remnants of the native collateral ligament for additional fixation. **J.** The adductor aponeurosis is repaired with 5-0 absorbable suture. This layer must be repaired separately from the collateral ligament as differential gliding between the two layers occurs with thumb motion.

**TECH FIG 4**

- A lazy-S incision is used for radial collateral ligament reconstruction. **B.** A dorsal radial sensory nerve branch is identified and protected.
TECH FIG 5 • A. Two holes are made in the base of the proximal phalanx using a small, then a medium gouge. A 28-gauge wire is placed through the bone tunnel to be used later for passage of the graft. B. An axial view of the proximal phalanx of a right thumb demonstrating the 1 and 5 o’clock positions of the gouge holes when viewed from the side. C. A single large hole is made in the metacarpal neck and another 28-gauge wire is placed through this hole, exiting ulnarly.

- Excise the remnant of the RCL, exposing the radial side of the metacarpal head, base of the proximal phalanx, and MCP joint.
- Deviate the MCP joint to visualize the articular cartilage and ensure the absence of significant arthrosis.

**Bone Preparation**
- Using hand-held gouges of increasing diameter in the manner previously detailed, make two holes in the radial base of the proximal phalanx.
  - The holes are made at the 1 and 5 o’clock positions in the base of the proximal phalanx if looking at the right thumb end on (TECH FIG 5A,B).
  - The holes are made at an angle of about 45 degrees directed toward each other to create a continuous bone tunnel within the medullary canal.
  - The holes must be spaced far enough apart to maintain a substantial bony bridge.
  - A 28-gauge stainless steel wire is passed from one hole to the other through the medullary canal to be used for later passage of the tendon graft in the manner described above for UCL reconstruction.
- Create a bone tunnel in the metacarpal neck beginning at the fossa from which the RCL normally originates on the radial side of the metacarpal head and extending slightly obliquely, from distal to proximal, across the metacarpal, exiting ulnarly (TECH FIG 5C).
- A second 28-gauge stainless steel wire is placed through this hole and the ends are secured with a second hemostat.
- Preset a 0.045-inch Kirschner wire in the metacarpal head to be used later for transfixing the MCP joint.

**Tendon Graft Passage**
- Introduce the tendon graft into the prepared bone tunnels using the techniques described for UCL reconstruction (TECH FIG 6A,B).
- The tension of the reconstruction is set and the graft secured in the manner reviewed.
- The MCP joint is transfixied and the wound closed (TECH FIG 6C).
- A forearm-based thumb spica splint is applied, leaving the thumb interphalangeal joint free.

TECH FIG 6 • A. Both tendon ends are pulled together through the metacarpal head, exiting ulnarly. B. Converging gouge holes are made at the base of the proximal phalanx and an oblique hole is made in the metacarpal head. Subsequently, the graft is passed through these holes. (continued)
PEARLS AND PITFALLS

<thead>
<tr>
<th>Category</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>Traction on the dorsoulnar digital nerve</td>
<td>Excessive traction on the dorsoulnar digital nerve may cause numbness, paresthesia, and dysesthesia on the dorsoulnar aspect of the thumb distal to the incision.</td>
</tr>
<tr>
<td>Tools</td>
<td>Using hand-held gouges gives the operator good control of the direction and progressive enlargement of the holes in the proximal phalanx and metacarpal. If power tools are used to make the holes, soft tissue adjacent to the holes can be inadvertently wrapped up in the spinning instrument. The heat generated by a burr may also burn the bone.</td>
</tr>
<tr>
<td>Making holes in the proximal phalanx</td>
<td>The most important aspect of making the holes in the base of the proximal phalanx is to make them wide enough apart to maintain a substantial bone bridge. The greatest risk is making the holes too close together. The consequence is that the bridge fractures when the tendon graft is pulled through the holes.</td>
</tr>
<tr>
<td>Tying the wire</td>
<td>The wire used for passage of the tendon graft should be tied with hemostats, not manually; it can cut the skin of the surgeon’s fingers if done manually.</td>
</tr>
<tr>
<td>Graft tension</td>
<td>The graft can be made too tight, limiting motion of the MP joint and possibly causing pain postoperatively. The knot in the graft should be sutured after the tension has been set and felt to be appropriate. Less likely is the possibility that the graft is too loose, allowing persistent laxity of the joint. After the tension is set, the joint should be flexed and extended to ascertain that the reconstruction is not too tight to allow motion or too loose to adequately correct the instability.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- The thumb is immobilized in a thumb spica cast for 6 weeks postoperatively.
- At 6 weeks after surgery, the cast and pin are removed.
  - The thumb is immobilized after cast removal in a customized, thermoplastic short opponens splint fashioned by the hand therapist.
  - The splint is worn most of the time except when the patient is exercising the thumb or is sedentary.
  - Therapeutic exercise is done with the therapist and at home and includes active and active assisted range of motion in flexion and extension, avoiding force on the proximal phalanx, which would stress the reconstruction.
  - Patients are instructed to do 12 repetitions four or more times per day.
  - After 2 weeks, the thermoplastic splint is eliminated except for strenuous activity.
  - Patients continue range-of-motion exercises and begin strengthening with soft putty and light gripping.
  - At 12 weeks after surgery, pinch and grip strengthening and light free weights are initiated.
  - Full, unrestricted activity is allowed 16 weeks postoperatively.
- Patients are expected to regain about 80% of the range of motion of the contralateral thumb MP joint and nearly full range of motion of the interphalangeal joint.
  - Key pinch strength should be more than 90% of the contralateral, uninjured thumb at final follow-up.

OUTCOMES

- Reconstruction of the UCL using the technique described in this chapter produces results only slightly less favorable than UCL repair.
- Range of motion of the MCP joint averaged 80% of the uninjured side. Motion of the interphalangeal joint is often limited initially after reconstruction but at final follow-up was 94% of the unoperated thumb. Key pinch strength averaged 95% and grip strength averaged 103% of the unoperated thumb not corrected for handedness.
- Sixty-nine percent of patients had no pain postoperatively and the remainder had mild or intermittent pain. Eighty-eight percent of patients had no functional limitations, 8% had minimal limitations, and 2% had moderate functional limitation.
None of the reconstructions that had normal or minimally degenerated cartilage required revision due to development or progression of degenerative disease.\(^\text{11}\)

Results of RCL reconstruction in the hands of the same authors were similar to those of UCL reconstruction.\(^\text{6}\)

Range of motion of the MCP joint on the operated side was 59% of the unoperated side and interphalangeal range of motion was 94% of the unoperated thumb.\(^\text{6}\)

Both grip and key pinch strength were equal in the operated and unoperated thumbs.\(^\text{6}\)

The MCP joints were equally stable to stress in operated and unoperated thumbs.\(^\text{6}\)

Patients had minimal pain and no significant functional limitations. All returned to their preoperative occupations.\(^\text{6}\)

COMPLICATIONS

Some patients develop transient hypesthesia on the dorsal aspect of the thumb distal to the incision due to intraoperative traction on a branch of the radial sensory nerve.

This generally resolves over several weeks.

Occasionally, patients develop stiffness of the MP joint that is persistent. This may be the result of the reconstruction being too tight.

The MCP joint occasionally develops some laxity postoperatively, which may be a consequence of the reconstruction being too loose or the patient being too aggressive during rehabilitation.

The bony bridge between the proximal phalangeal gouge holes can theoretically crack intraoperatively, but this has not happened to the authors or their colleagues.

If it did occur, an alternative form of fixation of the graft to the proximal phalanx would have to be used, like suturing the graft to the adjacent periosteum, pulling it out through a gouge hole on the opposite side of the phalanx, or employing a suture anchor.

REFERENCES

DEFINITION
- Fractures and dislocations of the carpometacarpal (CMC) joints of the index through small fingers involve intra-articular fractures at the base of the metacarpals or pure dislocations between the metacarpals and carpus. The fracture can involve the base of the metacarpal or the trapezoid, capitate, or hamate articular surface.
- These fractures and dislocations can result in instability and articular incongruity (FIG 1).

ANATOMY
- The CMC joints connect the metacarpals and the distal carpal row.
- The shape and degree of constraint present in the joints differ from finger to finger.
  - The index and middle fingers have highly constrained articulations due to the shape of the index CMC articulation and supporting soft tissues. These include the flexor carpi radialis tendon, extensor carpi radialis longus and brevis tendons, and very strong capsular insertions. This provides for a strong radial column for the hand, and efficient force transfer to the radius (FIG 2A).
  - The ring and small fingers have a gliding articulation on the hamate, which allows for the closure of the hand around objects and is very important in power grip. This mobility makes them more susceptible to injury. The extensor carpi ulnaris tendon attaches to the base of the small finger metacarpal.4
  - The deep motor branch of the ulnar nerve crosses around the base of the hamate hook and runs along the volar surface of the CMC joints (FIG 2B). It is vulnerable at the time of injury or during fixation.

PATHOGENESIS
- Injuries of the CMC joints may be divided into two broad categories.
  - The first, involving a load applied to a flexed metacarpal, is by far the most common mechanism. This injury usually involves the ring and small fingers displacing dorsally as a unit relative to the hamate. This may occur as a dislocation only or include a marginal fracture of the hamate.8
  - The second mechanism involves an axially directed force that creates a comminuted fracture of the articular surface (FIG 3A). Severe crushing injuries can cause multiple dislocations and fractures diffusely throughout the CMC region1,7 (FIG 3B, C).

NATURAL HISTORY
- The natural result of an untreated fixation dislocation is progressive arthritis of the involved joints.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The patient’s history is important to assess the mechanism of injury, which provides further clues regarding concomitant injuries in the extremity.
Examine the hand for tenderness and local swelling.
Assess neurovascular integrity, especially function of the deep branch of the ulnar nerve (first dorsal interosseous contraction).
Examine the limb for other injuries.
Associated injuries should be detected by examination and verified by radiographs.
Preoperative notation of nerve function is important when comparing function following reduction and fixation.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
Radiographs of the CMC joints require careful positioning to assess each joint.

The transverse metacarpal arch causes the CMC joints of the index and middle fingers to appear in an oblique projection when a standard PA radiograph is obtained of the ring and small finger CMC joints, and vice versa (**FIG 4A**).
A true frontal radiograph is most easily obtained by positioning the hand in an AP projection with the dorsum of the hand placed flat on the cassette (or image intensifier, if using fluoroscopy). The base of the affected metacarpal should lie on the cassette (**FIG 4B**). This will result in a far more accurate portrayal of the joint, essential for assessing the fracture as well as checking hardware position after fixation.
Visualization of the joint surfaces at the base of the ring and small fingers differs in a typical PA projection (**FIG 4C**) and a properly positioned film of the same patient (**FIG 4D**).
The same principle holds for obtaining lateral radiographs. A semisupinated lateral view will best visualize the base of the index and middle CMC joints, and a semipronated lateral view will best show the bases of the ring and small finger CMC joints. A CT scan should be obtained in most cases to assess for articular injury. CT also is especially helpful for visualizing impacted articular surface fragments. The best visualization and determination of fracture patterns will be possible if the scan is obtained after preliminary reduction of any displaced fractures or dislocations associated with a fracture (FIG 4E).

DIFFERENTIAL DIAGNOSIS
- Metacarpal fracture
- Carpal bone fracture
- Carpometacarpal fracture/dislocation
- Fracture associated with neurovascular injury

NONOPERATIVE MANAGEMENT
- Nondisplaced fractures can be treated in a below-elbow cast that incorporates the affected digit or digits and one adjacent digit. Special attention should be paid to positioning the hand in an intrinsic-plus position. Capsular contractures of the metacarpophalangeal (MCP) joints can develop relatively rapidly in hands with the MCP joints immobilized in extension.
- Radiographs following cast immobilization should be checked carefully to ensure that no dorsal subluxation is present and should be repeated at weekly intervals for the first 2 weeks to prevent healing in a displaced position.
- These injuries, especially those involving a dislocation, have a known propensity for recurrent dorsal subluxation following reduction. Most will require operative fixation. Some authors believe nonoperative management does have a role despite intra-articular displacement and shortening.

SURGICAL MANAGEMENT
Preoperative Planning
- Careful review of all imaging studies will facilitate planning of fracture fragment exposure and identify sites for internal fixation.

Positioning
- The patient is positioned supine on the operating table with a standard arm table.
- The surgeon often is more comfortable seated on the head side of the arm table. This avoids the neck strain that may
result from looking “over the top” that happens when the arm externally rotates and the surgeon is seated on the axilla side of the table (FIG 5A).

Approach

- A dorsal extensile approach provides satisfactory exposure of any of the CMC joints.
- Incisions placed between metacarpals allow access to two adjacent joints.
- Cross the wrist with oblique extensions if necessary.
- Marking out the anticipated locations of nearby nerve branches can be helpful (FIG 5B).

DORSAL EXPOSURE

- Following incision of the skin, careful spreading dissection should be used to locate and protect the dorsal cutaneous nerve branches in the operative field.
- Ulnar sensory nerves are most commonly encountered during exposure of the CMC joints of the ring and small fingers (TECH FIG 1), and radial sensory nerves during exposure of the index and middle finger CMC joints.
- Extensor tendons are mobilized and retracted.

FRACTURE EXPOSURE

- Careful mobilization of the fracture fragments with minimal soft tissue stripping is important.
- The rongeur is useful because it is helpful to débride fracture callus and hematoma.
- Incisions placed between metacarpals allow access to two adjacent joints.
- Cross the wrist with oblique extensions if necessary.
- Marking out the anticipated locations of nearby nerve branches can be helpful (FIG 5B).

FRACTURE REDUCTION

- The fracture is then reduced and held provisionally using fine K-wires (TECH FIG 2A). The surgeon must be aware of the planned location for definitive hardware placement, given the limited room available.
- Pins temporarily driven across the base of an articular fragment into the corresponding carpal bone can be helpful in stabilizing any mobile pieces of bone (TECH FIG 2B).
- The conventional technique of first reconstructing the articular surface, followed by securing the shaft to the reassembled joint surface, is useful.
Confirmation of the provisional reduction should be obtained with fluoroscopy before any definitive screw placement (TECH FIG 2C). The corresponding articular surface on the uninjured bone is used as a mold for the fragments, serving as a guide to reassembly of the injured bone.

This technique works regardless of whether the injury is in the metacarpal base, as pictured in these figures, or in a distal articular injury of one of the carpal bones (TECH FIG 2D).

**DEFINITIVE FIXATION**

- Wires can be replaced by screws if fragment size permits (TECH FIG 3A).
- Placing the fragments under compression manually and inserting screws sometimes is preferable to using the lag screw technique, which requires overdrilling the near side and may risk iatrogenic comminution.
- Simple K-wire fixation is satisfactory for isolated dislocations with fracture (TECH FIG 3B).
- The insertion point for a percutaneous wire often is quite distant from the dislocation site in crushed and severely swollen hands.

**TECH FIG 2**
A. Provisional fracture reduction using the hamate surface as a mold for articular reduction of the metacarpal base. B. Initial reduction of the shaft and stabilization of the articular surface. C. Fluoroscopic view of articular reduction. D. Dorsal hamate lip fixation with three screws.

**TECH FIG 3**
The construct can be protected by placing the affected metacarpal under slight distraction and pinning it to the adjacent metacarpal.

Alternatively, the proximally directed deforming force of the extensor carpi ulnaris can be reduced by detaching it from the base of the small finger metacarpal at the beginning of the procedure, and securing it to the hamate at the close, thereby avoiding proximal pull on the base of the small finger metacarpal.

I have never found it necessary to use this alternative approach, but it may be helpful in a delayed presentation, where myostatic contractures due to shortening are present.

Aftercare following operative fixation falls into three general phases: acute swelling control and wound healing (10–14 days), fracture consolidation and maintenance of digit range of motion (4–6 weeks), and restoration of global hand function and strength (2–6 months).

Immediate measures following surgery include strict elevation and range-of-motion exercises through a full arc of motion. This limits swelling, reduces pain, and prevents accumulation of protein-rich edema fluid that will slow rehabilitation.

The relative speed at which the hand can be mobilized during the weeks after surgery depends on a number of factors, including the magnitude of the original injury, stability of fixation, reliability of the patient, and specific occupational or athletic needs.

The radiograph in Tech Fig 2D shows the hand of a physician with stable fixation of a dorsal hamate injury who was mobilized and given a 1-pound lifting restriction shortly after surgery to allow continuation of his residency training.

In contrast, unreliable patients require immobilization for 6 weeks in a cast (see Tech Fig 3B).

Patients should be warned that full grip strength is the last thing that will recover and may take months. It is not uncommon for patients to report pain with a handshake for an extended period of time.

Opinions on outcomes vary with regard to overall success. A dichotomy exists between recommendation for operative and nonsurgical treatment. Kjaer-Petersen and colleagues found that, regardless of treatment, long-term symptoms were present in 38% of patients at 4.3 years of follow-up.

Petrie and Lamb, who used immediate, unrestricted motion, reported on results at 4.5 years. Even with metacarpal shortening and irregularities in the articular surface, only one patient had work limitations.

Another study found that pain was related to the degree of posttraumatic arthritis secondary to articular incongruity and advocated anatomic reductor and internal fixation.

Multiple CMC dislocations were reviewed by Lawliss and Gunther, and poor results were noted in dislocations of the second and third CMC joints (which require higher energy for dislocation) and in those patients with an ulnar nerve injury.

Complications include those common to any periarticular surgery:

- Failure of wound healing
- Hematoma formation
- Neurovascular injury
■ Neuroma formation
■ Tendon adhesions
■ Posttraumatic arthritis
■ Nonunion or malunion
■ Joint stiffness
■ Weakness

Occasionally small fragments may resorb, leading to collapse and articular incongruity (FIG 6).

Long-term arthritis can be treated with fusion of the affected joint.4

Alternatively, an interposition “anchovy” using the palmaris longus as a biologic spacer can be inserted after resection of the arthritic joint surfaces, analogous to that performed for thumb basal joint arthritis.3

REFERENCES

DEFINITION

- Metacarpal fractures are most significant when they disrupt function of the associated digit.
- The treatment of metacarpal fractures affects finger function and must be weighed against the sequelae of the fracture itself.
- Intra-articular fractures may involve the carpometacarpal (CMC) joint or metacarpophalangeal (MCP) joint.
  - CMC joint injuries are discussed in other chapters.
- Intra-articular MCP joint fractures have an increased risk of stiffness and posttraumatic arthritis.

ANATOMY

- The metacarpals are long tubular bones with relatively flat surfaces dorsally. The medial and lateral cortices converge volarly, making the cross-section triangular. The bone may be quite narrow in the mid-diaphyseal region, with the fourth metacarpal being particularly gracile.
- Dorsal and volar interossei muscles envelop the medial and lateral surfaces. When undisturbed, the muscles provide abundant blood supply to the underlying bone (FIG 1A). When severely disrupted, the muscles have the potential for disabling scarring and “intrinsic contracture.”
- Deep transverse intermetacarpal ligaments lie at the level of the metacarpal head and may contribute to posttraumatic MCP joint contracture (see Chapter HA-108). The adjacent lateral furrow or so-called collateral recess allows passage of the interosseous tendon and may serve as a portal of entry for Kirschner wire fixation into the intramedullary canal.

PATHOGENESIS

- Metacarpal fractures typically result from one of two mechanisms of injury:
  - Most commonly, an axial load is transmitted from the MCP joint down the shaft of the metacarpal. Such injuries include the spectrum of fractures from a low-energy fifth metacarpal neck “boxer’s fracture” to a high-energy comminuted shaft fracture caused by a blow from the steering wheel in a motor vehicle collision.
  - The metacarpal less commonly is injured by a crush-type injury that flattens the metacarpal arch bridging the carpus to the phalanges. Crush injuries typically involve multiple metacarpals and are often associated with other fractures and significant soft tissue trauma.
  - Extra-articular fracture orientation may be characterized as transverse, oblique, or spiral, and with or without comminution. As with other long tubular bones, the exact pattern depends on the degree of shear and torsion associated with the applied load. The fracture typically has apex-dorsal malalignment secondary to the flexion force applied by the lumbrical and interossei muscles.

NATURAL HISTORY

- Most metacarpal fractures heal uneventfully without surgery.
- Low-energy transverse or oblique fractures of a single metacarpal usually maintain acceptable alignment and heal without any measurable functional deficit.
- Spiral fractures, comminuted fractures, and fractures of multiple metacarpals are more likely to shorten and rotate, resulting in tendon imbalance and overlapping of the fingers.
- Fractures of the metacarpal neck (usually the fourth or fifth) may have varying degrees of apex-dorsal malalignment.
  - Flexion of the fourth or fifth metacarpal heads beyond 30 and 45 degrees, respectively, results in a visible pseudoextensor lag and sometimes pain in the palm during grasping.
  - Less angulation is tolerated in the index and middle metacarpals as there is less compensatory motion available at the radial-sided CMC joints.
- Cadaveric studies of fifth metacarpal neck “boxer’s fractures” have demonstrated that every 2 mm of shortening causes an average of 7 degrees of extensor lag and 30 degrees of angulation results in 22% loss of finger range of motion.
- Nevertheless, there is no well-defined relationship between angular fracture malalignment and symptoms. However,
rotational malalignment is poorly tolerated as it results in digital scissoring and difficulty with grasp.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Physical examination methods include:
  - Inspection. The examiner should visualize the fingers as the patient carries them through an arc of motion. All nail beds should point toward the scaphoid tubercle with finger flexion.
  - Extensor lag. The examiner should assess the resting posture of the MCP joint and active MCP extension. Apex-dorsal malalignment results in some loss of active MCP joint extension.
  - Palpation. The examiner should determine the degree of dorsal fracture eminence or palmar metacarpal head prominence. Dorsal callus is usually only a cosmetic concern. The palmar head prominence may be painful with grasp.

The examination is not complete without carefully assessing for associated injuries:

- Open wound: The most common (and often missed) open wound results from a tooth puncture into the MCP, the so-called fight bite. These injuries should be treated urgently with surgical débridement before infection develops.
  
- CMC dislocation: Metacarpal base fractures are often associated with CMC joint subluxation or dislocation. These injuries may go unrecognized until a true lateral radiograph of the hand is inspected.
  
- CMC fracture-dislocation
  
- MCP dislocation
  
- Fight bite
  
- Pathologic fracture (eg, enchondroma)

**DIFFERENTIAL DIAGNOSIS**

- CMC fracture-dislocation
- MCP dislocation
- Fight bite
- Pathologic fracture (eg, enchondroma)

**NONOPERATIVE MANAGEMENT**

- Nondisplaced and minimally displaced metacarpal fractures should be protected in a thermoplast splint or cast for 3 to 4 weeks, followed by gradual mobilization. The MCP joints should be immobilized in flexion to (1) relax the intrinsic muscles and prevent further deformity at the fracture site and (2) place the MCP collateral ligaments on stretch.

- Apex-dorsal malalignment of the border metacarpals may be partially corrected with reduction and splinting.

- Rotational malalignment cannot be reliably corrected with nonoperative means.

**Jahss Maneuver**

- Reduction is accomplished under a hematoma block with this maneuver (FIG 2).

- The metacarpal shaft is stabilized and the MCP joint flexed 90 degrees.

- While distracting at the fracture site, upward force is applied to the proximal phalanx and metacarpal head to realign the neck and shaft.

- A splint with three-point molding is applied with dorsal compression at the fracture site and volar support for the metacarpal head and base.

- A cast is applied 10 to 14 days later.

- Joint mobilization begins at 4 weeks.

**SURGICAL MANAGEMENT**

- Surgical reduction and stabilization is indicated for malrotated fractures, open fractures, unstable fractures (especially involving the border metacarpals), or fractures associated with joint disruption, tendon injury, or neurovascular injury.

- Relative indications for surgery include fractures associated with significant extensor lag, palmar metacarpal head

---

**FIG 2** Jahss maneuver: correction of apex dorsal malalignment as shown by Jahss in 1938.
prominence, more than 5 mm of shortening, and the presence of multiple displaced metacarpal fractures.

- Percutaneous surgical techniques are often adequate for low-energy metacarpal shaft fractures and for most metacarpal neck fractures.
- Open reduction and internal fixation should be considered for open fractures, shaft fractures with significant comminution, and fractures associated with joint disruption, tendon injury, or neurovascular injury.
- Dorsal plating is the most biomechanically stable fixation, although it is potentially more disruptive to the soft tissues than other methods, such as crossed Kirschner wires or interosseous wires.
- Crush-type injuries flatten the bony arch of the hand, often resulting in open metacarpal neck fractures with varying degrees of soft tissue injury. Carpal and CMC joint injuries also occur and are discussed in other chapters.

- Crush fractures associated with mild to moderate soft tissue injury with or without disruption of the extensor mechanism may be stabilized by conventional pinning techniques or by a T-type plate applied distally up to the proximal margin of the joint capsule (FIG 3A,B).
- Occasionally, crush injuries result in long oblique neck fractures, which may be stabilized with lag screws alone (FIG 3C).
- More stable internal fixation is recommended over percutaneous pins when early motion is necessary (eg, associated extensor laceration).
- Crush fractures associated with severe soft tissue injury or internal degloving are best pinned percutaneously (FIG 3D–F).
- The dorsal soft tissues are often tenuous and surgical incisions can result in necrosis and the need for otherwise unnecessary soft tissue coverage procedures.
- Metacarpal fractures resulting from projectiles are graded as either low or high energy.

**FIG 3** • A. Oblique view of the hand demonstrates fourth and fifth metacarpal shaft fractures. B. Repair may be achieved with conventional plates using a T-shape to gain additional fixation in the metaphyseal bone near the metacarpal head or base. C. Long oblique fractures of the fourth and fifth metacarpal heads have been stabilized with multiple lag screws. An adjacent transverse fracture of the ring finger proximal phalanx has been repaired with a plate. D. Clinical photograph of a crushed hand reveals global swelling and splitting of the skin indicative of severe internal degloving. E. Radiograph confirms fracture of all five metacarpals and the carpus. F. Fractures are stabilized with percutaneous pins to avoid additional trauma from surgical dissection.
- Simple comminuted fractures caused by low-energy projectiles with small entry or exit wounds are best treated with limited exposure and débridement, and fracture pinning (FIG 4A). Callus usually forms because the fracture fragments, although comminuted, remain vascularized.
- If there is a large area of bone loss, more rigid plate and screw fixation supplemented with bone graft may be safely performed.\(^3\)
- Complex, comminuted fractures resulting from high-energy projectiles and associated with large open wounds and metal debris should be carefully cleansed, taking measures to minimize devascularization of the fracture fragments.
- Tendons, nerves, and vessels may need to be repaired.
- Provisional fixation with Kirschner wires may be considered if serial débridements are anticipated.
- If and when soft tissues allow, consideration should be given to rigid stabilization of the fractures with a bridge plate technique to facilitate mobilization (FIG 4B).
- Bone grafting may be necessary but can be delayed until there is minimal risk of wound infection (FIG 4C).
- Simple thumb metacarpal shaft fractures usually heal in acceptable alignment with nonoperative management. The massively comminuted thumb metacarpal may be difficult to control in a splint or cast alone. Spanning external fixators are effective for these injuries in order to maintain the first web space while fracture consolidation occurs (FIG 4D,E).

**Preoperative Planning**
- A surgical technique is selected based on the clinical examination, radiographs, and the surgeon’s preference.
- The “best” technique is usually the method that is least disruptive to the soft tissues while allowing early digital mobilization.
- The “best” technique depends on patient factors. For example, a grossly contaminated and devitalized open metacarpal fracture may be treated with percutaneous Kirschner wires to minimize further soft tissue stripping. In contrast, a simple closed transverse metacarpal fracture in a dentist would be considered for dorsal plating to facilitate a prompt return to work.
- The “best” technique also depends on surgeon factors. A surgeon facile with the technique of collateral recess pinning may quickly stabilize multiple metacarpal fractures. A surgeon inexperienced in this technique may spend considerable time and frustration trying to pass wires. Poorly placed percutaneous wires in any technique may cause more soft tissue problems (eg, infection) than open reduction and fixation.

![FIG 4 • A. A radiograph of the hand shows percutaneous fixation of displaced metacarpal fractures from a gunshot wound. B. Higher-energy projectiles may cause considerable displacement and comminution, as shown in this radiograph. Bridge plating is performed to improve alignment while minimizing soft tissue dissection. C. This index metacarpal developed a nonunion and segmental defect after nonoperative treatment of a gunshot-related fracture. A locking plate applied with cancellous bone graft to fill the void resulted in solid healing. D. Fractures of the first ray, as shown in this radiograph, often result in contraction of the thumb–index web space. E. A clinical photograph shows application of an external fixator to allow fracture consolidation in a functional position.](image-url)
In the operating room, the contralateral hand is examined, note is made of the patient’s native digital rotation, and contralateral radiographs are reviewed to assess appropriate metacarpal length.

Positioning
- The patient is positioned supine with the affected extremity placed on a hand table. A brachial tourniquet is applied.
- Surgery may be performed under regional or general anesthesia.

Approach
- Percutaneous landmarks are described in the Techniques section.
- A single extra-articular metacarpal fracture is approached with a dorsal longitudinal incision.
- Crossing dorsal sensory nerves are sought and avoided, particularly as they pass over the bases of the border metacarpals.
- The extensor mechanism is retracted to one side and the underlying metacarpal exposed in an extraperiosteal fashion.
- At closure, hardware may often be covered by the fascia of the interosseous muscles.
- Multiple metacarpal fractures are exposed by way of separate dorsal longitudinal incisions placed between affected metacarpals. If necessary, each incision may be extended as a Y distally to facilitate exposure of each metacarpal head and neck. Alternatively, the incision may be designed as a lazy S to facilitate exposure of both metacarpals (FIG 5A,B).
- Intra-articular fractures are approached by longitudinally splitting the extensor tendon over the MCP (FIG 5C).

![A longitudinal incision may have legs distally (or proximally) to facilitate exposure of multiple metacarpal heads (bases). B. A curvilinear or S-shaped incision allows the skin to be sewn back for ease of operating without an assistant. C. The index metacarpophalangeal joint capsule is seen after dividing the interval between the extensor indicis proprius and the extensor digitorum communis.](image)

Closed Reduction and Pinning of Metacarpal Fractures

A multitude of methods for pinning metacarpal fractures have been described.
- We have found collateral recess pinning to be an expedient and elegant technique for managing the wide spectrum of closed and open, simple and comminuted, single and multiple metacarpal shaft fractures.
- In contrast, a technique called bouquet pinning is uniquely suited for neck fractures of the border metacarpals.
- These two techniques are illustrated in view of the technical challenge associated with these procedures.

Collateral Recess Pinning of Metacarpal Shaft or Neck Fractures

- Obtain gross alignment in a closed fashion (TECH FIG 1A).
- Flex the MCP joint to facilitate control of the distal fragment and subsequent pin placement (TECH FIG 1B).
- Place a 0.045-inch smooth Kirschner wire by hand onto the radial (or ulnar) collateral recess and confirm appropriate placement at the deepest concavity of the collateral recess (TECH FIG 1C).
- An oblique or near true lateral view confirms placement in the sagittal plane.
Advance the wire with power into the shoulder of the metacarpal and down the intramedullary canal to the fracture site (TECH FIG 1D).

Reduce the fracture and advance the wire, keeping it intramedullary and seating it in the bone of the metacarpal base (TECH FIG 1E).

Consider advancing the wire using a mallet rather than power in order to “bounce” off the far cortex and remain intramedullary.

Pass a second wire, completing fracture stabilization (TECH FIG 1F,G).

Reduction and fixation is optimized when the wires cross the fracture site.

**Bouquet Pinning of Metacarpal Neck Fracture**

Make a longitudinal 2-cm incision over the radial aspect of the second metacarpal base and CMC joint (TECH FIG 2A,B) for the index or on the corresponding ulnar side of the small metacarpal base.

The wrist extensor is elevated partially but not completely detached.

Prepare a 0.045-inch smooth Kirschner wire by cutting off the sharp tip, gently bending the pin along its length, and...
creating a deflection of the pin in the plane of the original bend about 3 mm from its leading end (TECH FIG 2C).

- Locate an entry site into the medullary canal at the proximal aspect of the metaphysis using fluoroscopy.
- Enter the canal with a 2-mm drill and enlarge the introitus to about 5 mm.
- Introduce the precontoured 0.045-inch Kirschner wire and direct it distally, at the most acute angle possible (TECH FIG 2D).
- Advance and direct the wire down the canal and across the reduced fracture site using two large needle holders (TECH FIG 2E).
- Insert several additional 0.045- or 0.035-inch Kirschner wires to complete the bouquet and maintain the reduction.

- The goal is to tension the wires off the intact proximal cortex and enter the distal fragment in varied locations, creating a “bouquet” effect.
- Cut the pins flush with the canal and “nudge” them inside with a bone tamp (TECH FIG 2F).
- A lateral radiograph confirms correction of the preoperative apex-dorsal angulation (TECH FIG 2G).

**Alternative Methods**

- The combination of a longitudinal “collateral recess” pin and a transverse pin is a technically simple method of fixation for certain border metacarpal neck and base fractures (TECH FIG 3).

**OPEN REDUCTION AND INTERNAL FIXATION OF METACARPAL FRACTURES**

- Traditional AO techniques may be used to stabilize metacarpal fractures: long oblique or spiral fractures are secured with multiple screws, while short oblique and transverse fracture patterns require plate fixation.

**Dynamic Compression Plating for Transverse Fractures**

- Dynamic compression plating is performed using a dorsal longitudinal approach.
■ Incorporate open wounds or previous incisions as needed (TECH FIG 4A).
■ Identify and protect dorsal sensory nerve branches (TECH FIG 4B).
■ Expose the fracture in an extraperiosteal fashion.
■ In addition to the dorsum, visualize both the radial and ulnar margins to help guide reduction.
■ Apply the appropriately sized dynamic compression plate to the dorsum of the distal fracture fragment and clamp it proximally to obtain provisional fracture reduction (TECH FIG 4C).
■ Plate size and length depend on the patient and the fracture. The most commonly used are 2.0 to 2.5 mm.
■ Add a subtle concave bend to the plate before application to the bone to help compress the volar cortices.
■ Assess sagittal and coronal plane alignment by direct inspection of the fracture site; assess rotation clinically with the aid of tenodesis (TECH FIG 4D).
■ Fill screw holes in compression mode, achieving at least four cortices of fixation in both the proximal and distal fragments (TECH FIG 4E).
■ Fluoroscopy confirms anatomic fracture reduction and appropriate hardware placement (TECH FIG 4F,G).
■ Close the periosteum and interosseous muscle fascia over the plate to provide a smooth gliding surface for the extensor mechanism (TECH FIG 4H).

**TECH FIG 4** • A. A malrotated open index metacarpal fracture from an industrial machine accident. B. A branch of the radial sensory nerve crosses the metacarpal. C. A 2.4-mm dynamic compression plate is secured distally with a screw and proximally with a clamp to obtain provisional reduction. D. Digital rotation is inspected. E. In the absence of comminution, the plate may be applied in compression mode. F,G. AP and lateral views demonstrate anatomic reduction and appropriate screw lengths. H. The plate is covered by fascia to minimize extensor tendon irritation.
Neutralization Plating with Lag Screw Fixation for Short Oblique Fractures

- A short oblique fracture can be compressed with a lag screw and protected with a neutralization plate. In this case of pathologic fracture, a lag screw crosses an enchondroma cavity filled with bone graft. A T-type plate has been selected to optimize distal fixation without disrupting the MCP joint capsule (TECH FIG 5A).

- The exposure of short oblique metacarpal fractures is similar to transverse fractures. Adequate bone must be exposed proximal and distal to the fracture site to allow at least four cortices of screw fixation (TECH FIG 5B,C).

- Provisional fracture reduction can usually be achieved with a fracture reduction clamp. If fracture geometry allows, a plate (2.0 to 2.5 mm) can be contoured and held in place without disturbing the reduction (TECH FIG 5D).

- A lag screw may be placed alone or through the plate. Lag screw placement through the plate reduces soft tissue dissection and improves stability (TECH FIG 5E,F).

- Screw holes are filled in the remainder of the plate to protect the fracture site (TECH FIG 5G,H). Standard cortical screws may be used, although many modern plate systems also have the option for locking screws to improve fixation in metaphyseal bone.

**TECH FIG 5** - A. Short oblique fractures can be lagged together before placement of a dorsal plate. B. This cadaver specimen demonstrates a short oblique fracture at the proximal metadiaphyseal junction of the index metacarpal. C. Fluoroscopy reveals the proximity of the fracture to the carpometacarpal joint. D. The unstable distal fragment is controlled by a small pointed clamp to facilitate reduction. The reduction is maintained by a second clamp, which may also be used to hold a plate. E. A screw is inserted across the fracture site with lag technique to achieve optimal compression. F. Fluoroscopy confirms the reduction. G. Additional screws are placed, neutralizing forces at the fracture site. H. Final radiograph.
Lag Screw Fixation for Long Oblique and Spiral Fractures

- Lag screws obviate the need for excessively long plates (TECH FIG 6A). Ideally, one screw is placed perpendicular to the fracture to maximize compression and another screw is placed perpendicular to the intramedullary axis of the metacarpal to resist axial loads.
- A long oblique ring metacarpal fracture is exposed enough to see the length of the fracture line; however, further proximal and distal dissection is unnecessary as a plate will not be used (TECH FIG 6B). The distal extent of the volar fracture fragment approaches the metacarpal head as clarified by careful fluoroscopic imaging (TECH FIG 6C).

- Long spiral and oblique fractures typically key into position easily with the aid of a pointed clamp (TECH FIG 6D). Fluoroscopy may be used to confirm reduction as the entire fracture length may be difficult to visualize (TECH FIG 6E). Rotational alignment should also be assessed clinically as described above.
- Lag screws are placed in different planes to achieve fracture compression and resist loads applied to the metacarpal (TECH FIG 6F).
- A final lag screw is placed proximally with strict adherence to good technique in order to avoid splintering of the metacarpal (TECH FIG 6G–I).
- Live fluoroscopy is best to confirm reduction and screw lengths when there are multiple screws in different planes (TECH FIG 6J).

TECH FIG 6 • A. Longer oblique and spiral fractures are more securely fixed with screws alone. Plate constructs must be excessively long to provide four cortices of fixation proximal and distal to the fracture site. B. A long oblique ring finger metacarpal fracture extends to the metacarpal head, but dissection distally can be kept to a minimum by using lag screws as the sole means of fixation. C. Fluoroscopy helps define the fracture anatomy, especially at the apex of the volar fragment—an area that will be hidden from direct inspection once the fracture is reduced. D. The pointed clamp secures the reduction while lag screws are placed. E. Fluoroscopy is used to confirm reduction because volar fracture lines may not be easily visible. Long oblique and spiral fractures may look well reduced dorsally while remaining displaced or malrotated. F. Ink marks the proximal extent of the fracture after two lag screws have been placed. G. Careful AO technique is followed to place a third 2.0-mm screw in the small remaining area. A 2.0-mm drill makes a glide hole through the dorsal cortex. (continued)
Metacarpal head fractures often occur in the coronal plane (TECH FIG 7A) and may be associated with fractures of the neck or shaft.

Make a longitudinal or curvilinear incision over the metacarpal head (TECH FIG 7B).

Split the extensor mechanism and incise the capsule longitudinally (TECH FIG 7C).

Flex the MCP joint to facilitate exposure of the fracture (TECH FIG 7D).

Reduce the fracture with a dental pick or small pointed reduction forceps.

Insert guidewires from a cannulated headless screw set to maintain the reduction (TECH FIG 7E).

Insert headless screws over the guidewires (TECH FIG 7F).

Close the extensor mechanism with 4-0 nonabsorbable suture (TECH FIG 7G).

Confirm appropriate screw placement and fracture reduction radiographically (TECH FIG 7H,I).
TECH FIG 7 • (continued) E. The fracture has been reduced with the proximal phalangeal base to restore metacarpal head congruity. Provisional fixation is achieved with two guidewires. F. Definitive fixation with cannulated headless screws facilitates early rehabilitation. G. The repaired extensor incision will tolerate active and active assisted motion immediately. H, I. AP and lateral views reveal a smooth articulation.

PEARLS AND PITFALLS

Indications
- Most metacarpal fractures have good functional results with nonoperative treatment.
- Surgery always causes some disturbance in the extensor mechanism, MCP joint capsule, or intrinsic muscles.

History
- Antecedent pain or minimal precipitating trauma should raise the possibility of a pathologic fracture.
- A fight-related injury may have an associated open wound. Some of these patients will have prior fracture deformities, which may be confused with an acute injury.

Examination
- Rotational malalignment is poorly tolerated and must not be overlooked.
- Crush injuries of the metacarpals may be associated with:
  - Fractures and dislocations of the carpus and CMC area
  - Compartment syndrome and carpal tunnel syndrome

Exposure
- Metacarpals heal quickly when exposure is limited and the bone remains within the well-vascularized bed of intrinsic musculature.
- Massive crush and high-energy projectile injuries cause the MOST internal tissue disruption and are often best treated with the LEAST surgical tissue dissection.
POSTOPERATIVE CARE

- Protective splints or casts are typically worn for 4 to 6 weeks after surgery depending on the stability of fixation, the soft tissue envelope, and treatment of associated injuries.
- The interphalangeal joints should undergo immediate active and active assisted motion to promote tendon gliding and prevent capsular contracture.
- It is also important to mobilize the MCP joint as this allows the greatest extensor excursion over the fracture site. If necessary due to swelling, comminution of the metacarpal neck, or troubles with soft tissue healing, the MCP joint may be immobilized in the safe position (flexed 70 degrees) for about 3 weeks.
- Kirschner wires are removed about 4 weeks after surgery. When callus is slow to form on radiographs and the fracture site remains tender, wires may be left in place for several more weeks if the pin sites remain free of infection.
- Bone grafting should be considered if union is not achieved by 8 to 12 weeks.
- Plates may be removed 4 to 6 months after surgery if they are causing pain or extensor tendon irritation.

OUTCOMES

- The literature provides no conclusive evidence that either of the methods of fixation of metacarpal fractures is superior.
- Surgical stabilization of a single closed extra-articual metacarpal fracture generally results in a good functional outcome. Nonoperative management of these injuries will also result in a good functional outcome, behooving the surgeon to identify an appropriate surgical indication—most commonly malrotation.
- Outcome after surgical management of multiple or open metacarpal fractures is less predictable and mostly depends on the patient’s long-term digital motion. Peritendinous adhesions and capsular contracture can be minimized by even small amounts of motion during the early postoperative period.
- Nonunion is rare and usually is associated with infection, segmental bone loss, or a compromised soft tissue envelope. Occasionally, an innocuous-appearing transverse fracture may be slow to heal due to the combination of soft tissue stripping for plate fixation and the small surface area of the fracture.

COMPLICATIONS

- Malunion (flexion or rotational deformity)
- Delayed union or nonunion (more common with surgery)
- Pin site or surgical wound infection
- Extensor tendon adhesions or rupture
- MCP or interphalangeal capsular contractures

REFERENCES

DEFINITION

- Extra-articular fractures of the phalanges include metaphyseal and diaphyseal fractures of the proximal, middle, and distal phalanges.
- Extra-articular fractures of the phalanx can range from an isolated injury, which is relatively simple to treat, to a complex trauma involving multiple structures; these latter injuries are often profoundly difficult to reconstruct and can severely affect the function of the hand.

ANATOMY

- The phalanges are the long, tubular bones of the hand that enable a functional arc of motion.
- While each phalanx of each ray is similar, there are anatomic differences that account for the normal cascade and curvature of the digits, allowing for flexion and extension.
- The extensor mechanism of the finger glides directly on top of the phalanges, with only a thin layer of periosteum and peritenon between bone and tendon (FIG 1).
- Fractures of the phalanges and the resultant bleeding, swelling, and scarring can greatly inhibit extensor function.
- Early motion of the extensor mechanism can help minimize adhesions between bone and tendon. This is an essential principle that must be kept in mind when treating these injuries.
- Hardware, particularly a plate, placed dorsally beneath the tendon may interfere with extensor tendon function and risk its integrity. This has led many to recommend alternate fixation methods as well as plate placement on the lateral aspect of the bone.

- A dorsal implant may abrade the tendon, especially if the end of the plate is at the level of the proximal interphalangeal joint.
- Even a low-profile dorsal plate can lead to extensor imbalance. A plate on the proximal phalanx effectively shortens and tightens the central slip tendon, leading to limited proximal interphalangeal flexion.
- There is even less room to place a dorsal plate under the triangular ligament and terminal tendon over the middle phalanx (FIG 2).

PATHOGENESIS

- Because the fingers project from the hand, they are subject to bending and twisting forces in a wide variety of situations.
- The fracture pattern depends on the position of the digit at the time of injury and the direction and degree of force applied.
- As a rule, long spiral fractures tend to result from torsional forces and transverse fractures tend to occur after angular and three-point bending forces.
- Fingers are also subject to direct trauma, such as a blow from a hammer, crush injury from a window or door, or even a gunshot.
- These injuries are often associated with skin, tendon, nerve, and artery injuries, all of which worsen the prognosis for recovery of function.
- Most distal phalangeal fractures are comminuted in nature and result from a crush mechanism. Significant displacement of the fragments is associated with a nail bed disruption.

**FIG 1** • A. Anatomic dissection of a digit showing the relationship and position of the lateral bands and extensor digitorum communis (EDC). B. Anatomic dissection showing the EDC with the important insertion of the central slip, which should not be detached if possible during the surgical approach.
Fractures of the proximal phalanx will generally assume a position of apex volar angulation.

The intrinsic muscle tendons, inserting on the proximal phalanx base, pull the proximal fragment into flexion and the central slip pulls the distal fragment into extension (FIG 3). Fractures of the middle phalanx deform less predictably but often assume an apex volar angulation due to the pull of the flexor digitorum sublimis tendon on the volar base of the middle phalanx proximal fragment and the force exerted by the terminal extensor tendon on the distal fragment.

Both the extensor and flexor tendons insert on the distal phalanx at the base only. The flexor tendon insertion is more distal than the extensor tendon insertion. It is possible to have an extra-articular fracture between the two insertion sites, a so-called Seymour fracture, which angulates in a dorsal apex direction.

NATURAL HISTORY

Extra-articular fractures of the phalanges usually heal without treatment, but often with deformity.

It has been shown that there is a linear relationship between the degree of proximal phalanx angulation and the extensor lag.\(^{13}\)

The correction of such deformity must be balanced with the potential for stiffness after surgical intervention as well as other potential surgical complications.

PATIENT HISTORY AND PHYSICAL FINDINGS:

Knowledge of the mechanism of injury, time from injury to treatment, previous treatments rendered, and the injury’s impact on the patient’s career and hobby skill set is critical. It must be determined whether the patient has previously injured the digit and what, if any, preinjury functional limitations existed.

The clinician should evaluate the cascade of the digits, looking for subtle changes in the attitude and position of the fingers. This may help to localize areas of injury. Pain with palpation helps localize the area of injury if there is no clear deformity of the digit and assesses fracture healing. Phalangeal fractures can be displaced in an AP or lateral plane, rotated, or shortened or can exhibit a combination of these deformities.

Resultant hand function will depend on the specific deformity and its location along the skeleton. The more proximal the fracture, the greater the potential deformity at the fingertip. Rotational deformity affects ultimate function the greatest, especially if it causes the fingers to scissor (FIG 4A).

Rotation can be evaluated by asking the patient to flex and extend the digits as a unit. The clinician should compare the relative position of the injured digit to adjacent digits on the injured and uninjured hand.

A digital anesthetic block can facilitate the examination. The digits should generally point toward the distal pole of the scaphoid during flexion.
It is often difficult for the patient to make a fist at the initial assessment due to pain and swelling. In these cases, comparing the plane of the nail bed of the injured finger to the adjacent nail beds and comparing with the other hand can provide a valuable clue to the presence of a rotational deformity (FIG 4B).

- Neurocirculatory status
  - Altered skin color and diminished turgor and capillary refill of the digit are clear indicators of vascular compromise.
  - Two-point discrimination can be used to assess innervation density and is an excellent method for evaluating the integrity of digital nerves.
- Condition of the soft tissue envelope
  - The skin may be visibly damaged with lacerations, degloving, or burns. Its condition will influence treatment.
  - A subungual hematoma is common with a distal phalanx fracture.
- Unstable fracture patterns must be recognized (Table 1).

**IMAGING AND OTHER DIAGNOSTIC STUDIES:**

- AP, oblique, and lateral radiographs will provide sufficient imaging for the majority of extra-articular phalangeal fractures.
  - Critical evaluation may show subtle rotational malalignment if a true lateral view of either the base or the condyles of a phalanx does not match up across its corresponding joint.
  - Slightly oblique lateral views are useful for imaging fractures at the base of the proximal phalanx, where the overlap on a true lateral view makes evaluation difficult.
- A mobile, small fluoroscopy unit allows magnification to help characterize subtle injuries and dynamic evaluation to gauge fragment stability.
- More sophisticated imaging (MRI, CT, ultrasound) is rarely needed to make the diagnosis of a phalangeal fracture or to guide treatment.

**DIFFERENTIAL DIAGNOSIS**

- While there are other causes of hand pain and deformity (e.g., osteoarthritis, congenital deformity, tumor, infection), the patient history and plain radiographs should leave little doubt that the patient has a phalangeal fracture.
- If a fracture is not evident, all the following diagnoses should be considered:
  - Acute sprains
  - Metacarpophalangeal (MP) and interphalangeal dislocations
  - Mallet finger
  - Phalangeal contusions
  - Benign and malignant lesions of the digits
  - Soft tissue injuries
  - Collateral ligament injury
  - Boutonnière or swan-neck injuries
  - Sagittal band ruptures
  - Tendon ruptures
  - Pulley ruptures
  - Stenosing tenosynovitis or trigger finger
  - Acute infection

**NONOPERATIVE MANAGEMENT**

- Many phalangeal fractures are stable and can be treated effectively by closed means. Each fracture must be addressed individually, taking into account the condition of the soft tissue envelope, the fracture characteristics, and the functional needs of the patient.
- Mild (nonrotational) deformities do well with immobilization and protection while the fractures heal, but unstable or malrotated fractures benefit from surgical intervention.
- Distal phalanx fractures are most commonly amenable to nonoperative treatment.

| Table 1 Unstable Extra-articular Fracture Patterns of the Phalanx |
|-----------------|-----------------|-----------------|
| Fracture Pattern | Cause (Forces) | Technique       |
| Spiral oblique fractures | Inherently unstable | Long oblique – Lag screws |
| P1 short transverse fractures | Intrinsic interossei tend to pull the proximal fragment into flexion. The distal segment is pulled into extension by the action of the central slip insertion into the base of the middle phalanx. | - Intrafocal pinning—intramedullary pinning across the metacarpophalangeal joint in flexion - Eaton-Belsky pinning |
| P2 short transverse fractures | Fractures proximal to the flexor digitorum superficialis (FDS) insertion cause extension of the proximal fragment and flexion of the distal fragment. Fractures distal to the FDS insertion become flexed due to the strong pull of the FDS. | - Oblique/crossed Kirschner wires |
| P3 transverse fractures proximal to the tuft | Instability possible with loss of support to the nail bed Action of the flexor digitorum profundus to the proximal fragment with a floating distal fragment | - Retrograde intramedullary pinning across the distal interphalangeal joint |
| Comminuted fractures | | - Oblique/crossed Kirschner wires |

- Long oblique – Lag screws
- Short oblique – Lag screws
- Kirschner wires
- Plate and screws
- Intrafocal pinning—intramedullary pinning across the metacarpophalangeal joint in flexion
- Eaton-Belsky pinning
- Oblique/crossed Kirschner wires
- Plate and screws
- Tension banding
- Retrograde intramedullary pinning across the distal interphalangeal joint
- Bladed plate and screws
- Blade plate and screws
- External fixator
Results are good or excellent in more than 70% of extra-articular phalangeal fractures treated nonoperatively.1,5,7,10

Early motion is always desirable, but it is somewhat less important with closed treatment.

Immobilization beyond 3 weeks has been shown to increase stiffness12 and lead to worse outcomes.

Closed treatment
- Less scarring to the extensor mechanism
- Less ability to move early, unless the fracture is very stable
- Minimal ability to hold a corrected deformity

Internal fixation
- Greater scarring of the extensors, especially with a dorsal approach and a dorsal implant
- Early motion essential
- Greatest ability to hold the fracture in a stable, corrected position

If a fracture is incomplete, complete but nondisplaced, or impacted (such as the metaphysis at the base of the proximal phalanx), a short period (1 to 2 weeks) of splinting followed by buddy taping to the adjacent digit is appropriate (FIG 5).

A fracture that can be adequately reduced but is relatively unstable can occasionally be held reduced with a splint.
- This has the advantage of avoiding a trip to the operating room and the possible complications of surgical fixation but requires close follow-up and serial radiographs to ensure that reduction is maintained (FIG 6).

**SURGICAL MANAGEMENT**

- When considering any surgery, it is necessary to balance the potential benefits of surgery with the risks of the procedure.
- The goal of surgery is to restore alignment and to stabilize the fracture to a degree sufficient to begin early motion.
Any phalangeal fracture with a significant injury to the soft tissue envelope has a worse prognosis.

Stable fixation (to the degree that it does not further compromise the soft tissues) and early motion assume a greater importance in phalangeal fractures with associated soft tissue injuries.

Patients with open fractures are treated with the appropriate intravenous antibiotic therapy. Once the decision is made to surgically intervene, the surgeon must decide which mode of fixation will best suit the fracture pattern (Table 1).

This decision is often made intraoperatively and is frequently based on the ability of the fracture to be adequately reduced closed.

Fractures that are reduced closed are stabilized externally with a cast or fixator or are held with Kirschner wires placed percutaneously.

Kirschner wiring and external fixation are techniques that, when appropriately applied, will result in acceptable outcomes without potential soft tissue surgical interruption and scarring.

Open reduction and internal fixation with plates and screws will potentially provide stable fixation but without early mobilization could result in decreased range of motion.

Overly aggressive soft tissue stripping will cause extensor tendon adhesions, and bulky implants will affect extensor tendon balance and function.

An algorithm can be used to aid in the decision-making process (FIG 7).

Methods

Percutaneous Wire Fixation

Closed reduction with percutaneous fixation can be used to treat the majority of unstable spiral fractures of the phalanges.

The technique is also suitable for transverse metaphyseal fractures, but it may be less suited for transverse diaphyseal fractures.

When the wires are inserted radial and ulnar to the extensor mechanism, percutaneous wire fixation offers the advantage of minimal disruption of the soft tissues in general, and the extensor mechanism in particular.

This technique is best suited for fractures less than 10 days old. After that time, early healing makes accurate closed reduction more difficult.

Kirschner wires provide less stable fixation than plates and screws and may restrict soft tissue gliding due to their prominence. This restriction of early motion may lead to increased stiffness.

Interosseous Wire Fixation

Interosseous wire fixation is more rigid than Kirschner wire fixation but requires open reduction and additional dissection to expose the bone surfaces.

This method of fixation is less bulky than a plate and, as such, is particularly well suited for fractures of the middle phalanx when percutaneous pinning is not possible.

Interosseous wiring works best with a transverse fracture. The wires provide compression to stabilize the fracture. Interosseous wiring will not work if the fracture is comminuted. Interosseous wiring is made more stable when it is combined with pin fixation and placed in a 90-degree configuration.

Lag Screw Fixation

Lag screw fixation is best suited for oblique and simple spiral fractures.

- Lag screws can be used alone if the length of the fracture is greater than twice the diameter of the bone at the level of the fracture.
- If the obliquity is less, a neutralization plate should be added.
- Comminuted and transverse fractures are not amenable to lag screw fixation.

Contemporary lag screws are extremely low profile, making them an excellent fixation option in the phalanx, especially the middle phalanx.

- Lag screw fixation is more rigid than Kirschner wire fixation, and unlike wires, the screws do not need to be removed.
- Lag screws can be inserted percutaneously, but the procedure can be technically challenging.

- Usually, an oblique fracture will be visualized best in the AP plane and the screws inserted from the lateral aspects.
- Spiral fractures frequently require the screws to be placed in two planes.
- Multiplanar screw fixation greatly increases the biomechanical stability (FIG 8).

Plate Fixation

Plate fixation is best suited for transverse fractures, short oblique fractures, periarticular metaphyseal fractures, and comminuted fractures, in which the plate serves as a bridge to maintain phalangeal length.

- Midshaft, transverse fractures are fixed with a straight plate. At least two screws should be placed in either side of the fracture site with fixation of four cortices (FIG 9).
- If close to the metaphysis, a T plate, a Y plate, or a condylar blade plate will allow improved fixation compared with a straight plate.

Displaced Phalanx Fracture

Reducible (Stable) Reducible (Unstable) Irreducible

Nonsurgical treatment
- Buddy taping
- Casting/splinting

Percutaneous treatment
- Kirschner wiring
- External fixation

Open surgical treatment
- Lag screw fixation
- Plate and screws
- Blade plating
- Tension band wiring

FIG 7 • Decision algorithm for the progression to open surgical treatment for phalangeal fractures and the subsequent treatment options for fixation.
Adding a lag screw across an oblique fracture, either through the plate or as an adjunct to plate fixation, will add to the rigidity of the construct.

Compression, obtained by eccentrically drilling one or more of the screws in the plate, will increase fracture stability.

Plate fixation requires more extensive soft tissue dissection and increases the risk of postoperative extensor scarring.

Immediate motion of the digits is essential to minimize the scarring.

Plates are more bulky and may lead to extensor mechanism imbalance, especially near the central slip insertion and on the middle phalanx.

Preoperative Planning

Preoperative posteroanterior, lateral, and oblique radiographs are essential.

Evaluation of these studies helps determine the plane of the fracture and the size of the fracture fragments, allowing the surgeon to choose the best surgical approach and the ideal fixation technique.

The surgeon must be certain that all potential implants are available. Surgical error can frequently be traced to implant availability problems.

Many sets include only one or two plates of a given size and shape. In the case of multiple digit involvement, extra plates and screws are helpful.

Intraoperative imaging using a mini fluoroscopy unit is essential, and its availability should be ensured.

The surgeon should plan for alternative approaches and means of fixation should comminution or soft tissue problems preclude the original plan.

Positioning

The patient is placed supine on the operating table with a radiolucent hand table attached.

A padded arm or forearm tourniquet is used for all cases.

Approach

The phalanx is most commonly approached laterally or dorsally. The exact approach used for open reduction is often based on the location of the fracture as it relates to the extensor mechanism (FIG 10).

The sagittal bands at the MP joint, the central slip insertion, and the triangular ligament should be preserved whenever possible (FIG 11).

Motion is necessarily delayed after surgery if these structures are incised and subsequently repaired.

A portion of the lateral band may be excised rather than repaired as part of the midaxial approach (FIG 12).

Longitudinal incisions in the midportion of the extensor tendon and especially in the midaxial interval between the extensor and the lateral band allow early motion.

At the middle phalanx level, a midaxial approach on the edge of the terminal tendon is preferred so that the tendon can be pulled to the side, exposing the bone (FIG 13).

The midaxial approach is also useful when using lag screw fixation, as the screws are usually inserted on the lateral aspect of the bone.
Fracture Reduction

- Before performing any reduction maneuver, obtain posterior-anterior and lateral C-arm images for reference.
- If the fracture is very close to the MP joint, a slightly oblique lateral view will show the fracture better by avoiding some of the overlap of the other MP joints.
- Unstable spiral fractures of the phalanges are usually shortened, rotated, and angulated (TECH FIG 1A).
- Begin the reduction by applying longitudinal traction.

- This can be accomplished with direct traction on the digit. Use a moist gauze, fingertraps, or a pointed towel clip applied distal to the fracture.
- While traction is applied, correct the rotational deformity (TECH FIG 1B). Any angular deformity is then corrected before placing a reduction clamp across the fracture.
- Flexing the MP joint stabilizes the proximal P-1 fragment by tightening the collateral ligaments.
- Apply a reduction clamp (a towel clip-like device with sharp points) across the fracture percutaneously to hold the reduction.

PERCUTANEOUS KIRSCHNER WIRE FIXATION
When considering the cross-sectional anatomy of the finger, remember that the bone lies in the dorsal two thirds, not in the midline (TECH FIG 1C). Thus, the clamp tips should enter the skin dorsal to the midlateral line.

- Placing the clamp at a slight angle so that it is more perpendicular to the fracture will aid stability of the reduction through fracture compression.
- Reduction can further be fine-tuned by twisting the clamp slightly when tightening.

**Fracture Stabilization**

- After checking the reduction with the fluoroscope, drill the Kirschner wires across the fracture site until they gain purchase in the far cortex (TECH FIG 1D).

- Usually 0.045-inch Kirschner wires are used in the proximal phalanx, although fixation in the small finger and in the more distal phalanges may require the smaller 0.035-inch Kirschner wire size (TECH FIG 2).
- Diamond-tipped smooth Kirschner wires are preferred.
- Crossed wires can be used to secure transverse fractures.
- This method is useful for metaphyseal fractures (TECH FIG 3) and to stabilize middle phalanx fractures to avoid the need for plate fixation (TECH FIG 4).
- Avoid distraction at the fracture site when using crossed wires.
Part 6 HAND, WRIST, AND FOREARM • Section IV HAND FRACTURES AND DISLOCATIONS

TECHNIQUES

INTEROSSEOUS WIRE FIXATION

Exposure
- Open reduction and fairly extensive fracture exposure is required for placement of the intraosseous wires, especially when using a dorsovolar wire.
- Expose the fracture using either a dorsal or midaxial approach.
- Place the bone in the “shotgun” position (apex dorsal) and gently elevate the soft tissues from the proximal and distal fragments 3 to 5 mm at the fracture site.
- Drill transverse and anteroposterior holes 2 to 5 mm away from the fracture site using a 0.045 smooth Kirschner wire.

Fracture Reduction and Stabilization
- Reduce the fracture and verify reduction through direct observation and with a mini C-arm.
- Pass a 24-gauge steel wire through the transverse hole and a second wire through the anteroposterior holes.
- Tighten the wire loops sequentially by pulling the wire away from the fracture and twisting slowly to stabilize and compress the fracture (TECH FIG 5).
- Do not fully tighten the first wire until the second wire has been at least partially tightened.
- Plan placement of the wire loops so as to lay them flat against bone and minimize soft tissue irritation.
- If greater stability is required, drill a 0.035 to 0.045 smooth Kirschner wire obliquely across the fracture.

TECH FIG 4 • A. AP and lateral radiographs showing a displaced fracture of the middle phalanx of the middle finger and minimally displaced middle phalanx fracture of the ring finger. Note the importance of the lateral radiograph to assess the displacement of the middle finger fracture. B. The middle finger fracture was stabilized with crossed pins. The ring finger was fixed with a single pin to avoid displacement after early motion was started. C. The healed fractures after pin removal.

TECH FIG 5 • AP radiograph of a middle phalanx infected nonunion treated by débridement, squaring of the fracture ends, and 90-90 interosseous wiring.
LAG SCREW FIXATION

- Lag screws can be inserted percutaneously, but the procedure is technically challenging. Precise reduction of the fracture is the first priority and should not be sacrificed in an attempt to limit incision length.
- Most often, the midaxial approach will provide the best exposure with the least amount of soft tissue stripping.
- Screw size and number are determined based on fracture location, fracture characteristics, and the size of the bone fragments (TECH FIG 6).
  - When considering the use of multiple screws and screw location within the fragment, screws should be placed at least two diameters from the tip of the fracture and centered within the fragment.
  - The distance between screws should be at least two screw diameters.
  - The screws’ orientation should be between perpendicular to the fracture line and perpendicular to the bone itself.
    - Screws placed perpendicular to the fracture provide maximal compression.
    - Screws placed more perpendicular to the bone provide axial stability.
    - Screws should always be drilled along a diameter (ie, crossing though the middle of the bone).
  - Reduce and hold the fracture with a clamp while the drill is advanced across the fracture site into the opposite cortex (TECH FIG 7A).
  - To gain a lag effect, create a gliding hole in the near cortex using a drill bit that is the same size as the screw’s outer diameter (TECH FIG 7B).

TECH FIG 6 • Screw size is determined by the bone size. Usually 1.5-mm or 2.0-mm screws are used in the proximal phalanx and 1.3-mm or 1.5-mm screws in the middle phalanx.

A. First drill
B. Overdrill

TECH FIG 7 • A. The tap drill for the chosen screw size is drilled from the near cortex, across the fracture and into the far cortex. The hole should be oriented so the drill crosses through the center of the bone and is centered in the far fragment as well. B. To gain a lag effect, the near cortex is opened to the outer diameter of the screw (overdrilled) so the screw threads will engage only in the far cortex, compressing the fractures as the screw is tightened.
Plates can be placed either dorsally or laterally on the bone. Lateral placement via the midaxial approach has the advantage of less extensor disruption and potentially fewer adhesions. Lateral plate placement effectively resists compressive forces. If the plate is applied to the dorsal surface, avoid overdrilling and placement of a long screw that may damage the flexor tendons. Once exposed, clear the fracture site of soft tissue and reduce the fracture.

Fixation of Metaphyseal Fractures: T-Plate Technique

- Provisionally place the plate on the bone using a pointed reduction clamp, a specialized plate-holding clamp, or a screw at one end of the plate.
- Insert the screw in the middle of the T plate first, but before screw tightening align the plate perpendicular to the adjacent joint (TECH FIG 9A).
- Perform the final fracture reduction and insert a screw on the other side of the fracture (TECH FIG 9B).
- Assess the length, angulation, and most importantly the rotation clinically and radiographically.

During final tightening, exert steady forward pressure and turn the screw slowly to avoid stripping the far cortex. Repeat the procedure for additional screws (TECH FIG 8). Alternatively, reduce the fracture with a clamp, then stabilize it with a Kirschner wire smaller than the core diameter of the screw. Place the first lag screw as described, then remove the Kirschner wire and insert the second screw through the predrilled Kirschner wire hole.

PLATE FIXATION

- Plates can be placed either dorsally or laterally on the bone.
- Lateral placement via the midaxial approach has the advantage of less extensor disruption and potentially fewer adhesions. Lateral plate placement effectively resists compressive forces.
- If the plate is applied to the dorsal surface, avoid overdrilling and placement of a long screw that may damage the flexor tendons.
- Once exposed, clear the fracture site of soft tissue and reduce the fracture.

Fixation of Metaphyseal Fractures: T-Plate Technique

- Provisionally place the plate on the bone using a pointed reduction clamp, a specialized plate-holding clamp, or a screw at one end of the plate.
- Insert the screw in the middle of the T plate first, but before screw tightening align the plate perpendicular to the adjacent joint (TECH FIG 9A).
- Perform the final fracture reduction and insert a screw on the other side of the fracture (TECH FIG 9B).
- Assess the length, angulation, and most importantly the rotation clinically and radiographically.

- Insert the remaining screws (TECH FIG 9C).
- In the case of comminution, the plate is used to bridge the fracture fragments (TECH FIG 10).
Chapter 32  OPERATIVE TREATMENT OF EXTRA-ARTICULAR PHALANGEAL FRACTURES 2389

TECH FIG 10 • A. Preoperative posteroanterior and lateral radiographs showing a comminuted index finger proximal phalanx fracture with significant shortening, angulation, and rotation, and a middle finger proximal phalanx fracture with reasonable alignment. The middle finger had a significant crush injury and a large volar wound. B. The index finger proximal phalanx fracture is fixed with a T plate, which is used to restore alignment, length, and rotation while bridging the fracture. Rather than risking additional vascular compromise to the middle finger with pins or open reduction, the relatively stable fracture of the middle proximal phalanx was treated by closed means. Active motion of both fingers was started 1 week after open reduction and internal fixation.

TECH FIG 11 • A. Intramedullary Kirschner wires can be stacked in the canal to provide intramedullary support to a phalangeal fracture. Wires are inserted from the sides to minimize extensor tendon damage. B. In the case of soft tissue damage with bone loss, a square U-shaped bend in a Kirschner wire can be used to temporarily maintain length while the soft tissue heals.

OTHER METHODS

- Some authors have described using Kirschner wires as stacked intramedullary nails to secure phalangeal fractures. Intrafocal pinning is an excellent way to stabilize juxta-articular fractures of the proximal phalanx.2
  - By placing several wires along the canal, the fracture can be stabilized sufficiently to allow early motion.
  - Inserting the wires along the sides minimizes extensor tendon injury (TECH FIG 12A).
- Other methods of fixation not commonly used for extra-articular phalangeal fractures include external fixation and bridging Kirschner wire fixation (TECH FIG 12B).
  - These rarely used methods are most useful for temporary fixation while allowing the soft tissue injuries to heal.
  - External fixation is more advantageous for border digits. For treatment of extra-articular phalangeal fractures, these fixators should not be placed across a joint if at all possible.

PEARLS AND PITFALLS

</table>
Kirschner wiring
- Avoid placing crossed pins with their intersection at the level of the fracture, as this may cause rigid distraction.
- Smooth pin wiring is not without complications.  

Plate fixation
- Placing the plate laterally or dorsolaterally may minimize the negative effects on the extensor mechanism.
- Do not detach the insertion of the central slip at the dorsal base of the middle phalanx.
- Augmenting fixation with a lag screw either through or adjacent to the plate markedly increases fracture stability.
- If plating dorsally, avoid placing overly long screws, which may damage flexor tendons.
- Always check plate placement and length fluoroscopically.
- Thoughtful placement of temporary Kirschner wires will avoid frustration with simultaneous fracture reduction and plate placement.
- Temporary Kirschner wire placement can maintain fracture reduction as well as take the place of predrilling for screws; replace the Kirschner wire with an appropriately sized screw.
- After a midaxial approach and placement of a plate on the proximal phalanx, excise rather than repair the lateral band to minimize scarring and maximize motion.

External fixation
- Useful in markedly comminuted fractures with bone loss
- Avoid spanning joints if possible.
- Most applicable for border digits

Distal phalanx fractures
- Nonunions can be painful.
- Support of the nail bed can help prevent later nail deformities.
- Temporary pinning through the distal interphalangeal joint can provide stability and is an easier technique than cross-pinning in the distal phalanx.

Problems
- Recognize and correct malalignment in the operating room. Clinical and radiographic assessment is required throughout the process of fracture reduction and stabilization. Always compare with the contralateral hand.
- With postoperative swelling, it is our practice to always include more than one digit in the postoperative dressing to avoid potential vascular complications.

Postoperative care
- Early evaluation and treatment by an experienced hand therapist will improve outcome.
- Diligent pin care in Kirschner wire and external fixator constructs is necessary to avoid infection.

POSTOPERATIVE CARE
- Postoperative care depends on the location of the injury and the bony fixation.
- The best outcomes are achieved with restoration of anatomic alignment, respect for the soft tissue envelope, and early range of motion.
- Treatment by an experienced hand therapist is a key component.
  - In the early phases, therapy consists of edema control and mobilization of adjacent digits and joints.
  - If adequate fracture stabilization is obtained, then mobilization of the involved digit is started almost immediately.
  - If fracture fixation is not ideal, active motion of the involved segment should be started no later than 3 to 4 weeks after surgery regardless of the radiographic appearance.
  - Protected mobilization should include removable splints that allow motion of adjacent digits and joints. As healing progresses, these splints are eliminated and buddy taping is employed.
- Return to full activity is usually possible by 8 weeks.

OUTCOMES
- Virtually all phalangeal fractures will heal in 4 to 6 weeks. Malalignment, especially rotation, and stiffness will diminish the outcome.
- Most simple fractures treated with splinting, percutaneous pinning, or open reduction and internal fixation will regain near-full motion in 2 to 6 months, if the principles are followed and the proper intraoperative and postoperative techniques are employed.
- In complex injuries where early motion is delayed because of concomitant soft tissue injury or prolonged splinting, the final outcome will be worse.
- Sometimes hardware removal, tenolysis, and joint release are needed to improve motion.
  - Such procedures should be attempted only after tissue equilibrium has been reached (usually at least 4 months after the initial injury or surgery).

COMPLICATIONS
- Loss of motion
  - Surgical: careful soft tissue handling with avoidance of prominent hardware
  - Postoperative: Elevation, ice, early motion of all non-injured joints, and controlled mobilization of injured segments as soon as possible are the best preventive measures.
- If the problem persists and despite good therapy passive motion greatly exceeds active motion, tenolysis is a reliable method of treatment.
- Malunion
  - Malreduction is common and, once secured with a plate and screws, difficult to correct. It is important to assess rotation on all phalangeal fractures before final fixation.
- Accurate assessment is often difficult because the patient cannot make a full fist. Therefore, a reduction that was
thought to be adequate in the face of restricted motion may prove inadequate once full motion is regained.
- If significant enough, osteotomy should be considered.
- Neurovascular injury while pinning a fracture
- By observing the cross-sectional anatomy of the digit, damage to the neurovascular bundle can usually be avoided when inserting the wires.
- Care must be taken when the wire passes through the second cortex, as it will usually be heading directly toward the neurovascular bundle.
- Inserting the wires initially by hand until bone contact is made and using small open incisions may decrease the chance of injury when inserting the wire close to the neurovascular bundle.
- Complex regional pain syndrome
- Early recognition and treatment are essential.
- A high index of suspicion is needed to identify key symptoms:
  - Swelling despite elevation and other edema-control efforts
  - Stiffness, especially in adjacent digits, despite efforts toward early mobilization
  - Color changes in the hand
  - Mottling or shiny appearance of the skin
  - Abnormal hair growth
  - Burning pain in the hand
- Tendon rupture
- Nonunion
- Infection
- Pin loosening and migration
- Implant failure
- Pain and symptoms from retained hardware

DEFINITION
- Phalangeal condylar fractures include unicondylar and bi-condylar intra-articular fracture of the distal ends of the proximal and middle phalanx. Proximal phalangeal condylar fractures are more common.
- Table 1 demonstrates the variety of condylar fracture patterns typically observed.

ANATOMY
- Collateral ligaments, finger position, and direction of force play a role in both fracture pattern and the direction of displacement (FIG 1).
- Blood is supplied to the condyles by a branch of the digital artery and vein that travels with the collateral ligaments. Care must be taken not to disrupt this blood supply or to strip small fragments of their soft tissue attachments.

PATHOGENESIS
- These fractures often are sports-related injuries.
- The mechanism is hypothesized to be tension or rotation force through the collateral ligaments for an oblique fracture and compression and subluxation in the case of a coronal fracture.1,5
- Fractures often are unstable because there is a minimal periosteal sleeve, and forces seen at the joint are substantial.

Most commonly, the condyle toward the midline of the hand (ie, the middle finger axis) is fractured: the ulnar condyle in the index finger and thumb and the radial condyle in the ring and small fingers.

**NATURAL HISTORY**

- In developed countries, these fractures rarely go untreated, but they often are undertreated given that their presentation may be interpreted as a “minimally displaced finger fracture.”
- Similar to any proximal interphalangeal (PIP) joint injury, lack of immobilization in full extension or prolonged immobilization will likely lead to a stiff finger.
- If treated conservatively, displacement of the fracture, a common occurrence, will lead either to early painful arthritic changes, or rotational malalignment on full flexion, or both.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- A typical patient is a 24-year-old male baseball player who has sustained an angular impact to the finger from the ball.
- A high index of suspicion is required when evaluating these patients. The patient often is still able to bend the finger, and the fracture line can be subtle, but even nondisplaced fractures are prone to subsequent displacement.
- Joint subluxation is an absolute indication for surgery and must be assessed carefully both radiographically and clinically.
- With any fracture displacement, a rotational deformity of the finger usually occurs, best assessed either looking end on at the digit or evaluating position with PIP flexion (FIG 2A).
- Subtle joint depression may lead to angular deformity; this is best assessed by examining fingers in full extension (FIG 2B).

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- The fracture pattern dictates the type of fixation or treatment.
- Multiple views should be obtained as needed to understand the geometry. Fluoroscopy often is helpful in obtaining precise views.
- Osteochondral fragments often are larger than they appear, because the cartilage is radiolucent.
- Hidden fracture lines are common and often are not visualized until surgery.
- CT occasionally is helpful.
DIFFERENTIAL DIAGNOSIS
- Collateral ligament or volar plate avulsion
- PIP dislocation
- Distal shaft fracture

NONOPERATIVE MANAGEMENT
- Reports regarding the results of nonoperative treatment present conflicting results.
- Weiss et al found five of seven nondisplaced fractures treated conservatively went on to displace and required surgery.
- In an 11-year follow-up study, using a functional outcome score, O’Rourke et al. demonstrated several interesting points:
  - 27% of patients experienced joint aching in cold weather.
  - Four patients at 1 year follow-up had moderate pain and considered arthrodesis. However, by the time they got off the waiting list their symptoms had subsided to the point that they declined surgery.
  - No patient had less movement in the joint at year 11 than at year 1.
  - 25% of patients had continued improvement in range of motion after 12 months follow-up.
  - Three patients with displaced bicondylar fractures treated conservatively had outcomes of good, fair, and poor, respectively.
  - Three patients with displaced unicondylar fractures treated conservatively had a good outcome; however, in O’Rourke et al’s discussion, they conclude that these fractures should be treated with reduction and fixation.
- Operating on nondisplaced or minimally displaced fractures can be viewed in two ways:
  - On the other hand, there is minimal morbidity in percutaneous pinning, and that would minimize the likelihood of displacement in a fracture that often is unstable.
  - Given the propensity for displacement and the potential functional difficulties with malunion, we recommend, at a minimum, percutaneous stabilization of most condylar fractures.
  - Several review texts suggest that coronal fractures of less than 25% of the joint surface with a stable congruent joint can be treated nonoperatively or with fragment excision. Although this may be true, there are few biomechanical or clinical outcomes data to support the statement.

SURGICAL MANAGEMENT
Preoperative Planning
- Preoperative planning should be mindful of the goals of treatment of any articular fracture established by the AO:
  - Anatomic reduction of the articular surface
  - Restoration of stability
  - Minimizing soft tissue injury
  - Early mobilization
  - Access to a mini C-arm is highly advantageous.
  - Fluoroscopic examination under anesthesia provides a good sense of joint stability and fracture fragment orientation.
  - Fracture reduction, implant placement, and fracture stability are effectively evaluated fluoroscopically.

Positioning
- The patient is positioned supine with a hand table.
- If an assistant is unavailable, finger-trap traction also may be helpful.

Approach
- A unicondylar fracture typically is approached either between the central slip and lateral band (FIG 3) or via a mid-axial approach.
The lateral (mid-axial) approach is suggested as a means to minimize extensor mechanism scarring, but only if significant joint incongruity or comminution is absent.
- If more extensive joint visualization is needed, the extensor mechanism can be incised and repaired later (FIG 4).
- A bicondylar or triplane fracture requires a more global joint and fragment exposure.
- A dorsal, slightly curvilinear incision is made.
- The extensor tendon may be split longitudinally, but preferably incisions are made on its borders, allowing mobilization and excellent joint exposure.
- A palmar approach is rarely used except for volar coronal shear fractures.

### SHORT AND LONG OBLIQUE FRACTURE WITH PERCUTANEOUS REDUCTION, K-WIRES, MINIFRAGMENT SCREWS, OR CANNULATED HEADLESS COMPRESSION SCREWS

#### Tips for Achieving Fixation
- Visualize the fracture well using live fluoroscopy.
  - Fracture displacement typically is in an oblique plane, sometimes not well appreciated on the straight anteroposterior or lateral views.
  - Use of the view on live fluoroscopy that best shows the displacement will make it possible to determine when reduction has truly been achieved.
- Apply traction and rotation to the distal aspect of the finger to assist reduction through ligamentotaxis (TECH FIG 1A).
- If necessary, make a Brunner-style volar incision, and retract the flexor tendons to expose the volar plate.
- If possible, reflect the volar plate on one side and a little up the lateral edge for exposure via a triangle-shaped flap.
- If more complete exposure is needed, make a transverse incision along the proximal edge of the volar plate, leaving enough proximal cuff to reattach the volar plate.
- Elevate the volar plate on a distal hinge, repair the fracture, and then reattach the volar plate.
- The PIP joint is prone to stiffness from injury, so every effort should be made to minimize surgical injury to the soft tissues.
- Avoid at all costs stripping soft tissue attachments from small fracture fragments.

### TECHNIQUES

**SHORT AND LONG OBLIQUE FRACTURE WITH PERCUTANEOUS REDUCTION, K-WIRES, MINIFRAGMENT SCREWS, OR CANNULATED HEADLESS COMPRESSION SCREWS**

**Tips for Achieving Fixation**
- Visualize the fracture well using live fluoroscopy.
  - Fracture displacement typically is in an oblique plane, sometimes not well appreciated on the straight anteroposterior or lateral views.
  - Use of the view on live fluoroscopy that best shows the displacement will make it possible to determine when reduction has truly been achieved.
- Apply traction and rotation to the distal aspect of the finger to assist reduction through ligamentotaxis (TECH FIG 1A).
  - Try percutaneous manipulation of the fragment with a dental pick.
  - If reduction is achieved, place either a pointed reduction clamp or the first K-wire to hold it.
  - If the dental pick does not work, place one prong of a pointed reduction clamp through the skin into the stable condyle, then place the other prong into the fragment and try to reduce the fragment with a slight rotation of the clamp (TECH FIG 1B).
  - Resist the urge to use clamp compression to force a reduction, because the small fragments shatter easily.
Chapter 33  ORIF OF PHALANGEAL CONDYLAR FRACTURES

**TECHNIQUES**

- Hold the PIP joint in extension while driving wires.
  - This position keeps the lateral bands dorsal, and the entry of the K-wire can be just volar to the lateral bands.
  - The condyle, as viewed on a lateral image, is the area with the least excursion of the collateral ligaments; therefore, K-wires in the volar position cause the least restriction of motion.
- The use of 0.028-inch K-wires avoids further fragmentation of fragments and usually provides sufficient fixation.

**Fixation Choices**

- In our practice, if we can achieve a percutaneous reduction, we prefer the use of multiple 0.028-inch K-wires.
- If we have to open to achieve the reduction, we prefer the stability of screw fixation.
  - Occasionally, fragments are too small or comminuted for screw fixation, necessitating the use of K-wires.

**K-Wire Fixation**

- A single K-wire is not sufficient fixation.
- Drive two K-wires from the fragment into the shaft either transversely or obliquely depending on the fracture orientation (TECH FIG 2).
  - The first wire should be placed perpendicular to the fracture line to maximize fixation and minimize displacement while capturing the reduction.
  - Additional wires should be placed slightly oblique to the first wire so that the fracture fragment cannot displace along the axis of two parallel wires.
  - The best bone quality is found distal and volar; therefore, to avoid injury, insert wires from contralateral

**Screw Fixation**

- Screw fixation should avoid the collateral ligaments by one of four methods (TECH FIG 3):
  - Flexing the joint and passing the screw distal and dorsal to the collateral ligaments
  - Keeping the joint in extension, with subperiosteal stripping of a limited portion of the collateral ligament origin from proximal to distal
  - Excising a small window in the collateral ligament for the screw head, which is gently countersunk
  - Placing the screw proximal to the collateral ligament if the fracture extends far enough proximally
- Screw fixation must not impinge on the collateral ligaments through any of the four methods listed, or the screw will cause permanent difficulties with joint motion.
- Screw fixation should be with 1.0- or 1.3-mm screws placed in lag fashion (TECH FIG 4A–E).
- For longer oblique fractures, make a stab incision, spread with a snap, and place three screws or three or more wires spaced along the fracture (TECH FIG 4F).
TECH FIG 3 • The four methods for screw placement to minimize impingement on collaterals. Methods A and C require seating the screw head almost flush with the bone. A. Creation of a small window in the collateral for screw placement. B. Reflection of the proximal part of the collateral ligament for screw placement. C. Flexion to allow exposure of the condyle for screw placement. D. In a longer fracture, placement of the screw proximal to collateral insertion.

TECH FIG 4 • Placement of a lag screw. A. 0.076-inch drilling is done through both cortices. B. The joint is flexed to permit placement of the screw out of the way of the collateral ligaments. C. Overdrilling only the proximal cortex with a 1.0-mm drill. D. Compression of fragments by a reduction clamp while placing the lag screw. E. Position of the screw head after extension of the joint. F. Long oblique fracture maintained with three 0.028-inch K-wires.
The first screw should be placed in lag mode, perpendicular to the fracture line, to prevent displacement of the fracture during compression.

If there is good compression, the second and third screws can be in neutralization mode.

If compression from the first screw was poor, additional screws can be placed in the lag mode.

Consider placing one screw more perpendicular to the long axis of the phalanx to resist axial forces.

While screws are being placed, the reduction can be held either by a reduction clamp or with a temporary K-wire. The hole made by the temporary K-wire, after removal, can be used for the last screw.

**DORSAL AND VOLAR CORONAL SHEAR FRACTURE WITH SCREWS OR K-WIRES**

- A dorsal approach typically is used for dorsal fractures and a volar approach for volar fractures.
- Dental picks are used for all fragment manipulation and reduction.
- Traction generally does not help reduction.
- Because fragments usually are very small, fixation with 0.028-inch K-wires may involve crossing the joint surface.
- Typically, a trade-off must be made in terms of implant position.
- For example, in a dorsal shear fragment, it may be necessary for a K-wire to pass through the dorsal articular surface of the fragment into the condyle below. Try to stay as dorsal as possible to minimize impingement in extension, while still securing the fragment adequately. It is possible to bury a screw beneath the articular surface, but if it is possible to use K-wires, they are preferred for their small and temporary footprint. A dorsal shear fracture with a nonarticular component would be a better choice for screw fixation than an all-articular fragment.
- We do not have experience with absorbable implants, but would be concerned about their use due to the small size of the fragments and resorption products.

**BICONDYLAR FRACTURE WITH OPEN REDUCTION AND INTERNAL FIXATION**

- Use a dental pick to align the condylar fragments and secure with a K-wire or screw.
- Similar to previous discussion, if reduction is achieved percutaneously, one or two K-wires may be used to secure the condyles to each other.
- Typically, open reduction is required, in which case screws are preferred whenever possible.
- Occasionally, if it is difficult to secure the two condylar fragments to each other, try reducing the largest condylar piece to the shaft and hold it with a K-wire. Then reduce the smaller condylar piece or pieces to the main construct. Once the entire reduction is achieved and held with clamps or K-wires, a screw can be placed transversely across the condyles.
- If minimal metaphyseal comminution is present, the condylar fragments are secured to the shaft using K-wires (TECH FIG 5).
**Condylar Plate**
- If metaphyseal comminution is present, consider a condylar plate (TECH FIG 6).
- The reduction starts with the condylar fragments, ignoring any proximal comminution.
- These fragments are held temporarily while the condylar plate is drilled and placed into just the distal fragment.
- Care must be taken to align the plate on the condyles so that the plate aligns with the shaft, once the condylar/plate construct is reduced to the shaft, bypassing the comminution.

**TECH FIG 6 • A,B.** Radiographs of a bicondylar fracture. **C,D.** Postoperative radiographs after reduction and application of a condylar plate fixation. (Courtesy of Alan Freeland, MD.)

**TRIPLANE FRACTURE WITH OPEN REDUCTION AND FIXATION USING LAG SCREWS AND K-WIRES**
- An extensile dorsal approach is used.
- TECH FIG 7 shows a triplane fracture in a 42-year-old carpenter with a table saw injury, who was treated as follows:
  - The collateral ligaments were attached to the two volar condylar pieces.
  - Lag screws were placed into each condyle from dorsal to volar.
  - A K-wire was used to secure the condyles to the shaft and keep the joint reduced.
  - Metaphyseal comminution has been treated with bone grafting and, in some cases, distraction external fixation for 3 weeks, after which motion is commenced.¹

**TECH FIG 7 •** Triplane fracture in a 42-year-old carpenter with a table saw injury. **A.** Lateral radiograph shows the injury. **B.** Clinical photograph of the injury with the collateral ligaments attached to the two volar condylar pieces. **C,D.** Postreduction photograph and radiograph demonstrating lag screws placed into each condyle from dorsal to volar. PEARLS AND PITFALLS

| Difficulties with closed reduction and pinning | • Try using traction with rotation, a dental pick, pointed reduction clamp, or a K-wire as a joystick into the displaced fragment. |
| Preventing fracture of a small fragment | • Make sure the screw diameter is no more than one third the size of the fragment and is placed one screw diameter from the edge of the fragment. |
| Maintaining reduction and pinning small fragments | • Use a cannulated reduction forceps. |
| Obtaining maximum mechanical stability | • Place the screw from the fragment into the phalanx, “from the island to the mainland.” |
| Maximizing reduction with small intra-articular fragments | • Reduce the large fragments first. Often the smaller pieces then fall into place with soft tissue tensioning or can be excised: “Rule of Vassals, or Majority Rule.” |
| Minimizing postoperative adhesions | • Avoid plating the phalanges whenever possible. Meticulous handling of soft tissue, and sharp dissection where possible rather than blunt spreading minimizes tissue trauma and permits early active range of motion (AROM). |

POSTOPERATIVE CARE

• Fracture stability dictates the protocol, but most patients should be started on AROM within 1 week, with extension splinting of the PIP joint while at rest.
  • It is important for the surgeon and therapist to communicate regarding the extent of injuries, type of fracture fixation used, and co-existing conditions, because these variables will affect the rate of healing and progression of therapy.
  • Exercises should be performed at least six times per day.
  • When immobilization is involved, it is extremely important for the patient to perform AROM to all noninvolved joints to prevent secondary weakness and stiff joints in the involved extremity, as well as to aid edema control.
• 1–7 days after surgery
  • Control edema with Coban wraps (3M, St. Paul, MN), compressive digit sleeves, elevation and AROM, and contrast baths (if no pin or sutures are present).
  • A hand-based safe-position splint including the involved digit and an adjacent digit is worn between exercises and at night. Use a forearm-based splint including all digits if multiple digits are involved.
  • AROM exercises are used based on the stability of fracture:
    • Composite flexion and extension of the digits
    • Blocking of the PIP and DIP joints to provide differential gliding of the flexor digitorum superficialis and profundus tendons (especially important following a volar exposure)
    • Reverse blocking (metaphalangeal [MP] joints passively flexed with active interphalangeal [IP] joint extension), flexor and extensor tendon glides
  • 7–14 days post-surgery
    • Gentle assisted AROM and passive ROM may begin as tolerated, again based on fracture stability. Passive ROM should not begin with K-wires in place.
    • Avoid painful ROM and monitor splints closely for excessive forces on the PIP joint. This can result in a counterproductive inflammatory and fibroblastic response.
    • Early scar management (approximately 10–14 days)
      • When the incision or pin site has healed, begin scar massage with lotion.
      • Superficial heat application applied before scar massage helps increase scar pliability.
  • If scar sensitivity develops, introduce scar desensitization, to include stimulation of the sensitive scar with graded textures and tactile pressure and tapping of scar, progressing as the patient develops increased tolerance to each stimulus.
  • If scar adherence persists, use iontophoresis with Iodex (Baar Products, Inc., Downingtown, PA) to soften the scar.
  • For a raised scar, encourage scar remodeling by use of a nocturnal scar pad, such as elastomere or Otoform K (AliMed, Deham, MA).
  • After initial fracture healing (about 4–6 weeks)
    • Assisted and passive ROM should be started if they have not been initiated earlier.
    • Continue the “safe position” splint between exercises and at night.
    • As the patient’s pain level decreases and functional use of the involved digit increases, reduce the splint to a gutter splint worn at night to prevent PIP flexion contracture.
  • If a flexion contracture develops at the PIP joint, consider serial extension casting of the involved digit. The contracture should be no more than 45 degrees, because the patient will have difficulty donning the serial cast with any greater degree of joint contracture. Dynamic splinting or static progressive splinting by day may be used as needed.
    • Progressively wean splints as passive ROM improves, and encourage active ROM.
    • Strengthening (about 8 weeks)
      • Progressive strengthening can be initiated with light putty and further progressed with activities appropriate for the patient’s occupation.
    • About 10 weeks
      • Discharge all splinting.
      • Encourage unrestricted use of the involved digit and hand.
    • In closed fractures, with a good soft tissue envelope and blood supply, K-wires should be removed at about 3 weeks to facilitate rehabilitation.

Overcoming Issues Related to Rehabilitation

Decreased PIP Joint Flexion

• The reason for decreased flexion at the PIP joint must be determined. If the joint has full PIP joint flexion on passive ROM and decreased PIP joint flexion on active ROM, the problem most likely is caused by adhesions.
Treatment should attempt to regain ROM through active exercise:
- Before treatments, application of heat is useful to increase tissue extensibility for increased ROM gains and assist the patient with increased tolerance to exercise.
- Superficial modalities such as moist hot pack, paraffin, and fluidotherapy may be used. Benefits of fluidotherapy include the ability to actively stretch with application of heat.
- Ultrasound may be used to heat deeper tissues.

Exercises
- Tendon glides
- Isolated blocking of the flexor digitorum superficialis and profundus tendons to maximize differential tendon gliding
- Active flexion of the digit against resistance, such as hook fist exercises performed with therapeutic putty, or raking the digits through putty
- Blocking splint for exercise: the MP joints are blocked in extension by a splint with the PIP joints free. The patient performs active PIP flexion and extension to increase differential glide of the tendons (FIG 5A).
- Neuromuscular electrostimulation of the flexor digitorum superficialis and profundus may be used to assist active ROM and tendon glide.
- If the fracture is healed and passive ROM of the joint is limited in flexion, passive ROM exercises and splinting alternatives will assist to progressively stretch a tight joint capsule and elongate shortened ligaments. Splinting options include:
  - Static progressive splinting
  - Use of a dynamic flexion splint (FIG 5B)

Passive ROM and joint mobilizations are appropriate if the fracture is healed.
- Use of heat (as discussed earlier) to increase tissue extensibility will make the patient more comfortable and help increase ROM. To assist stretch into flexion with heat, try wrapping the digit(s) in flexion with Coban and dipping them in paraffin.

**Decreased PIP Joint Extension**
- The appropriate treatment approach depends on the structures involved. If the PIP joint can be passively placed into full extension but is unable to actively extend, the extensor apparatus may be scarred down.
- The following treatments are beneficial to increase active extension of the PIP joint.
  - Before beginning the exercises, use of superficial heat modalities and ultrasound will assist to increase tissue extensibility, ROM gains, and the patient’s tolerance to exercises.
  - Active exercises include:
    - Active reverse blocking (passively flex the MP joints while actively extending the IP joints to transmit the extension force to the IP joints).
    - A reverse blocking splint is helpful to assist the patient with reverse blocking (FIG 5C).
  - Block the MP joint in flexion while actively extending the PIP joint into extension with simultaneous neuromuscular electrostimulation of the extensor digitorum communis muscle and the intrinsic muscles.
  - Active extension against resistance, such as theraputty
If the fracture is healed and passive ROM of the PIP is limited with extension, exercises and splinting can assist with improving passive ROM.
- Serial casting PIP into extension
- Finger-based dynamic PIP extension splint (FIG 5D)
- Dynamic extension splint with MP block in flexion
- Passive ROM and joint mobilizations with heat applied before these manual activities are appropriate if the fracture is healed.

**Scar Adhesions Limiting Tendon Glide**
- Active ROM, including extensor/flexor tendon glides, and scar massage and reverse scar massage (opposite the direction of the adhesion with active ROM) are key to decreasing adhesions of the tendon.
- These modalities work well in conjunction and may be used individually or in combination based on the patient’s individual needs.
  - Superficial heat (eg, fluidotherapy, moist heat, paraffin)
  - Ultrasound
  - Scar pad (eg, elastomere, Otoform K)
  - Iontophoresis with Iodex to soften scar

**OUTCOMES**
- In one series of 36 patients, the arc of motion of the PIP joint averaged 72 degrees with a 13-degree extensor lag. Patients with volar coronal fractures fared worse, with an average arc of 57 degrees.5
- In the McCue series of 32 patients treated with open reduction and two K-wires, flexion averaged greater than 93 degrees and extensor lag averaged less than 5 degrees.3

**COMPLICATIONS**
- Loss of PIP joint motion is the most common complication.
  - Fixation must be secure enough to allow early motion.
  - Delay of motion of the hand by more than a few weeks significantly decreases final outcome. Ideally, motion should be initiated in the immediate postoperative period.
  - Increases in motion may be obtained up to 1 year after the injury, although opportunity does decrease with time.2
  - Dorsal capsulotomies and extensor tenolysis are options for patients lacking flexion.
  - Loss of reduction is common if fractures are not stabilized or are stabilized with only one point of fixation.5

**REFERENCES**
DEFINITION

- The laymen’s term “jammed finger” often is used to indicate an injury sustained to the proximal interphalangeal (PIP) joint. If the force behind this injury is sufficient, the joint may suffer a fracture-dislocation, an injury that may be difficult to treat.

- PIP fracture-dislocations in the dorsal direction are caused by disruption of the volar fibrocartilaginous plate, fragmentation of the middle phalanx where it attaches to this plate, and damage to the collateral ligaments on each side of the joint. Instability with dorsal displacement of the middle phalanx may result, accentuated by the unbalanced pull of the central slip.

- Stiffness, pain, persistent subluxation, osteoarthritis, and permanent dysfunction are common sequelae, even with dedicated treatment in the best of circumstances.

- Dynamic external skeletal traction, extension block pinning or pinning, transarticular pinning, open reduction with internal fixation (ORIF), and volar plate arthroplasty are the techniques most often used to address this problem.

- None of these techniques have proven to be satisfactory for all patients in all instances.

- Extension block pinning has been used with reasonable success to reduce and stabilize unstable PIP fracture-dislocations.

  - A K-wire is placed into the head of the proximal phalanx, mechanically blocking full extension and thereby preventing dorsal subluxation of the middle phalanx.

  - The advantages of this technique include its simplicity and the early mobility it affords an injured joint. It can be used alone or in combination with volar plate arthroplasty or ORIF.

ANATOMY

- The PIP joint acts mostly as a hinge joint in the sagittal plane, although it does possess a few additional degrees of motion in the coronal and axial planes. It has an average range of flexion–extension of 105 degrees.

- The joint has a great deal of stability throughout its range of motion.

- When healthy, the joint is most stable in full extension.

  - A tongue-and-groove structure, formed by the bicondylar head of the proximal phalanx and the reciprocal concave surfaces of the middle phalanx, contours closely in this position.

  - As the joint flexes, the ligamentous elements take up responsibility for maintaining stability.

  - The volar plate, a structure that is ligamentous at its origin on the proximal phalanx and cartilaginous at its insertion on the middle phalanx, and the two collateral ligaments, one on the radial and one on the ulnar side of the joint, are the most important (FIG 1).

  - Two out of three of these structures must be impaired for displacement of the middle phalanx to occur.

PATHOGENESIS

- Although the PIP joint may become dislocated in any direction, displacement of the middle phalanx dorsally is the most common.

- Simultaneous hyperextension and compression forces—such as those seen when a ball strikes the tip of the finger—stress the volar plate and the collateral ligaments.

  - Type I injury

    - If the force of injury is mild, partial disruption of the collateral ligaments and the volar plate at its distal insertion on the middle phalanx are the only consequences.

    - The articular surfaces remain intact and the joint is stable.

    - If appropriate treatment is initiated promptly, an excellent long-term result is anticipated.

  - Type II injury

    - If the force of injury is more substantial, bilateral longitudinal splitting of the collateral ligaments may occur in addition to rupture of the volar plate. Complete dorsal displacement of the middle phalanx is then possible due to unopposed pull of the central slip.

    - The joint can be readily reduced and usually is stable following the reduction.

  - Type III injury—stable

    - If an avulsion fracture of the middle phalanx occurs at the attachment of the volar plate, the joint may still remain stable. When less than 30% to 40% of the joint surface is involved, the joint is stable following reduction because collateral ligament integrity is maintained.

  - Type III injury—unstable

    - If the fracture at the base of the middle phalanx involves more than 40% to 50% of the articular surface, collateral ligament support is lost. The joint exhibits persistent dorsal subluxation of the middle phalanx due to unopposed pull of the extensor tendon and lack of volar restraints.
■ Closed reduction may not be possible, and treatment is more difficult, often leading to unsatisfactory overall results.20

**NATURAL HISTORY**

■ The outcome following even a minor injury is often less satisfactory than the patient anticipates. Although it is possible for a PIP joint that has suffered a fracture-dislocation to regain fully normal function, this often is not the case. Persistence of a stiff joint with a cosmetically thickened outline is common.
  ■ Delay in treatment or lack of vigilant care negatively affects outcome.10
  ■ Prolonged immobilization of the joint following reduction leads to stiffness. Early mobilization can avoid stiffness and promote nutrition of the damaged articular cartilage.19
  ■ Patients should be reassured, however, that carefully planned treatment and compliance with the postoperative therapy regimen leads to long-term satisfactory results in most cases.10

**PATIENT HISTORY AND PHYSICAL FINDINGS**

■ The history should elicit the manner in which the digit was injured, the nature of any medical treatment or manipulation of the digit before the current visit, and how much time has elapsed since the injury.
  ■ The likelihood of a favorable result diminishes with increased time from injury, particularly beyond 6 weeks.9
  ■ The digit will look surprisingly normal at presentation in many cases, particularly if it was previously reduced.
  ■ A transverse skin injury on the volar side of the PIP joint may indicate that the volar plate has been disrupted.25
  ■ The integrity of the neurovascular status should be documented on examination before digital anesthetic block and reduction.18
  ■ With the forearm supinated and the hand relaxed, observe the position of the patient’s fingers. Note the axial and rotational alignment of the digit.
  ■ The uninjured, quiescent hand has increasing flexion tone in the digits from the radial side to the ulnar side,2 a phenomenon known as the flexion or resting cascade (FIG 2A).
  ■ Observe the patient’s fingers directly and fluoroscopically as he or she attempts to move them through a normal range of motion. Dorsal subluxation often can be detected visually and through palpation.
  ■ Digital or wrist block anesthesia can be used to relieve discomfort associated with motion (FIG 2B).
  ■ If the joint can be moved through a full arc of motion without subluxation, adequate joint stability remains, and only brief immobilization will be required.
  ■ If redisplacement occurs, significant instability results. The position of redisplacement is a clue both to the specific site of ligament injury and the optimal position for joint immobilization.8 Loss of active extension implies central slip injury.
  ■ For grossly stable digits, manipulate the joint passively through the normal range of motion. Gentle lateral and dorsovolar shearing stresses are applied at full extension and at 30 degrees of flexion. The findings are compared to those of the contralateral uninjured digit (FIG 2C).
  ■ The position of the PIP joint at the point of instability suggests which of the soft tissue supports has been injured. Instability at more than 70 degrees of flexion indicates damage to the collateral ligaments. Instability in extension indicates disruption of both the collateral ligaments and the volar plate. The degree of joint laxity suggests the extent of injury to the ligaments, from microscopic tearing to complete rupture.
  ■ Palpate the PIP joint from all sides to determine point tenderness. Point tenderness often is valuable in localizing the injured structure.
  ■ Absence of point tenderness on the condyles may rule out significant injury to these structures. If the volar lip of the middle phalanx has been fractured, minor tenderness over the dorsum of the middle phalanx and greater tenderness volarly and laterally will be present.3

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

■ Obtain anteroposterior, lateral, and oblique radiographs of the injured digit. Assess the digit for joint dislocation, subluxation, and fracture.18
  ■ Evaluate the radiographs before performing the physical examination to detect potentially unstable fractures or dislocations before they are manipulated.18
  ■ Radiographs of the hand as a whole (eg, the “fanned four-finger lateral” view) are not adequate. Subtle fracture-dislocations may be missed due to poor depiction of the areas of suspected pathology.23
  ■ Fluoroscopy is extremely valuable in defining the pathoanatomy and determining stability.
CT scanning occasionally is indicated, particularly to assess suspected articular depression.  

**DIFFERENTIAL DIAGNOSIS**
- Fracture
- Fracture-dislocation
- PIP dislocation
- Collateral ligament and PIP joint sprain
- PIP volar plate injury
- PIP joint infection
- Localized soft tissue infection
- Flexor digitorum profundus tendon rupture
- Extensor tendon central slip injury
- Closed pulley rupture (flexor sheath)
- Swan neck/boutonniere deformity

**NONOPERATIVE MANAGEMENT**
- Most type I, type II, and type III stable injuries (and some type III unstable injuries) are amenable to nonoperative treatment.
- The joint can be immobilized for a short time to afford the patient comfort and to allow soft tissue recovery.
- A dorsal splint is applied to the digit at 20 to 30 degrees of flexion, avoiding immobilization beyond 30 degrees to lessen the risk of flexion contracture.
- The duration of immobilization reflects the minimum amount of time needed to effect healing and obtain joint stability. Type I injuries are immobilized for several days; type III injuries may be immobilized for up to 3 weeks.
- Avoidance of prolonged immobilization and patient education are the most important aspects of this treatment, because stiffness and contracture are very common.
- Extension block splinting allows early motion of a joint while preventing extension past an angle where instability is possible.
- First, the position in which the joint re-displaces is determined.
- A length of aluminum splint is then bent to an angle 10 or 15 degrees greater than this point of redisplacement and secured to the dorsum of the hand with adhesive tape or as part of a short-arm cast. The hand is positioned with 25 degrees of extension at the wrist and 45 to 60 degrees of flexion at the metacarpophalangeal joint (FIG 3A,B).
- If the angle of the splint is greater than 60 degrees, the arc of motion may be insufficient for the patient to achieve adequate flexibility, and it may be necessary to consider another treatment regimen.
- An extension block splint made from two pieces of AlumaFoam (Hartmann International, Rock Hill, SC) and spanning only the finger itself is another option (FIG 3C,D).
- The two Alumafoam pieces are held to each side of the PIP joint with adhesive tape and are bent such that they
come into contact with each other at a particular degree of extension, thus preventing motion beyond that point.21
- In general, extension block splinting is recommended for fractures involving less than 40% of the articular surface. Successful results have been noted, however, with fractures involving up to 75% of the joint.12
- Following application of the splint, radiographs are taken to confirm satisfactory reduction, and the patient is encouraged to flex the finger as much as the swelling allows.
- As the fracture-dislocation heals, the extension block splint is progressively adjusted toward full extension, usually during a period of 3 to 8 weeks.7 Weekly radiographs and splint adjustments are required.
- In certain instances, the digit may be too short, stocky, or swollen for such treatment, or patient compliance and sophistication for such a regimen may be in question. In such a case, extension block pinning may be the better option.
- Because of the possibility of recurrent subluxation, the use of conservative treatment must be matched with frequent and careful assessment of the joint. Serial radiographs should be obtained weekly to document continued reduction of the joint and progressive healing of any fractures.7

SURGICAL MANAGEMENT
- Operative treatment is indicated for those unstable fracture-dislocations in which closed treatment does not provide a congruent reduction of the joint. This includes most type III unstable injuries with fractures that involve more than 40% to 50% of the volar articular surface.
- As noted earlier, many surgical options are available. The choice of procedure is based on the exact nature of the injury and the surgeon’s comfort with each option.
- Dynamic skeletal traction methods, which use the principle of ligamentotaxis to maintain concentric joint reduction, are especially useful when the fracture is significantly comminuted.1
  - These methods allow early active range of motion.
  - Drawbacks include the following:
    - Significant prowess on the part of the surgeon is required, as are close postoperative supervision and adjustment.
    - The external device may be cumbersome for the patient.
  - ORIF is especially useful when the avulsed volar fragment is large and minimally comminuted.11 If the joint is stabilized with transarticular pinning as part of the ORIF procedure, however, stiffness usually results.
  - Volar plate arthroplasty, or the use of the distal aspect of the fibrocartilaginous volar plate to resurface the comminuted volar articular surface of the middle phalanx, is another option that can be employed when comminution of the volar fragment makes other techniques infeasible.7 Most authors have reported reasonably favorable results, but residual stiffness and contracture have been reported as well.9
  - Simple reduction with transarticular pinning (with no attempt at articular reconstruction) may be useful in injuries with less than 40% articular involvement. Extension block splinting may be just as effective in these milder instances, however, and it enjoys a lower risk of joint contracture.10
  - Extension block pinning is a viable alternative for mild to moderately unstable fracture-dislocations under the following circumstances:
    - The fracture-dislocation cannot be reduced and stabilized effectively with an extension block splint.14,22,24
    - Patient compliance is uncertain.
    - The finger is too short or swollen to fit appropriately into an extension block splint.
    - It may be used alone or in combination with an ORIF or a volar plate arthroplasty procedure.3

Preoperative Planning
- Before the operation, the patient should be provided realistic expectations regarding outcome.
  - He or she should be aware of the possibility that immobilization, splinting, and long-term rehabilitation may be necessary.
  - The patient should be instructed to keep the injured hand clean before the procedure and to avoid additional skin injury to minimize the potential for infection. Fingernails should be trimmed and cleaned and the hands thoroughly scrubbed with antiseptic soap before the operation.
  - Intraoperative decision-making often is necessary. The surgeon should be comfortable in the performance of a number of alternative procedures and should have the necessary equipment available should findings require an alteration in the original surgical plan.

Positioning
- The method of preparing, draping, and positioning the upper extremity is the same as for most hand surgeries.
  - A well-padded, proximal upper extremity tourniquet is applied.

Approach
- Because extension block pinning is a percutaneous technique, no approach is required.

EXTENSION BLOCK PINNING14,22,24
- The PIP joint is reduced by flexing the joint to 90 degrees and applying axial traction.
  - Concentric reduction of the joint is confirmed with fluoroscopy (TECH FIG 1A).
  - If an open wound is present or the joint cannot be manipulated into an acceptable reduction, such as may occur with soft tissue entrapment, open reduction becomes necessary.
  - Following reduction through either open or closed methods, and with the joint flexed 90 degrees or more, a smooth 0.035- to 0.045-inch K-wire is placed percutaneously into the distal, dorsal aspect of the proximal phalanx across the dorsal lip of the base of the middle phalanx (TECH FIG 1B).
  - The wire is inserted in a retrograde direction, approximately 30 degrees off the long axis of the proximal phalanx.
  - When placing the K-wire centrally, hyperflexing the PIP joint prevents tethering of the extensor mechanism to the proximal phalanx, which would limit joint flexion. Alternatively, the K-wire can be placed to one side of the central tendon to avoid tethering the extensor mechanism.
The wire is guided with fluoroscopy through the shaft of the proximal phalanx and is left protruding from the head of the bone. Fluoroscopy is used to confirm a congruous joint reduction following the procedure.

The joint is then passively extended to the limit of the K-wire, and the reduction of the joint is again critically evaluated fluoroscopically (TECH FIG 1C).

If the joint continues to subluxate dorsally at extension, a V-shaped gap between the articular surfaces of the head of the proximal phalanx and the dorsal lip of the middle phalanx will be seen on radiograph. With the pin in this position (TECH FIG 1D), the patient will be able to move the finger actively but will not be able to extend the digit beyond the point where subluxation is possible due to mechanical blockage by the pin (TECH FIG 1E,F).

An arc of more than 60 degrees is ideal.

**TECH FIG 1** • Dorsal block pinning. A. Fluoroscopic view confirms adequate joint reduction. Note that fracture reduction is not anatomic but is considered acceptable in this clinical scenario. B. Insertion of the retrograde K-wire with the joint hyperflexed to avoid tethering the extensor mechanism. C. Passive intraoperative extension of the joint to the level of the K-wire. The dorsal joint remains concentrically reduced. D. The K-wire is left protruding through the bone, and its placement is confirmed by fluoroscopy. E,F. The patient should be able to move the finger through an arc of about 60 degrees.

**PEARLS AND PITFALLS**

- The patient’s ability to comply with fairly complex and intensive hand therapy should be confirmed before surgery.
- The insertion point for the K-wire can be located by a freehand technique and then confirmed with fluoroscopy.
- Easy passive flexion of the joint through an arc of 60 degrees or greater should be confirmed following pin insertion.
- The surgeon should remain hypervigilant for the presence of a V sign in full passive extension.
- The surgeon should ensure that the skin is not tented by the Kirschner wire.
**POSTOPERATIVE CARE**

- The patient should have a thermoplastic splint fabricated for protection and should begin a supervised program with a hand therapist 3 to 5 days after surgery.
- Gentle active range-of-motion exercises are allowed immediately and should be encouraged in most cases.
- If the injury is especially serious—eg, injuries that required volar plate arthroplasty or that contained significant comminution—immobilization for up to 2 weeks may be indicated.
- Pin care must be explained carefully and performed regularly.
- The pin is removed 3 weeks after surgery, and vigorous active flexion and extension are encouraged. Reverse blocking is initiated.
- Full extension should be limited for 1 additional week.
- Active and passive joint exercises, including dynamic extension splinting, is initiated after 6 to 8 weeks of therapy, until full motion is achieved.
- Buddy taping or wrapping can be used, if added, longer-term protection is needed.

**OUTCOMES**

- The outcome for intervention into PIP fracture-dislocations depends mostly on the severity of the initial injury.
- Because few cases of extension block pinning used as the sole intervention are available in the literature, it is difficult to assess the long-term outcome of the procedure.
- Inoue and Tamara reported the use of extension block pinning in 14 cases of fracture-dislocation of the PIP joint with an average fracture fragment size of 38% of the articular surface (range 25% to 60%). Ten patients regained full range of motion, and four patients regained a more limited range (89, 65, 64, and 40 degrees, respectively). The average ROM for all patients was 94.4 degrees.
- The authors attributed the four cases with less satisfactory results to the use of a 60-degree extension block splint post-operatively in one patient and significant comminution in the other three patients.
- Viegas reported the use of this technique in three cases of fracture-dislocation of the PIP joint. One case involved a 45% single fragment fracture seen 1 day postinjury and another a 35% comminuted fracture seen 17 days post-injury. Following pin removal and 1 month of passive and active exercises, both patients regained full range of motion. A third case involved a 75% comminuted fracture seen 2 days post-injury. The patient’s ROM after pin removal was 30 to 65 degrees. Because the patient did not return for further care, no final outcome was available.
- Twyman and David reported the use of this technique in two cases of fracture-dislocation of the PIP joint. The extent of injury in each patient was not specified, but quick recovery to satisfactory ROM in both patients was reported (20 to 100 degrees and 15 to 110 degrees, respectively).

**COMPLICATIONS**

- Persistent pain and swelling
- Stiffness
- Flexion contracture and extensor lag
- Redisplacement of the joint and persistent subluxation
- Angulation and rotation of the middle phalanx
- Weakness
- Boutonniere deformity
- Post-traumatic arthritis (not necessarily symptomatic)

**REFERENCES**

DEFINITION

- Proximal interphalangeal (PIP) joint bone injuries may affect the convex side of the joint (end of the proximal phalanx) or the concave side of the joint (base of the middle phalanx).
- Convex-side injuries are typically simple (two-fragment) injuries best treated with open reduction and internal fixation if surgery is required.
- Concave-side injuries tend to be comminuted (multifragmented), presenting either as fracture-subluxations or dislocations or a pilon fracture.
- Fracture subluxations-dislocations typically involve dorsal displacement of the main (dorsal) fragment of the middle phalanx (FIG 1A), although volar and lateral subluxations and dislocations are less common (FIG 1B,C).
- Dorsal fracture-dislocations typically occur after a hyperextension injury of the PIP joint.
- Pilon fractures are compression fractures of the base of the middle phalanx (rarely the distal phalanx) and are characterized by depression of the central articular component and splaying of the articular margins.
  - This may be associated with longitudinal fracture extension that may reach most of the length of the middle phalanx.
  - There is typically marked comminution of the base of the middle phalanx (FIG 1D,E).
  - The fracture typically occurs due to a longitudinal (end-on) force, crushing the base of the middle phalanx (rarely the distal phalanx or thumb proximal phalanx). This may occur due to a fall or miscatching a ball (eg, at cricket or baseball).

ANATOMY

- The distal end of the proximal phalanx is a convex surface made up of two condyles. The proximal end of the middle phalanx is a concave surface (FIG 2A).
The two bones are linked and stabilized by ligaments (FIG 2B).
These structures resist dorsal subluxation of the PIP joint when loaded:
- Volar plate
- Collateral ligaments (radial and ulnar)

PATHOGENESIS
- The tendon attachments are dorsal proximal and weak through the central slip and volar distal and strong through the flexor digitorum superficialis tendon slips. Thus, the flexor forces dominate the extensor forces.
- The shape of the joint and the soft tissue restraints allow a powerful lever arm to work for flexion. If, however, the volar restraint fails (particularly in a dorsal fracture-dislocation), the resultant forces lead to dorsal subluxation and proximal migration of the main dorsal fracture fragment of the middle phalanx (FIG 3A).
- Research work and clinical experience have shown that the joint will be stable if up to 42% of the volar half of the middle phalanx articular surface is damaged as measured on a lateral radiograph (FIG 3B).
- In practice, subluxation can occur with as little as 10% to 15% of joint surface loss, but that is uncommon.
- For pilon fractures, the condyles of the proximal phalanx are driven up into the base of the middle phalanx, displacing the central part of the articular surface distally and splaying the dorsal-volar and lateral margins of the middle phalanx joint surface. This injury is longitudinally unstable and results in proximal migration and diminution or obliteration of the joint space, usually with significant articular incongruity.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Most patients present within a few days, although later presenters (up to 2 to 3 weeks) are common and some very late presenters (after 6 weeks) are also seen.
  - The delays are usually due to underestimation of the severity of the injury either by the patient (who thinks he or she has a sprain and it will resolve) or medical/paramedical staff (who fail to perform or interpret properly an adequate radiograph).
  - The finger will be swollen and tender, centered around the PIP joint.
  - An angular deformity may be evident.
  - Subluxation of the joint may be clinically evident, visually or by palpation.
  - There will be reduced range of movement throughout the finger and particularly in the PIP joint.

Fracture-Dislocation Involving the Proximal Interphalangeal Joint
- Most are mild injuries with limited volar plate avulsion that reduce either spontaneously or with assistance, usually under local anesthesia (FIG 4A–D). Radiographs may reveal a small volar bone avulsion from the base of the middle phalanx. These injuries are longitudinally stable.
  - The examiner must test for stability through a full arc of motion.
  - If there is a tendency for subluxation, the position of the joint that allows this instability is recorded.
  - More severe injuries (ie, involving a greater part of the volar lip) may be longitudinally unstable, resulting in persistent subluxation of the PIP joint with attendant clinical findings as described above.
Subluxation and dislocation are best visualized on the lateral radiograph and may be quite subtle, appearing as joint incongruity at the dorsum of the joint (the triangle sign, due to dorsal overhang of the base of the middle phalanx) (FIG 4E).

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- The key investigation is plain radiology.
- Often only radiographs of the hand are taken in the emergency department. These are not adequate. Posteroanterior and lateral radiographs need to be taken, centered on the PIP joint of the injured finger (FIG 5).
- The key information obtained from the radiographs (supplemented by physical examination) can be used to differentiate stable from unstable injuries, either of fracture-subluxations or dislocations or pilon fractures.
- Fluoroscopy can be of great value in assessing the injury and joint stability.

**DIFFERENTIAL DIAGNOSIS**
- Soft tissue
  - Volar plate injury
  - Collateral ligament injury
  - Central slip injury
- Bone
  - Proximal phalanx condylar injury
  - Proximal phalanx distal diaphyseal injury
  - Middle phalanx proximal diaphyseal injury

**NONOPERATIVE MANAGEMENT**
- If the injury is stable, early protected mobilization can start within 1 week of injury.

**Fracture-Dislocation**
- A stable injury (the majority of cases) can be treated with early mobilization concentrating on regaining extension, which is commonly lost.
  - Only if there is significant pre-existing volar plate laxity (often occurs in young women) is there a need for an extension block splint for up to 6 weeks.
  - Most patients regain full or nearly full movement but may be left with minor swelling and stiffness and mild cold discomfort.
  - Heavy activity may cause discomfort.
  - In approximately 5% of patients the joint remains significantly swollen and uncomfortable beyond 6 weeks. This is probably due to persistent joint synovitis, which usually resolves with a steroid injection.
  - If the joint is unstable but there is limited volar joint damage (less than about 30 degrees), it may reduce when held in flexion with a dorsal block splint.
Joint reduction and congruity must be documented radiologically and should not require more than about 50 degrees of joint flexion, or unacceptable PIP joint stiffness may result.

Patients should be encouraged to flex and extend to the splint. They should be seen weekly for 4 weeks. Flexion of the splint is reduced by about 10 degrees each week. At each increase in extension, the reduction needs to be precisely checked radiologically.

A reasonable range of movement with only a mild flexion contracture and loss of flexion is anticipated.

Pilon Fractures

The minority of pilon fractures have minimal displacement (less than 1 mm) and a reasonable joint space (FIG 6). These are usually stable injuries but must be carefully assessed clinically.

Most of these patients can achieve a range of movement from 10 to 20 degrees short of full extension to 70 to 80 degrees of flexion with only mild discomfort.

Patients can start early gentle mobilization with part-time protection in a splint at night and outdoors for 4 weeks.

Patients treated with early, protected mobilization need clinical and radiologic review weekly for at least 2 to 3 weeks.

Most patients will achieve a nearly full range of motion with minimal pain, stiffness, or swelling.

If there is greater displacement, then surgery is almost always needed to achieve longitudinal stability and early movement.

**Surgical Management**

Preoperative Planning

The proximal wire is always placed at or near the center of rotation of the injured joint.

Distal wire placement needs to be planned.

For fractures localized to the base of the middle phalanx, the distal wire can be anywhere from the midpart of the middle phalanx or more distal. In fact, the middle phalanx is narrowest at this point, so the wire is more easily placed distally.

**FIG 5** • Hand radiographs are interpretable only with a true lateral radiograph of the proximal interphalangeal joint.

**FIG 6** • Pilon fracture that was sufficiently congruent and comfortable to respond to early mobilization with a good long-term result. This could not have been predicted radiologically, and all cases require clinical assessment.
If the fracture extends distally, as can easily occur with pilon fractures, the distal wire should be distal to that extension to ensure adequate fixation and stability. The distal wire can be placed as far distal as the head of the middle phalanx.

I have never had a fracture so distal that the distal wire could not gain adequate fixation.

The procedure is best performed under local anesthesia. This allows the patient to participate during the operation. The patients also understand what has happened and is often clearer about the postoperative regimen.

At least 10 mL of plain 0.5% bupivacaine is injected at the midmetacarpal level. Bupivacaine works more slowly than lidocaine, but if given before skin preparation, it usually works completely by the time surgery starts. It then provides prolonged anesthesia for 12 to 36 hours. This helps reduce postoperative pain.

**Positioning**

Informed consent is needed, with a discussion of the risks and benefits of the various conservative (nonoperative) and surgical options.

**Approach**

The operation is performed closed with insertion of percutaneous wires.

---

**INSERTING THE WIRES**

- I use 1.1-mm K-wires: 0.9-mm wires are too flexible and 1.6-mm wires are too rigid. I know that 1.2-mm wires have been used successfully. I suspect that wires from 1.0 to 1.3 mm are fine, but I recommend 1.1-mm wires.
- Identify the level of the center of rotation of the PIP joint with the image intensifier and mark this level on the skin (**TECH FIG 1A,B**).

---

Risks include infection, nerve injury, stiffness, scar tenderness, nonunion, malunion, the need for revision procedures, and the risk associated with any operation (ie, making the patient worse).

The digit needs to be marked very clearly, especially if the patient is receiving general anesthesia (the minority of patients).

Typically 1.5 g of cefuroxime is administered preoperatively. There is no need for postoperative antibiotics.

The patient lies supine with the affected hand out on an armboard at 90 degrees to the table (ie, standard position for hand surgery).

A proximal arm tourniquet is applied as a backup to the digital tourniquet.

The skin is prepared with chlorhexidine in an alcohol solution with a pink dye to ensure that all the fingers have been fully painted. If the finger has had adhesive dressings on it or has not been well cleaned, the anesthetized finger is scrubbed before skin preparation.

The operated arm is draped steriley.

---

**TECH FIG 1 • A, B**. Checking the position for the first wire at the level of the center of rotation of the proximal interphalangeal joint with the image intensifier and marking it on the skin. **C**. Wire inserted across the head of the proximal phalanx and confirmed on the image intensifier before advancing further. **(continued)**
TECH FIG 1 • (continued) D,E.
Finding and marking the position of the distal wire as for the proximal wire. This placement is more distal in the head of the middle phalanx than average because the distal interphalangeal joint was also injured. F,G. Inserting the distal wire and confirming its position on the image intensifier.

- Placing this wire too far proximal of the construct will restrict full joint movement. This is the most important step in the whole procedure.
- Identify an appropriate level in the distal half to two thirds of the middle phalanx, distal to any fracture extension in the shaft of the middle phalanx, with the image intensifier.
- Mark this level on the skin.
- This wire may be inserted near the center of rotation of the distal interphalangeal (DIP) joint, in the distal middle phalanx. This is acceptable because the bone is wider and provides more margin for error (TECH FIG 1D,E).

- Insert the wire partially through the middle phalanx and check carefully (posteroanterior and lateral) on the image intensifier (TECH FIG 1F,G).
- Aim to be perpendicular to the long axis of the finger and parallel to both the plane of rotation and the first wire (which should also be in the plane of rotation).
- Insert the wire so equal lengths are present on either side of the finger (by doing this for the proximal wire, where it is less important, you will have a guide for the distal wire). This helps in the wire bending. If one end is too short it can become difficult to bend, especially in patients with long fingers.

BENDING THE WIRE

- Wire bending is the more technically demanding part of the procedure. It is important to understand and follow the steps carefully.
- One may create the construct in reverse of that described below, but this results in motion on the proximal wire rather than the distal wire, which in theory increases the risk of pin track and PIP joint sepsis.
- To ensure enough but not too much clearance from the finger, the wire is held with a medium needle holder against the skin, then manually bent past a right angle (because there is spring in the wire).
- Bend the opposite half of the wire to the same degree and in the same direction.
- Bend the distal wire on each side through 90 degrees (TECH FIG 2A,B).
- Bend each half of the distal wires to make the linkage between the wires (TECH FIG 2C,D).
- It is critical that this bend is sufficiently distal in the wire (proximal relative to the finger) to ensure that the construct is long enough and provides adequate joint distraction.
- If the bend is not distal enough, it is difficult to salvage, and you will probably need to remove the distal wire and insert a new wire.
- Grip the distal wires with the medium needle holder just after the second bend and bend the distal end back up about 135 degrees, creating a Z shape (TECH FIG 2E).
- The proximal wire will sit in the distal narrow angle of the Z.
- It important to put the Zs at the same level, although the construct can tolerate some mismatch.
- If the Zs are at different levels, careful unbending or further bending of the wires should help.
- The proximal wire is flicked into place in the distal angle of the Z (TECH FIG 2F).
- It should bow, showing that tension has been applied across the construct and thus traction across the joint.
- Improved fracture and joint alignment can be visualized on the image intensifier.
TECH FIG 2 • A,B. Grasping the distal wire with the needle holder and making the first bend. C,D. Start and completion of the second wire bend. E. Third wire bend shown on a freestanding wire. F. The properly bent distal wire is placed around the proximal wire distracting the joint.

TIDYING UP AND ENSURING THE CONSTRUCT DOES NOT DISENGAGE

Proximal Wire
- Bend the proximal wire down. Place the medium needle holder on the wire, pushing the Z construct of the distal wire against the skin (TECH FIG 3A,B).
- This ensures that the construct is neither too bulky nor too close to the finger, allowing for some swelling.
- A distance of about 3 to 4 mm is effective.
- Bend the proximal wire down about 135 degrees (TECH FIG 3C).
- Cut the proximal wire with wire cutters about 3 mm after the bend and crimp the cut ends (TECH FIG 3D,E).
- If too short, it cannot be bent; if too long, it will abut the finger.

TECH FIG 3 • A,B. Grasping the proximal wire and making the first bend on the proximal wire shown on a patient. C. Bend the wire approximately 135 degrees. D. Cut the proximal wire 3 mm after the bend. E. Crimping cut ends of proximal wires.
**Chapter 35  DYNAMIC EXTERNAL FIXATION OF PROXIMAL INTERPHALANGEAL JOINT FRACTURE-DISLOCATIONS 2417**

**TECHNIQUES**

**TECH FIG 5 •** Drawing of a Suzuki frame showing a third (middle) wire in position, where it can act as a force couple.

**Distal Wire**
- Crimp the distal point of the wire and the part of the proximal wire just outside the skin down together with the medium needle holders (TECH FIG 4A).
- Do not crimp too far or the middle phalanx wire will be gripped and not allow full rotation.
- The wire has to be bent enough to ensure that the construct cannot disengage.
- Bend the distal tail of each Z over to ensure that the proximal wire cannot disengage (TECH FIG 4B).
- This process leaves slightly irregular cut wire ends. These need to be kept close to the construct and typically do not cause problems, but if they do they can be covered postoperatively.
- Check the final fracture position on the image intensifier (TECH FIG 4C,D).

**Force Couple**
- Some surgeons advocate a force couple—that is, a third wire in the proximal end of the middle phalanx that hooks under the bent distal middle phalanx wire to force the middle phalanx volar and improve dorsal joint subluxation (TECH FIG 5).
- We have not needed a force couple, nor is there any evidence as yet to support its use.

**TECH FIG 4 •** A,B. Distal wire bends completed. The fourth bend is just to prevent disengagement of the construct. C,D. The position of the final construct on a patient on whom, for the only time in my practice, I used a double fixator on one finger. The proximal interphalangeal joint had a pilon fracture, which is well but not perfectly reduced. The distal interphalangeal joint had a fracture-dislocation that is also well but not perfectly reduced.

**At the end of the operation, if the patient is under local anesthesia, ask him or her to watch the injured digit while extending the PIP joint to neutral and flexing to at least 90 degrees.**
- This method of educating the patient is painless and gives him or her greater confidence in the postoperative period.
PEARLS AND PITFALLS

- External fixation is typically very reliable and flexible in the treatment of PIP fractures and dislocations. The indications for open reduction and internal fixation are extremely limited due to the degree of fracture comminution and the morbidity associated with even limited open methods of treatment.
- At operation the key is to place the proximal wire at or just proximal to the center of rotation of the PIP joint in the head of the proximal phalanx.
- Bending of the wires requires practice but with experience becomes easy. It is important to avoid putting twist into the wires to optimize motion in the construct.
- Sufficient tension in the construct and across the joint is critical.
- If inadequate, the wire bends may be adjusted, but probably the distal wire will need to be replaced.

POSTOPERATIVE CARE

- The construct should not disimpact if made properly. If it does, it can usually be adjusted in clinic with further wire bending. Local anesthesia may be needed.
- The hand is elevated maximally for 3 to 5 days and movement is started once the patient is comfortable.
- The use of a long-acting local anesthetic means the patient can go home and start taking simple oral analgesics (eg, ibuprofen and diclofenac, paracetamol and codeine, or both).
- Opiate analgesics are rarely required, and almost no patient complains of significant pain.
- The analgesics should continue for at least 24 hours but not longer than 1 week.
- Long slow stretches both into extension and into flexion are emphasized. They should be performed hourly.
- The stretches should be held for 5 minutes at a time. They should not be painful, although they need to be at least on the edge of discomfort or in the mildly uncomfortable range. Painful stretches will lead to more swelling, increase the risk of complex regional pain syndrome type I, and discourage the patient from performing exercises.
- Formal therapy visits begin the second postoperative week. In addition to PIP motion, DIP motion is emphasized. The therapist works with these patients at least weekly.
- The patient is checked after 5 to 7 days.
- The dressing is removed and radiographs are performed to ensure that the reduction has been maintained.
- The dressings are left off and the patient is instructed in pin track care (see below), care of the sharp wire points (ie, covering them with tape if necessary), and stretching exercises, supported by a hand therapist.
- The pins are cleaned and dried as one would for their hand day to day.
- Assuming the pin tracks stay dry, nothing more needs to be done.
- If the pin tracks start oozing, clean with preboiled water four times a day.
- If the pin sites do not improve within 24 hours, I advise the patient to seek medical help for antibiotics.
- The redness and oozing should resolve within 2 to 3 days. If not, the patient may require intravenous antibiotics and early pin removal, but this is extremely rare.
- The patient is checked again about 2 weeks postoperatively.
- At this stage the finger will still be mildly swollen.
- There should be minimal or no pain except with stretches.
- The pin tracks should be clean and dry.
- The range of movement should be in the PIP joint a fixed flexion deformity of no more than 10 degrees and flexion to at least 50 degrees, and in the DIP joint full extension and flexion to at least 50 degrees.
- If this has been achieved, the patient returns to the office 4 to 5 weeks postoperatively for wire removal. There appears no good reason to leave the wires in longer, and the incidence of pin track sepsis increases after 4 weeks.
- Final review takes place 10 to 12 weeks after surgery.

OUTCOMES

- The finger will still be mildly swollen; this will never resolve fully.
- The final range of movement will have been achieved; it should be about 10 to 90 degrees in the PIP joint and full (0 to 70 degrees) in the DIP joint. There should be no rest pain but there will probably be some aches with heavy use. The pin tracks should have healed with minimal if any tenderness or cosmetic abnormality.
- Pilon fractures typically reduce only in part, with at least one impacted fragment remaining impacted in the middle phalanx.
- Because the concave side of the joint seems to tolerate some incongruency well, this fragment is not routinely disimpacted.
- Fracture-dislocations also tend to reduce incompletely, with some mild residual dorsal subluxation of the joint surface (ie, widening of the joint on the lateral view). If mild, this too is well tolerated.
- Traction devices generally give reliable results, with range of motion of about 89 degrees and only 2% poor results; open reduction and internal fixation gives range of motion of 79 degrees and 10% to 12% poor results.

COMPLICATIONS

- Complications are uncommon but recovery is never full, as indicated above.
- Pin track infection is the most common risk, but if the wires are removed between 4 and 5 weeks it is uncommon (less than 10% of cases). It typically resolves with cleaning, elevation, and 2 to 3 days of oral antibiotics (typically flucloxacillin 500 mg four times a day and amoxicillin 500 mg three times a day).
- Mild malunition is accepted and well tolerated.
- Nonunion has not occurred as a functional problem, although radiographs may show odd ununited peripheral fragments of bone.
- Nerve injury may occur.
- Significant poor results and persistent rest pain occur in only about 3% to 5% of patients.
REFERENCES

DEFINITION
- Proximal interphalangeal (PIP) joint fracture-dislocations are intra-articular injuries that include a concomitant soft tissue injury to the surrounding capsular and ligamentous structures.
- The injury can result from axial, bending, and torsional loads, or combinations thereof.
- These injuries of the finger are relatively common and potentially disabling, and may result in:
  - Joint stiffness
  - Persistent subluxation
  - Posttraumatic arthritis
  - Chronic pain
- Stability and alignment are more important goals than articular congruency in determining a successful outcome.\(^{18}\)
- Evaluation and treatment may be delayed, with the injury dismissed as a “jammed finger.”

ANATOMY
- The PIP joint is a hinge joint, consisting of radial and ulnar condyles on the proximal phalanx, with matching concavities on the middle phalangeal base. This construction allows for a wide range of motion (ROM) in flexion and extension, but relative rigidity in abduction and adduction.
- The PIP joint has an arc of motion of 120 degrees and accounts for 85% of the motion required to grasp an object.\(^2\)
- The joint derives its stability from its bony articular congruence and its soft tissue restraints (FIG 1).
- The volar plate resists dorsal stress, is taut in extension, and often fails distally from bone.
- Checkrein ligaments are slender proximal extensions of the volar plate under which branches of the digital arteries pass, supplying the joint and vincula and nourishing the flexor tendons.
- Collateral ligaments, the primary soft tissue restraints, have two components:
  - The proper collateral ligaments (radial and ulnar), which insert on the middle phalanx, provide the principal resistance to abduction/adduction stress. These ligaments are commonly injured in dorsal dislocations. Injury to the radial collateral ligament is more common than injury to the ulnar collateral ligament by nearly six-fold.
  - The accessory collateral ligaments arise from a conjoined origin just volar to the proper collateral ligament and insert on the volar plate.
  - The extensor complex limits volarly directed stress.
  - The central slip attaches to the dorsal tubercle on the base of the middle phalanx.
  - The conjoint lateral bands run obliquely on each side of the joint.
  - The transverse retinacular ligament connects the central slip and the conjoint lateral bands and extends laterally.
- For a dislocation to occur, at least one, often two, and sometimes all three of these structures must be significantly disrupted.

PATHOGENESIS AND CLASSIFICATION
- The PIP joint is uniquely susceptible to injury.
- The pattern of joint injury depends on the direction, degree, and rate of force application.
- The three main groups of PIP fracture dislocations are defined by the mechanism of injury force and the direction of deformity (FIG 2).
- Dorsal subluxation, or dislocation of the middle, the most common type, is caused by hyperextension and axial loading of the middle phalanx against the head of the proximal phalanx. The result is a fracture involving the base of the middle phalanx and dorsal positioning of the middle phalanx.
- This injury can be subclassified into three types based on the amount of volar middle phalanx articular surface involved, as determined on a lateral radiograph.\(^{13}\) The degree of instability is directly proportional to volar lip fragment size due to the loss of collateral ligament support, and the articular buttress (see Fig 3B in Chap. HA-35).
- Stable: less than 30% of the articular surface, reduced in extension
Chapter 36  ORIF OF PROXIMAL INTERPHALANGEAL JOINT FRACTURE-DISLOCATIONS

Tenuous: 30% to 50% of the articular surface, reduction maintained with less than 30 degrees of flexion

Unstable: either more than 50% of the articular surface or 30% to 50% of the articular surface, but requiring more than 30 degrees of flexion to maintain reduction

Volar subluxation, or dislocation of the middle phalanx, is less common and is thought to be caused by forced flexion of an extended joint.

Stable: joint reduction in extension

Unstable: palmar subluxation of middle phalanx with the joint extended

Pilon injuries are not associated with significant subluxation or dislocation. They are caused by an axial force on a partially flexed PIP joint, resulting in comminution of the articular surface of the middle phalanx (most commonly, volar and dorsal articular fragments surrounding a central depressed fragment)

Unicondylar fractures of the head of the proximal phalanx, another variant of this injury type, are included in a classification system proposed by Weiss and Hastings21 (see Chap. HA-33).

These injuries also can be accompanied by dislocation of the PIP joint and nearly always are unstable and require operative fixation. They often are amenable to the same approaches and fixation methods presented here.

NATURAL HISTORY

Following injury, the PIP joint quickly stiffens. Pain and instability limit motion initially; then the joint capsule and ligaments become fibrotic.

Over time the unreduced PIP joint will become arthritic and painful.

HISTORY AND PHYSICAL FINDINGS

Patients present following a traumatic event to the digit, frequently one that occurred some time ago.

In the acute setting, the primary complaints are pain and swelling of the joint and digit.

Patients with subacute and chronic injuries are focused primarily on stiffness, loss of function, and persistent swelling, and secondarily on pain.

The history must include a detailed description of the mechanism of injury and any previous treatment.

- Inspection
  - Evaluate the skin and soft tissues for swelling and for any open or healed wounds that could indicate an open fracture-dislocation.
  - Deformity in extension or flexion indicates whether the dislocation is volar or dorsal, respectively.
  - Axial or rotational malalignment may result from articular depression of a condyle. This can be recognized clinically as subtle angulation when full digital extension is attempted.

- Tenderness
  - The acute location of greatest tenderness on palpation may indicate which soft tissue structures are injured.

- ROM
  - Adequate evaluation may be difficult in the acute setting due to pain. After neurologic examination, a digital block may be necessary.

- Elson test (FIG 3)
  - From a 90-degree flexed position over the edge of a table, ask the patient to actively extend the PIP joint of the involved finger against resistance. If the central slip is intact, the examiner will feel an extension force from the middle phalanx. In addition, the distal interphalangeal (DIP)
Part 6  HAND, WRIST, AND FOREARM  •  Section IV  HAND FRACTURES AND DISLOCATIONS

joint remains flail during this effort, because the competent central slip prevents the lateral bands from acting distally.

- An absence of extension force at the PIP joint and fixed extension at the DIP joint (due to the extensor action of the lateral bands alone) is diagnostic of a complete rupture of the central slip. In the acute setting, the patient may be reluctant to perform this test due to pain, but this can be relieved by proximal infiltration with local anesthetic around the dorsal sensory nerves of the digit.7

- Note the range of motion through which the joint remains reduced. In the case of a dorsal dislocation, the degree of extension that results in instability or redislocation determines the angle for the extension block splint.

- An irreducible joint is consistent with entrapment of a soft tissue structure (eg, volar plate, collateral ligament, flexor or extensor tendon) in the joint, which usually necessitates urgent surgery.

- The neurovascular examination usually is normal.

- Subjective complaints of paresthesias and objective measure of capillary refill should be noted, both pre- and post-reduction.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Posteroanterior (PA), lateral, and partially supinated and pronated oblique radiographs of the involved digit(s) are required.

- Oblique views help to identify fracture planes and determine the extent of comminution, valuable for surgical planning.

- It is critical to determine amount of articular involvement on a true lateral film in full PIP joint extension to evaluate stability of the joint.

- Radiographs can be misleading, suggesting that a very simple fracture involving only a small fragment of the bone has occurred. This fragment is potentially the major attachment of a collateral ligament, the volar plate, or a tendon. The resultant incompetence of these structures can render the joint grossly or potentially unstable (FIG 4A).

- V sign13 (FIG 4B)

- On a postreduction true lateral radiograph of the digit, divergence of the dorsal articular surfaces from the central portion of the joint creates a V-shaped gap between the articular surfaces of the head of the proximal phalanx and the undamaged portion of the middle phalanx base.

- The presence of this sign indicates an incompletely reduced joint.

- Dynamic fluoroscopy is extremely valuable in evaluating the reduction and its stability.

- Hinged flexion is a variant of the V sign in which congruent rotation of the joint is replaced by abnormal translation as the joint is actively flexed and extended across the flattened fracture segments.

- The joint position that results in instability or redislocation is best determined fluoroscopically.

**DIFFERENTIAL DIAGNOSIS**

- Pure dislocation (simple or complex)

- Extra-articular fractures

- “Jammed finger”—collateral sprain9,14,23

- Volar plate injury

- Central slip injury

**NONOPERATIVE MANAGEMENT**

- Prompt recognition of the complexity of injury and an understanding of the appropriate treatment options are essential for optimal management of these fractures.

- Although fractures and dislocations of the PIP joint have the potential to be disabling, most can be treated with closed reduction, splinting, early motion, and close follow-up.

- Closed reduction is almost always successful for acute dorsal PIP dislocations. Volar dislocations are more problematic, especially if the deformity has a rotary component.

- Reductions performed immediately after the injury often can be accomplished without anesthesia. If reduction is delayed, a digital block with 1% lidocaine (without epinephrine) is helpful.

- Always make sure to complete a careful neurologic examination of the digit before performing an anesthetic block. Confirm adequate anesthesia before manipulation.

- Be gentle, and limit the number of attempts. Irreducible dislocations usually are caused by soft tissue interposition.

- Dorsal dislocations can be reduced with gentle traction on the finger with the wrist in the neutral position, followed by pressing the base of the middle phalanx in a volar direction while holding the proximal phalanx steady.

ORIF, open reduction with internal fixation; P-2, middle phalanx; ROM, range of motion.

Volar dislocations without a rotatory component usually are reducible with gentle traction.
- Place the wrist in the neutral position and apply a dorsally directed force to the middle phalanx and a volarly directed force on the proximal phalanx.
- These dislocations, which usually can be treated with closed reduction, commonly involve an avulsion of the central slip.
- Volar dislocations with a rotatory component often are difficult to reduce by closed means. The head of the proximal phalanx becomes trapped between the central slip and one of the lateral bands of the extensor mechanism.
- These injuries occasionally can be reduced closed by placing the metacarpophalangeal (MCP) and PIP joints in 90 degrees of flexion with the wrist extended, applying light traction, and rotating the middle phalanx in the direction opposite to the deformity.

Surgical Management

Surgical management is difficult for two reasons:
- The fracture fragments can be small and comminuted, making anatomic reduction and stabilization with implants difficult.
- The need for early mobilization of the joint to prevent stiffness requires rigid fixation of these fragments.
- These fractures have a high risk of redisplacement, and patients must be warned of the possibility that repeat surgical treatment of the fracture may be necessary.
- The specific injury and fracture pattern often dictate the most appropriate method of treatment. Some methods can be used in combination.
- For stable, reducible fractures, typically involving less than 30% of the articular surface, treatment includes:
  - Extension block splinting and pinning
  - Traction, dynamic or static (see Chap. HA-35).
- Unstable, irreducible fractures, typically involving more than 30% to 50% of the joint, require:
  - External fixation
  - Percutaneous fixation
  - Open reduction with internal fixation using K-wires, screws, cerclage wires
- When dorsal fracture-dislocations are associated with bone loss or fracture comminution to such a degree that a stable reduction is unobtainable using the methods listed earlier, two salvage procedures are commonly employed.

- **Volar plate arthroplasty.** The volar plate is advanced into the middle phalangeal defect, simultaneously restoring stability and resurfacing the damaged articular surface (see Chap. HA-37).
- **Hemi-hamate autograft reconstruction.** The fractured middle phalangeal base is débrided, and the defect is replaced using a size-matched portion of the dorsal/distal hamate osteoarticular surface and secured with mini-fragment screws (see Chap. HA-38).

Table 1 illustrates some of the indications, advantages, and disadvantages of open reduction and internal fixation and some of the salvage options discussed in this chapter.

**Indications**
- Unstable and tenuous fractures requiring more than 30 degrees of flexion to maintain reduction
- Closed management of these fractures requires extreme flexion to prevent redislocation is likely to result in a flexion contracture.
- Fractures with fragments that are irreducible by closed methods and amenable to internal fixation with available hardware
- Significant articular depression, displacement, or incongruity

**Goals**
- Stable, anatomic fixation of the fracture resulting in a concentric reduction of the PIP joint
- Early range of motion designed to enhance cartilage and soft tissue healing, enhance joint remodeling, and minimize adhesions and contractures
- Anatomic restoration of the congruous joint surface is a desirable but less important treatment goal and does not supersede a concentric PIP reduction and early motion.

**Preoperative Planning**
- Radiographic evaluation, as discussed earlier
- The surgeon must be adept at using the various techniques, and the patient should be counseled that intraoperative observations will dictate the definitive method of fixation.

**Positioning**
- The patient is placed supine with a radiolucent hand table.
- A brachial tourniquet is placed on the upper arm before draping and is inflated to 250 mm Hg just before the incision is made.
Surgery can be performed under a wrist or digital block, but an axillary block is preferred to obtain adequate sensory anesthesia and motor relaxation of the flexors and extensors.

The operative hand is supinated, and a “lead hand” can be used to hold it in place.

Operative Equipment
- A mini C-arm fluoroscopy unit is necessary to confirm fracture reduction, joint reduction, and correct placement of implants.
- Mini-fragment plate and screw set
- 24-gauge wire
- K-wires

Approach
- The volar (Bruner) approach, the dorsal (Chamay) approach, and the mid-axial approach are all useful.
- The approach is chosen based on the fracture pattern and the direction of instability.
- When most of the fracture comminution is dorsal, a Chamay or mid-axial approach is selected.
- When most of the comminution is volar, as is more common with dorsal fracture-dislocations, a volar Bruner incision is employed.

EXPOSURE

Volar Approach (Bruner)\textsuperscript{3,10}
- A palmar zigzag skin incision is made from the MCP joint crease across the PIP joint to the DIP flexion crease. In a larger or longer digit, two limbs of a Bruner incision may be necessary between the flexion creases (TECH FIG 1A,B).
- An ulnarily based, thick subcutaneous flap is mobilized at the level of the flexor sheath.
- The digital neurovascular structures are mobilized from the flexor sheath apparatus.
  - These procedures are necessary to avoid traction on the associated structures if the joint is dorsally displaced during exposure and fixation.
- The flexor sheath over the PIP joint (including the A3 pulley) is incised on three sides, creating a rectangular flap between the A2 and A4 pulleys (TECH FIG 1C).
  - Alternatively, the flexor sheath may be split longitudinally to expose the underlying flexor tendons.
- The flexor digitorum profundus and flexor digitorum superficialis tendons are retracted to the side to expose the volar plate (TECH FIG 1D).
  - A Penrose drain placed around the tendons permits atraumatic retraction.
- The PIP joint and bare surface of the volar fragment are exposed by dividing the volar plate in the transverse plane just proximal to its distal insertion.
  - Make sure to leave a small amount of the distal portion attached to the bony fragment of the middle phalanx for later repair.
  - Retract the main portion of the volar plate proximally, creating a proximally based flap. The volar plate is not excised.
- Sharp recession of the collateral ligaments at their proximal or distal volar attachments may be required to access fragments that are more dorsal than the volar third of the middle phalangeal base or to reduce chronic subluxations.
  - Most often, the collateral ligaments are elevated only from their middle phalangeal insertion.

TECH FIG 1 • A. The Bruner approach uses a palmar zigzag skin incision from the metacarpophalangeal (MCP) flexion crease across the PIP joint level to the DIP flexion crease. B. In larger digits, two limbs may be necessary between flexion creases. C. Once the flexor sheath is exposed, it can be incised on three sides between the A2 and A4 pulleys and the flap retracted laterally. Alternatively, the sheath can be split down its center longitudinally to expose the flexor tendons. The pathways of the incisions are demonstrated by the dotted line. D. After retraction of the incised flexor sheath, the flexor digitorum and profundus tendons (FDP, FDS) are exposed. Gently retract them to one side with a blunt retractor to expose the volar plate and the base of the middle phalanx. Not uncommonly, the volar plate is still attached to the volar lip of the middle phalangeal fracture fragment. E,F. Shotgun exposure of the PIP joint. E. The PIP joint is distracted while the flexor tendons are retracted laterally. F. The joint is then gently hyperextended until it maintains this shotgun alignment of its own accord (~130 degrees), exposing the articular surfaces (arrow, fractured volar middle phalanx base). (D-F: hand is to the left and the finger is to the right).
Chapter 36  ORIF OF PROXIMAL INTERPHALANGEAL JOINT FRACTURE-DISLOCATIONS

TECHNIQUES

If comprehensive exposure of the PIP joint is required, the collateral ligaments are released from their site of insertion, and the PIP joint is distracted and then gently hyperextended until it maintains this alignment of its own accord (about 130 degrees). This has been referred to as “shotgun” exposure of the joint6 (TECH FIG 1E,F).

Watch the neurovascular bundles closely during this hyperextension maneuver to ensure they can easily subluxate dorsally.

Dorsal Approach (Chamay)4

A longitudinal skin incision is made over the dorsal aspect of the proximal phalanx proximally and then is curved laterally and distally around the dorsal aspect of the PIP joint. After superficial dissection is carried down to expose the extensor mechanism, a distally based, V-shaped flap of central slip is created, with the apex of the flap extending to the proximal third of the proximal phalanx. This pedicle flap of central slip is then pulled distally with a hooked retractor to expose the PIP joint.

The first structure encountered in the subcutaneous fat is Cleland’s ligament, which contains fibers that run volar to dorsal and consist of thin fascial layers surrounding the digital nerve and artery with skin. It can be isolated from adjacent fat at the level of the PIP joint.

Once Cleland’s ligament is divided, carry the dissection slightly volarward, deep to the neurovascular bundle, and expose the lateral aspect of the middle phalanx and lateral margin of the flexor sheath.

The neurovascular bundle remains in the volar flap.

Enter the joint between the volar plate and the accessory collateral ligament and inspect the joint.

Additional exposure is gained by elevating the collateral ligament at the origin or the insertion.

Mid-Axial Approach

Identify the midaxial line by marking the axes of the IP joints and drawing a line through these points proximally and distally (TECH FIG 3A).

If comprehensive exposure of the PIP joint is required, the collateral ligaments are released from their site of insertion, and the PIP joint is distracted and then gently hyperextended until it maintains this alignment of its own accord (about 130 degrees). This has been referred to as “shotgun” exposure of the joint6 (TECH FIG 1E,F).

The repair is strong and will allow early active motion within the first 48 hours.

Midlateral Midaxial

A. Diagrams demonstrating the midaxial (blue line) and midlateral (red line) approaches. The midlateral approach is shown for reference, but the midaxial approach is the one most often used clinically. Midaxial approach (blue): flex the finger and mark the motion axes of the IP joints by marking the points at the IP joints where the flexion creases end dorsally. Draw a line through these points proximally and distally (blue line). B. In a cross-section diagram of these approaches, the midaxial dissection will be dorsal to the neurovascular bundle and the midlateral dissection will be at the level of the neurovascular bundle.

FRACTURE AND JOINT REDUCTION

The joint and fractures are exposed, cleansed of hematoma, and fully evaluated.

If soft tissues are interposed, a fine curved hemostat or dental pick may be introduced to clear the fracture site.

Make the skin incision on this midaxial line. The digital nerve and artery lie about 2 mm volar to the margin of the incision (TECH FIG 3B).

Avoid a radial-sided incision on the index finger and an ulnar-sided incision on the small finger. These surfaces are important for contact and should be protected from potential scar sensitivity.

The first structure encountered in the subcutaneous fat is Cleland’s ligament, which contains fibers that run volar to dorsal and consist of thin fascial layers surrounding the digital nerve and artery with skin. It can be isolated from adjacent fat at the level of the PIP joint.

Once Cleland’s ligament is divided, carry the dissection slightly volarward, deep to the neurovascular bundle, and expose the lateral aspect of the middle phalanx and lateral margin of the flexor sheath.

The neurovascular bundle remains in the volar flap.

Enter the joint between the volar plate and the accessory collateral ligament and inspect the joint.

Additional exposure is gained by elevating the collateral ligament at the origin or the insertion.

A dental pick or Freer elevator may be used to carefully manipulate and elevate depressed articular fragments, restoring articular congruity.

Maintain cancellous and subchondral bone on the articular cartilage-bearing fragments.
- Cancellous bone grafting may be required to prevent articular surface collapse in highly comminuted fractures.
- Allo- or autograft (often harvested from the dorsal distal radius) can be used. The graft material is packed into the metaphysis through either direct application or a cortical window.
- Small 0.045- or 0.030-inch K-wires may be used to provisionally stabilize the reduction.
- Preliminary joint reduction, fracture reduction, and articular restoration are confirmed under direct vision and with fluoroscopy.
- Fracture fixation may proceed through various methods, depending on fracture pattern and surgeon-preference.

**MINI-FRAGMENT FIXATION**

- Screw fixation, if attainable, provides excellent stability and may allow earlier ROM and improved functional restoration. This form of stabilization is indicated for larger and fewer fragments (TECH FIG 4A–D).
  - Be aware that these fragments are often more comminuted than believed, and screws may further comminute the bone, making ultimate fixation difficult.
  - After anatomic reduction of the fragments is achieved by careful manipulation and the fragments are stabilized with clamps or K-wires (as needed), appropriately sized screws, typically in the 1.0- to 1.7-mm range, are chosen.
  - The screw hole is drilled as perpendicular to the fracture plane as possible.
  - The depth is measured.
- If possible, an interfragmentary lag technique is preferred. This is done by overdrilling the near fragment cortex with a drill equal to the screw’s outer diameter.
  - A self-tapping, minifragment cortical screw is placed.
  - Countersinking of screws or use of headless screws may be helpful to avoid soft tissue tethering and tendon irritation (TECH FIG 4E).
- If the fragment is large enough, two screws, or a screw and a supplementary threaded K-wire (0.028 inch), can be used to prevent rotation of the fragment (TECH FIG 4F,G).
- After the procedure, PIP joint ROM usually is compromised, with a residual flexion contracture occurring in more than 80% of cases of volar fracture and dorsal instability.

**TECH FIG 4 • A–C.** Preoperative AP, lateral, and oblique radiographs demonstrating a displaced small finger PIP intra-articular fracture with a large dorsal/ulnar fragment. **D,E.** Intraoperative photos show the dorsal approach to the PIP joint. **D.** The fragment was large enough to be amenable to microscrew fixation. **E.** Using standard AO technique, a 1.7-mm screw was placed to achieve stable fixation of the fragment. The head of the screw has been countersunk. (continued)
CERCLAGE WIRE TECHNIQUE

- The cerclage wire technique allows reduction of multiple small articular fragments and provides adequate fixation to allow early ROM exercises (TECH FIG 5A).
  - A thorough joint release is required, which carries the risk of increased fibrosis and stiffness postoperatively.
  - A volar incision with a “shotgun” exposure of the PIP joint is used (TECH FIG 5B).
  - Judicious elevation of the central slip is performed.

- A thin ring of periosteum around the bony fragments of the middle phalanx is cleared by sharp dissection.
- This allows the wire loop to seat directly against bone, providing firm fixation of the fracture fragments.
- The normal shape of the base of the middle phalanx (reverse funnel contour) also aids in fixation of the wire and prevents postoperative slippage, even with early ROM.
- 24-gauge steel wire is formed into a loop and twisted on itself until the loop is partially closed, just larger than the base of the middle phalanx.
- After fracture reduction, the loop of wire is seated and gently tightened, allowing circumferential compression of the fracture fragments (TECH FIG 5C).
- Final confirmation of articular reduction is made, with careful attention to the correction of central depression and joint subluxation (TECH FIG 5D).
- The twisted portion of the loop is placed on the volar or volar lateral surface or the middle phalanx base, flush to the cortex, at the edge of the volar plate.
- The wire is covered by the repaired volar plate to prevent mechanical irritation of the flexor tendons.

**Supplementary K-Wire Addition**

- A supplementary K-wire may be necessary, depending on fracture configuration (TECH FIG 6A,B).
- The cerclage wire is loosely twisted around the base of the middle phalanx, maintaining the position of the articular fragments prior to the replacement of the central and volar depressed fragment (TECH FIG 6C).
- After replacement of the central fragment and further fixation with a K-wire, the cerclage wire is tightened (TECH FIG 6D,E) and the tail cut.
CLOSURE AND SPLINTING

- The volar plate and central slip flaps are closed with a 4-0 nonabsorbable suture.
- The flexor tendon sheath is closed using either absorbable or nonabsorbable 5-0 or 6-0 suture.
- The tourniquet is deflated, and hemostasis is achieved with bipolar cautery.
- The skin is closed with 5-0 nylon suture.
- The patient is placed into an intrinsic-plus volar splint.

The skin is closed with 5-0 nylon suture. Usually, the MP joints are flexed 70 to 90 degrees and the IP joints are extended based on the stability of fixation and joint reduction.

PEARLS AND PITFALLS

- PIP fracture-dislocations often are missed by athletic trainers and patients, dismissed as a “jammed finger.”
- Avoid forceful passive testing for stability, which can convert a partial tear to a complete one. Instability of any of these structures to passive stress is unlikely to change the management of an injury that is stable with active range of motion. The one potential exception to this is complete rupture of the radial collateral ligament of the index finger PIP joint in a young active patient. This injury may be surgically repaired primarily because stability at this joint (required for a normal pinch grip) may be more important than full ROM.
- Make sure to preserve the A2 and A4 pulleys. Failure to do so will result in bowstringing of the flexor tendons and a failed outcome.
- Screw fixation should not be attempted for fracture fragments that are too small or too comminuted (eg, more than three fragments).
- To avoid recurrent dislocation, any bony defect remaining behind the repaired volar plate complex should be filled with bone graft.

POSTOPERATIVE CARE

- Progressive active and active assisted range of motion does not begin until postoperative day 2 to 5, depending on initial patient comfort.
- A thermoplastic splint provides protected mobilization.
- Relatively more aggressive flexion than extension (less than 30 degrees) is pursued with the therapist.
- Close weekly follow-up for the first 3 weeks is necessary to monitor for any loss of reduction.
- All restrictions on motion are removed at 5 to 6 weeks, and radiographic signs of healing are followed.
- Therapy is continued for 1 to 2 months after removal of the splint, to recover motion and strengthen the hand.

OUTCOMES

- Green and Akelman reported on two patients with dorsal fracture-dislocations who underwent ORIF and reported an average active range of motion of 95 degrees at 1-year follow-up, with neither patient demonstrating any evidence of subluxation.
- Hastings and Carroll reported on 15 patients treated with ORIF using various combinations of K-wire fixation, tension band wire fixation, and screw fixation. Eventual average postoperative ROM was 17 to 90 degrees.
- Dietch et al reported on 24 patients with unstable dorsal fracture dislocations of the PIP joint treated with two methods, volar plate arthroplasty and ORIF. At an average follow-up of 46 months, results indicated that if reduction of the joint is maintained, patients could expect few functional deficits despite radiographic degenerative changes and loss of mobility.
- Weiss reported on 12 patients with dorsal fracture-dislocations treated with cerclage wire fixation and reported an average ROM of 89 degrees at 2 years follow-up, with no complications and only one patient with evidence of radiographic degenerative changes.
- Stern et al reported on 20 patients with pilon fracture-dislocations of the PIP joint. They used three treatment methods: splinting, skeletal traction, and open reduction with K-wire fixation. After a clinical and radiographic follow-up of 25 months, skeletal traction led to fewer complications and clinically comparable outcomes to open reduction (achieving an average ROM of 80 degrees vs. 70 degrees, respectively).
- While clinical experience supports anatomic reduction of intra-articular fractures in weight-bearing joints such as the hip or knee, most laboratory and clinical reports support the theory that anatomic surface restoration is unnecessary if subluxation is corrected and motion is instituted shortly after injury.

COMPLICATIONS

- Degenerative arthritis
- Loss of PIP joint motion, stiffness, flexion contracture, and extensor lag
- Loss of fixation or redisplacement
- Persistent subluxation or dislocation
- Infection
- Malunion
- Boutonnière deformity
- Pain
REFERENCES

DEFINITION
- Volar plate arthroplasty (VPA) provides a volar restraint to dorsal subluxation and dislocation of either the middle or distal phalanx base to maintain reduction of the proximal interphalangeal (PIP) or distal interphalangeal (DIP) joint. It resurfaces the volar portion of the injured joint using local tissue (volar plate).
- VPA is used much more commonly for PIP joint stability than DIP joint stability.

ANATOMY
- The volar plate, which is the primary restraint against hyperextension instability, lies palmar to both the PIP and DIP joints, separating the joint from the flexor tendon(s).
  - At its origin, the volar plate is “swallowtail” shaped and connected only by proximal checkrein ligaments to the phalanx and fibrosseous tendon sheath (FIG 1A).
  - Distally, the VP is primarily cartilaginous. It inserts centrally via the periosteme and laterally with a conjoined insertion through the collateral ligaments (FIG 1B).
  - The volar plate glides proximally and distally with joint motion.
- The collateral ligaments originate on the dorsal radial and dorsal ulnar surfaces proximal to the joint. The proper collateral ligaments insert on the volar radial and volar ulnar surface distal to the joint, and the accessory collateral ligaments insert into the lateral margin of the volar plate, creating a box-type configuration (see Fig 1B).
  - In subacute or chronic cases of dorsal joint subluxation or dislocation, these ligaments contract, thereby accentuating the deformity by virtue of their oblique orientation.
  - The flexor digitorum superficialis (FDS) inserts just distal to the volar plate on the middle phalanx.
  - Due to the direction of pull, forces exerted by the FDS may accentuate dorsal subluxation of the middle phalanx base when the volar restraints are lost.

PATHOGENESIS
- Injuries to the PIP and DIP are caused by longitudinal compression or hyperextension forces (common in sports injuries) and typically occur in young, active individuals.
- Dorsal fracture dislocations of the PIP occur with damage to the volar articular surface of the middle phalanx when a force drives it dorsally against the condyles of the proximal phalanx.
- Chronic subluxation or dislocation (more than 6 weeks) often occurs, especially with the PIP joint when the injury is perceived as minor and is considered a “sprain.”

NATURAL HISTORY
- Chronic subluxation of the PIP joint leads to poor function and degenerative arthritis.
  - Flexion of the joint is limited and painful.
- Despite optimal surgical treatment, PIP joint fracture-dislocations often result in some loss of PIP or DIP joint motion.
- PIP joint injuries, even those that do not require surgical treatment, commonly result in a protracted period of symptoms (eg, swelling, stiffness, pain) beyond what patients expect from a “minor” injury.

PATIENT HISTORY AND PHYSICAL FINDINGS
- When taking the patient’s history, ask about the mechanism of injury, time since injury, any prior injuries, and the direction of deformity. Time since injury and mechanism of injury help determine the most appropriate treatment for any particular PIP joint injury.
Inspect the finger for any swelling or deformity. Clinical deformity may be subtle, even with significant subluxation.

Examine range of motion, noting degrees of PIP motion. With joint subluxation, patients will have painful and limited flexion.

Examine joint stability; joints that are dislocatable will need intervention for stability (eg, extension block splinting, VPA).

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Every patient with a PIP injury must have anteroposterior, lateral, and oblique radiographs to evaluate for a PIP joint fracture or subluxation (FIG 2A).
  - The severity of the fracture and degree of involvement of the middle phalanx often are much greater than they appear on these radiographs.
  - In evaluating for a subluxation by radiographs, a true lateral view of the PIP joint is mandatory. A dorsal V sign at the joint indicates that the articular surfaces are neither congruent nor parallel (FIG 2B).
  - Fluoroscopy allows dynamic evaluation of the joint and its stability and often is also the best way to obtain magnified images and a perfect lateral view.
  - CT scans rarely are needed but can effectively evaluate the articular surfaces and define the bone loss.

**DIFFERENTIAL DIAGNOSIS**

- Acute central slip injury (ie, boutonniere deformity)
- PIP joint fracture
- PIP dislocation
- Volar plate or collateral ligament sprain without instability

**NONOPERATIVE MANAGEMENT**

- Closed reduction and extension block splinting are appropriate for PIP fracture subluxations when a stable concentric joint reduction is obtained and maintained in an acceptable position.
  - If more than 65 degrees of flexion is required to maintain reduction, surgical reconstruction should be strongly considered.
  - Articular defects will often dramatically remodel in a concentrically reduced, mobilized joint.

**SURGICAL MANAGEMENT**

- For simplicity, the techniques here describe VPA for the PIP joint, but the same principles may apply to the DIP joint. The primary difference is that the FDP insertion on the volar base of the distal phalanx makes exposure of the volar plate more complicated.
- **Indications**
  - Acute fracture-dislocations that are unstable after closed reduction of the PIP joint in cases in which the volar base of the middle phalanx is not reconstructable, or if surgical reconstruction is less likely to achieve a functional result
  - Chronic subluxations or dislocations up to 2 years following trauma
  - A normal articular contour of the proximal phalanx is a prerequisite.
  - An intact dorsal cortex and dorsal articular surface are required.
  - Some authors (eg, Burton4) use VPA for chronic osteoarthritis in select situations.

**Preoperative Planning**

- Fractures typically involve over 30% of the surface of the middle phalanx base, and the joint is subluxated or dislocated. If the fracture involves under 30% of the joint surface, it typically can be managed either in a closed manner or with less invasive techniques for the acute scenario.
- The literature is unclear whether a specific degree of involvement of the articular surface precludes VPA (ie, is too large), but involvement of the dorsal cortex is a contraindication.
  - VPA is a less successful treatment for injuries involving over 50% to 60% of the middle phalanx articular surface. In these cases, recurrent subluxation is common.
  - In chronic dislocations, soft tissue contracture and heterotopic bone may make dissection and relocation more complex.

**Positioning**

- The patient is positioned supine on the operating table with the affected arm on a hand table.
- Intraoperative fluoroscopy is critical to this procedure, and it is important to position the hand relative to the fluoroscopy unit so that a true lateral view of the injured PIP joint may easily be obtained.
- The surgery is performed under tourniquet control.
PRIMARY INCISIONS AND EXCISIONS ON THE VOLAR SIDE

- The joint is exposed using two limbs of a Bruner incision centered at the PIP flexion crease, elevating a radially based flap (TECH FIG 1A).
- The radial and ulnar neurovascular bundles are identified and mobilized throughout the field to prevent a traction injury when the PIP joint is hyperextended to achieve optimal visualization (TECH FIG 1B).
- The flexor sheath is incised as a rectangular flap between the A2 and A4 pulleys and protected for later repair.
- The flexor tendons are atraumatically retracted radially or ulnarily, as needed to visualize the volar plate (TECH FIG 1C,D).

DETACHMENT OF THE VOLAR PLATE

- The volar plate is detached from the middle phalanx or fracture fragments, including as much tissue as possible.
- The volar plate is incised from the proper and accessory collateral ligaments through an incision along its radial-and ulnar-most margins (Tech Fig 1D).
- The volar plate flap must be as long and broad as possible to maintain adequate stability of the arthroplasty. It should be symmetrical radially and ulnarily to avoid angular deformities.
- The collateral ligaments are excised.
- The joint is then hyperextended approximately 180 degrees (“shotgunning”) to achieve maximum visualization of the base of the middle phalanx (TECH FIG 2).
- Small fragments of depressed articular cartilage or subchondral bone are débrided and saved for possible later use.
- Care is taken to avoid over-resection and loss of the dorsal articular support.

TECH FIG 1 • A. The Bruner incision is centered over the PIP flexion crease, with the vertex on the ulnar side. B. To prevent traction injuries, mobilization of the neurovascular bundles is necessary. C. Illustration of retraction of the flexor tendons and neurovascular bundles relative to the volar plate. D. The flexor tendons must be retracted radially and ulnarily to access the volar plate. The proposed incision to detach and mobilize the volar plate is outlined in pen.

TECH FIG 2 • Shotgunning. Hyperextending the joint allows clear visualization of the volar plate to the left, the avulsed bone, and the articular surface of each phalanx. The trough is fashioned symmetrically in the coronal plane, at the dorsal-most aspect of the articular defect to the right.
SHAPING THE ARTICULAR SURFACE OF THE MIDDLE PHALANX

- A transverse trough is fashioned with an osteotome or a rongeur across the middle phalanx and finished with a small curette, at the juncture between the intact articular surface and the fracture defect (Tech Fig 2).
- This trough must be symmetric in the coronal plane to avoid angular deformity. The depth of the trough at its dorsal side should be the thickness of the volar plate, thereby allowing a smooth transition from articular cartilage to transposed volar plate.

TRANSPOSING THE VOLAR PLATE

- A 3-0 nonabsorbable grasping suture (eg, Bunnell fashion) is placed in both the ulnar- and radial-most margins of the volar plate flap (TECH FIG 3A).
- Two straight Keith needles are passed through each side of the base of the middle phalanx using a wire driver. They are placed as far radially, ulnarly, and distally in the bone defect as possible, and directed centrally to penetrate the cortex distal to the central slip insertion (TECH FIG 3B).
- The sutures are tensioned as the middle phalanx is flexed, bringing the volar plate into the defect at a level that produces a smooth transition from the intact dorsal base of the middle phalanx to the volar plate.
- The joint should remain flexed about 20 to 25 degrees so the volar plate can advance both distally and dorsally.
- Examine the reduction with a true lateral fluoroscopic view on a mini C-arm (TECH FIG 3C).
- The base of the middle phalanx should glide over the head of the proximal phalanx and should not hinge open dorsally.
- The fingertip should be able to touch the distal palmar crease (110 degrees of flexion).
- If the PIP joint lacks substantial extension or has inadequate flexion, it may be necessary to advance the volar plate distally by teasing the checkrein ligaments from their origin or by fractional lengthening through step-cutting (Tech Fig 3A).

**TECH FIG 3**

- **A.** Sutting the volar plate. Sutures are passed through the margins of the volar plate and through the base of the middle phalanx using straight Keith needles. The volar plate is advanced into the trough, resurfacing the PIP joint. It may be necessary to advance the volar plate by step-cut lengthening of the checkrein ligaments. **B.** Bone resection. This diagram shows the needle holes in relation to the resected bone, the collateral ligament stubs, and the extensor mechanism central tendon. The holes in the middle phalanx should be as far dorsal and lateral as possible for maximum stability. **C.** The PIP joint has now been reduced and stabilized as shown.
**SECURING THE VOLAR PLATE**

- The sutures may be tied over a button dorsally.
- Alternatively, the sutures may be tied directly onto periosteum via a small incision distal to the central slip insertion. Care must be taken to ensure the sutures do not entrap the lateral bands or injure the central slip.

- In the acute setting, fractured bone fragments collected during the volar plate detachment may be placed in the defect of the middle phalanx, distal to the advanced volar plate. This provides support to the base of the phalanx.
- A K-wire is used with the joint in slight flexion to maintain reduction for 3 weeks (TECH FIG 4).
- Alternatively, the joint reduction can be maintained with an articulated external fixator to allow for early motion.

**TECH FIG 4** Lateral diagram of VPA. The overall diagram of this procedure illustrates the joint with a double-ended K-wire for stability and the volar plate secured by sutures.

**PEARLS AND PITFALLS**

**POSTOPERATIVE CARE**

- The K-wire PIP joint fixation is removed at 2 to 3 weeks, when active flexion and extension are begun.
- An extension block splint is used during weeks 3 to 6 after the operation.
- Motion of the DIP is encouraged before K-wire removal, because deficits in DIP motion have been reported after VPA.
- After 6 weeks, the pullout suture, if one was used, is removed.
- A dynamic extension splint may be used at 6 weeks if the achieved extension is not as expected based on intraoperative range of motion.

**OUTCOMES**

- More normal PIP motion is restored in acute injuries than in chronic injuries: 85 degrees of active PIP motion versus 60 degrees.
- Patients can expect to see continued improvement in range of motion up to 1 year after VPA.
- Mild contractures of the DIP joint (10 to 20 degrees) are common. Patients are encouraged in DIP motion during rehabilitation.

**COMPLICATIONS**

- Angular deformities
- Pin and wire track infections
- Pain
- Stiffness
- Degenerative arthrosis

**REFERENCES**

DEFINITION
- Proximal interphalangeal (PIP) joint fracture-dislocations occur with the following fracture patterns:
  - Palmar lip fracture-dislocations: Fracture of the middle phalanx palmar lip with dorsal subluxation of the middle phalanx on the head of the proximal phalanx
  - Dorsal lip fracture-dislocations: Fracture of the dorsal lip of the middle phalanx with palmar subluxation of the middle phalanx
  - Pilon fractures: Pilon fractures include a loss of continuity of both the dorsal and palmar cortical margins of the middle phalangeal articular surface. The base of the middle phalanx usually is highly comminuted, and the articular fragments may be significantly impacted.
- PIP fractures are further classified as “stable” or “unstable.”
  - Stable fractures maintain concentric joint reduction throughout the range of motion (ROM).
  - Unstable fractures sublux or dislocate during parts of the motion arc.
- Dorsal lip fracture treatment is complicated by the need to re-establish continuity of the extensor tendon insertion onto the middle phalanx.
- Pilon fractures are best treated with some form of traction and early motion.
- Unstable palmar lip fractures are amenable to treatment with hemi-hamate autograft and are the focus of this chapter.

ANATOMY
- The PIP joint is a complex hinge articulation that provides more than 95 degrees of flexion while maintaining stable, concentric reduction of the joint surfaces.
- Several forces encourage dorsal migration of the middle phalanx: the extensor tendon lifts the middle phalanx and the mid-middle phalanx superficialis insertion levered in a hook, preventing dorsal translation.
- The only restraints on middle phalangeal dorsal translation are the palmar plate and the cup-shaped geometry of the middle phalanx articular surface. The middle phalangeal palmar lip wraps around the proximal phalanx head and acts as a hook, preventing dorsal translation.
- Palmar lip fractures disrupt both of the restraints to dorsal subluxation. The palmar plate is no longer attached, and the middle phalangeal palmar lip is disrupted. The slope of the remaining middle phalangeal articular surface encourages the middle phalanx to travel up and over the proximal phalangeal head.
- A direct relation exists between the amount of palmar articular surface disrupted and stability (FIG 1B).
  - Hastings has shown that when 42% of the palmar articular surface is damaged, the joint always exhibits dorsal instability.
- In the clinical setting, fractures with as little as 30% articular surface involvement can be unstable.

FIG 1 - A. Unstable PIP fracture-dislocation. The upward pull of the central tendon insertion and the distal superficialis insertion pull and push the middle phalanx up and over the proximal phalangeal head. The only forces preventing dorsal subluxation are the middle phalanx palmar lip and the palmar plate, both of which are lost in an unstable PIP palmar lip fracture. B. PIP instability after a fracture. A direct relation exists between the amount of middle phalanx palmar lip destroyed by the fracture and the resultant PIP joint stability. Articular damage in excess of 50% of the joint surface always renders the joint unstable, whereas fractures involving less than 30% usually are stable. Tenuous fractures (ie, those with articular damage of 30% to 50% of the joint surface), must be assessed with lateral radiographs. If the joint will not stay reduced with less than 30 degrees of flexion, it must be classified as “unstable.”
Hemi-hamate arthroplasty restores stability by rebuilding the cup-shaped geometry of the middle phalangeal base and restoring the palmar plate attachment.

**PATHOGENESIS**

- The middle phalangeal palmar lip fracture that is associated with unstable dorsal PIP fracture-dislocations is created by either avulsion of the fracture fragment or an impaction shear mechanism.
- Avulsion fractures result from PIP joint hyperextension and traction through the palmar plate attachment (FIG 2A).
  - The fracture fragment is not comminuted and represents less than 30% of the articular surface.
  - These injuries usually are stable and rarely require surgical intervention. If the joint is unstable, osteosynthesis with lag screws often is possible because of the lack of comminution and the substantial size of the fragment.
- Impaction shear PIP fracture-dislocations result from a longitudinally applied load to the tip of the finger with the PIP joint slightly flexed, such as in a mishandled ball catch. The force drives the middle phalanx into and over the proximal phalangeal head, resulting in a middle phalangeal palmar lip fracture that is highly comminuted (FIG 2B).
  - Up to 80% of the joint surface can be involved, and the articular fragments are often deeply impacted into the soft metaphyseal bone.
- Disruption of the terminal extensor tendon (mallet finger) often occurs in association with unstable dorsal PIP fracture-dislocations.

**NATURAL HISTORY**

- The long-term prognosis for PIP fracture-dislocations is theoretically affected by the quality of the joint surface restoration and the maintenance of concentric reduction of the middle phalanx on the proximal phalangeal head.
- The PIP joint seems to tolerate less than perfect restoration of a smooth joint surface. As long as motion is initiated quickly, small gaps and step-offs seem to be tolerated. Long-term, some remodeling occurs, and most patients do not need to be treated for symptomatic posttraumatic degenerative arthritis.
- Joint reduction that is less than perfect is not well tolerated. When the middle phalanx rides dorsally on the proximal phalangeal head, PIP flexion occurs by “hinging” at the fracture margin. The joint pivots on the palmar edge of the fracture, and the proximal phalanx falls into the fracture defect at the palmar base of the middle phalanx. The proximal phalangeal articular cartilage suffers accelerated wear, while the remaining undamaged middle phalangeal articular surface remains unused throughout the motion arc (FIG 3).
- Treatment of unstable PIP palmar lip fractures is directed toward re-establishing joint stability so that flexion occurs by “gliding” of the remaining middle phalangeal articular cartilage on the head of the proximal phalanx.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Assess alignment in the coronal plane. Lateral deviation suggests asymmetric compression of articular fragments.

**FIG 2 • Fracture types.**

A. Avulsion fracture. Avulsion fractures usually are caused by a forced PIP joint hyperextension. The fragment is not comminuted and involves less than 30% of the joint surface. The PIP joint is most often stable.

B. Impaction shear fracture. This type of PIP fracture-dislocation is caused by a longitudinal load to the joint. The fracture fragments are comminuted and impacted into the middle phalanx. The joint reduction often is unstable.

**FIG 3 • Gliding or hinging.**

A. Normal PIP flexion occurs as the middle phalanx glides around the proximal phalanx head.

B. When the middle phalanx palmar lip is lost, PIP flexion can occur by hinging at the fracture margin. Treatment of unstable PIP fracture-dislocations must rebuild the cup-shaped middle phalangeal base and restore a normal gliding motion.
- Assess alignment in the sagittal plane. Lack of colinearity of the middle and proximal phalanges suggests persistent joint subluxation or dislocation.
- Associated mallet injuries must be treated concurrently with a DIP extension splint.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain radiographs in the posteroanterior (PA) and lateral planes provide the mainstay of radiographic evaluation of PIP fracture-dislocations.
- Inspect the lateral radiograph to determine the percentage of joint surface fractured and the quality of the reduction.
- If the joint is not concentrically reduced with less than 30 degrees of flexion, the joint is classified as unstable and must be treated appropriately (see Fig 1B).
- On every lateral radiograph taken throughout the treatment course, carefully scrutinize the quality of the reduction. The remaining articular cartilage on the middle phalanx base must be in full contact with the proximal phalanx head. Any dorsal gap between the two surfaces—a “V” sign—indicates persistent instability and must be corrected (FIG 4).
- The percentage of the middle phalanx articular surface consumed by the fracture can be used to predict joint reduction stability.5,6,9 (see Fig 1B):
  - Less than 30%: The reduction usually is stable. The middle phalanx almost always remains concentrically reduced on the head of the proximal phalanx throughout a full ROM.
  - 30% to 50%: The reduction is tenuous. The middle phalanx may or may not subluxate dorsally when the PIP joint is extended. If any subluxation is noted on the lateral radiograph with the PIP joint fully extended, flex the joint to 30 degrees and repeat the lateral radiograph.
  - If concentric reduction is achieved and the palmar fragments are sitting where they will reconstitute a palmar lip, some form of extension block treatment may be employed.
  - If the joint will not stay reduced with less than 30 degrees of flexion, the joint is unstable and must be treated accordingly.
  - Over 50%: The PIP joint is unstable, and surgical intervention usually is required to rebuild the cup-shaped geometry of the middle phalanx base and to reattach the palmar plate.
- Inspect the PA view to determine asymmetric compression of middle phalanx articular fragments leading to varus or valgus angulation.
- CT or MRI evaluation rarely is necessary.

**DIFFERENTIAL DIAGNOSIS**
- In patients with a history of recent trauma and radiographic confirmation of a large PIP palmar lip fracture associated with dorsal subluxation, the diagnosis of an unstable PIP dorsal fracture-dislocation is obvious.
- Dorsal dislocation and disruption of the middle phalanx palmar lip also may be seen in chronic PIP fracture-dislocations and occasionally in association with various forms of arthritis.

**NONOPERATIVE MANAGEMENT**
- Unstable PIP fracture-dislocations rarely can be managed nonoperatively. When over 50% of the middle phalanx articular surface is consumed by fracture, all restraints to dorsal subluxation are lost. The cup-shaped geometry of the middle phalanx base must be restored and the palmar plate reattached. Both goals can be accomplished with ostesynthesis of a single large fragment,2,3,8 palmar plate arthroplasty,1 or a hemi-hamate osteochondral autograft.5,15,16
- Stable PIP fracture-dislocations are treated nonoperatively. If the joint does not hyperextend and the lateral radiograph in full extension confirms concentric reduction, buddy tape the fingers and allow early ROM. If the joint hyperextends, some flexion must be maintained for 3 weeks while the fracture fragments consolidate enough to restore functional palmar plate continuity. Apply a dorsal blocking splint that prevents PIP hyperextension but allows full active flexion.
- Nonoperative treatment of tenuous PIP fracture-dislocations requires careful thought, patient cooperation, and meticulous follow-up.
  - The primary treatment goal is to maintain joint reduction while the middle phalanx palmar fragments consolidate and restore the cup-shaped geometry of the middle phalanx base. Joint reduction must be achievable with less than 30 degrees of flexion, and the palmar fragments must fall into a position that will restore the middle phalanx palmar lip.
  - A secondary goal is to provide immediate active ROM. Any treatment method that prevents extension past 30 degrees and allows full flexion can be employed. Options range from simple extension block splints11 or pins14 to external traction12,13 or complex frame constructions.7,10

**SURGICAL MANAGEMENT**
- Hemi-hamate osteochondral autograft is indicated for the treatment of unstable PIP fracture-dislocations. The middle phalanx dorsal cortex must be intact.
- Hemi-hamate arthroplasty is a valuable salvage procedure for treatment that has failed with traction, external fixation devices, extension block splinting, or palmar plate arthroplasty.
- Chronic PIP dorsal dislocations also are amenable to treatment with hemi-hamate autograft if enough intact cartilage remains on both sides of the joint. Undamaged cartilage must be present on the palmar 50% of the proximal phalanx head and on at least a small rim of the middle phalanx dorsal articular surface.

**FIG 4 • Unstable PIP palmar lip fracture-dislocation. Extensive damage has occurred to the palmar lip of the middle phalanx, but the dorsal cortical margin and a small amount of dorsal articular cartilage remain intact. Even slight dorsal subluxation can be detected by looking for a V-shaped gap between the middle and proximal phalanges.**
Preoperative Planning

- Review the radiographs to determine the extent of articular surface damaged by the fracture, joint stability, and the quality of the remaining articular surface.
- Patients with extensive pre-existing degenerative arthritis may be better served with a PIP arthrodensis or total joint arthroplasty than with hemi-hamate arthroplasty.
- Assess the finger for radial or ulnar deviation. If coronal plane angulation is observed, it will be necessary to level the middle phalangeal joint surface during fracture site preparation and graft placement.
- Examine the patient for a mallet finger. If the terminal extensor tendon has been damaged, plan to include a mallet splint in the postoperative regimen.

Positioning

- Position the patient supine with the arm extended onto a radiolucent hand table.
- A mini C-arm is required for the procedure.
- Either regional or general anesthesia may be used, depending on the patient’s or surgeon’s preference.
- Perioperative antibiotics are provided.
- An upper arm tourniquet is applied. This is preferred over a forearm tourniquet, which puts pressure on the flexor muscles and causes excessive finger flexion.
- If necessary, the dorsum of the hand is shaved at the fourth and fifth carpometacarpal (CMC) joints to facilitate harvesting of the graft.

Approach

- We recommend performing the PIP portion of the procedure through a Brunner incision, because this incision provides excellent visualization of the fracture, the pulley system, and the neurovascular bundles.
- The hamate graft is harvested through a transverse incision at the level of the fourth and fifth CMC joints.

FRACTURE SITE PREPARATION

- Use a lead hand to position the hand palm up with the fingers extended. It will be necessary to remove the lead hand intermittently to facilitate use of fluoroscopy.
- Make a Brunner incision from the base of the finger to the DIP flexor crease (TECH FIG 1A).
- Coagulate intervening vessels with bipolar cautery as the full-thickness flaps are elevated.
- Identify the neurovascular bundles proximally and mobilize them away from the flexor sheath throughout the length of the dissection.
- Divide Cleland’s ligaments dorsal to the neurovascular bundles. This allows full visualization of the collateral ligaments and facilitates retraction of the neurovascular bundles without excessive traction.
- Retract skin flaps with 5-0 nylon suture.
- Open the flexor tendon sheath from the distal end of the A2 pulley to the proximal edge of the A4 pulley. Start the dissection with a longitudinal incision along the edge of the flexor tendon sheath that is closest to the surgeon.
- Create a flexor tendon sheath flap by making transverse incisions at the proximal end of A4 and the distal margin of A2. Elevate the flexor tendon sheath flap away from the surgeon (TECH FIG 1B).
- Take care to prevent superficial damage to the flexor tendons while incising the flexor sheath.
- With the flexor tendons retracted away from the midline, make longitudinal incisions down the lateral margins of the palmar plate to separate the palmar plate from the accessory collateral ligaments. The distal attachment of the palmar plate will already be detached (ie, avulsed) as a result of the injury, but it still may need to be gently mobilized. Leave any remaining bone fragments attached to the distal edge of the palmar plate.
- If the fragments are large enough to accept interfragmentary screws, consider open reduction and internal fixation instead of proceeding with the hemi-hamate autograft.
- Release the collateral ligaments distally. Leave a small stump on the middle phalanx to facilitate repair at the end of the procedure.
- “Shotgun” the joint open (TECH FIG 1C).
- Retract the flexor tendons away from the midline.
- Hyperextend the PIP joint to expose the base of the middle phalanx and the head of the proximal phalanx.
- If necessary, use a Freer elevator to prevent impingement of the intact dorsal base of the middle phalanx against the head of the proximal phalanx.
- Caution: forceful hyperextension may lead to fracture of the dorsal articular fragment.
- Only if absolutely necessary, release 1 to 2 mm of the A4 pulley to facilitate adequate mobilization of the flexor tendons. The A4 pulley is essential for finger function and must not be released completely.
- Assess the damage to the articular surfaces of the middle phalanx and the head of the proximal phalanx.
- Prepare the middle phalanx to receive the autograft (see Tech Fig 1C).
- Elevate and excise impacted fragments of articular cartilage.
- Use an oscillating saw to level the surface of the bony defect and to remove sufficient bone to allow graft placement. Make the cuts parallel to the dorsal margin of the articular surface and the long axis of the phalangeal shaft. Make the height of the intact articular surfaces equal at both the radial and ulnar margins. Limit thermal osteonecrosis with liberal use of irrigation.
- The proximal to distal length of the cut usually is only about 5 to 7 mm. Take care to avoid notching the dorsal or distal portion of the cut, because this may weaken the shaft.
- Carefully measure the defect in the middle phalanx base to determine the appropriate graft size. Make notes of
A Brunner incision, as depicted in this cadaver dissection, provides excellent visualization of the neurovascular structures, the flexor tendons, and the fracture site. Creating a flexor tendon sheath flap. Elevate a flap of the flexor tendon sheath from the distal end of the A2 pulley to the proximal edge of the A4 pulley. Preserve the flap so that it may be used to cover the palmar plate and the graft during closure. “Shotgun” the joint and prepare the fracture site. The PIP joint has been hyperextended 180 degrees to expose the fracture site. Note the palmar plate (A), the collateral ligaments (B) and the fracture defect (C). The fracture defect must be prepared so that it is of equal height and thickness on the radial and ulnar sides of the middle phalanx. Measuring graft dimensions. Measure the fracture defect to determine the medial-to-lateral width (A), proximal-to-distal depth (B), and anterior-to-posterior height (C) of the needed graft. Transfer these measurements to the dorsal surface of the hamate.

- **A**: Width of the fracture defect. Measure the distance from the radial margin to the ulnar margin of the fracture defect. The graft must be centered on the central ridge of the proximal phalanx. Prepare the fracture site so that radial and ulnar extent of the fracture defect are equal.
- **B**: The proximal-to-distal size of the defect. To avoid creating an uneven joint surface that causes angulation in the coronal plane, the proximal-to-distal defect size should be equal on the radial and ulnar margins or the middle phalanx.
- **C**: Height of articular surface at the central ridge. Measure the distance from the dorsal aspect of the fracture defect to what would be the most palmar extent of the middle phalanx palm. It will be necessary to estimate this based on a lateral view of the proximal phalanx and from the preoperative radiographs (percentage of joint involvement).

Return the joint to neutral and place a moist sponge on the finger incision while the graft is harvested.

**HARVESTING THE HAMATE GRAFT**

- Identify the distal articular margin of the hamate with fluoroscopy and mark the skin with a transverse line.
- Make a transverse 2-cm incision just proximal to the articular line.
- Bluntly dissect to mobilize the subcutaneous nerves, vessels, and extensor tendons.
- Longitudinally incise the hamate-CMC joint capsule, and then subperiosteally elevate the flaps to provide adequate visualization of the articular surfaces and the dorsum of the hamate (**TECH FIG 2A**).
- The apex of the distal articular surface between the fourth and fifth metacarpal articular surfaces will become the
new central ridge of the middle phalangeal base once the
graft is transferred.

- A 12-mm segment is trimmed from the flexible plastic
  ruler that accompanies the marking pen. A fine-tipped
  marker is preferred, because it will not bleed as much on
  the bone. Less soft tissue on the dorsum of the hamate
  also helps prevent the ink from bleeding.

- Using a fine-tip marker and ruler, mark the dimensions
  of the graft on the hamate. To ensure stability of the
  CMC joints, leave at least 2 mm of the radial edge of the
  fourth metacarpal–hamate articulation and 2 mm of the
  ulnar edge of the fifth metacarpal–hamate surface.

- Harvest a graft that is of adequate height to fill the mid-
  dle phalanx defect, but do not fracture the dorsal cortex
  of the hamate.

- Use an oscillating saw to make the cuts in the hamate
  very carefully. Alternatively, define the graft dimensions
  with a series of holes made with a K-wire, and then make
  the cuts with an osteotome (TECH FIG 2B).

  - To ensure that the graft is not too small, make the os-
    teotomies on the outside of the measured lines.

  - Protect the articular surfaces at the base of the fourth
    and fifth metacarpals with a Freer elevator.

- Estimate the depth of the cuts by marking the saw
  blade or osteotome and measuring how deeply it
  penetrates the hamate.

- Create a notch in the hamate cortex proximal to the
  most proximal cut using a rongeur or by making an an-
  gled cut from proximal to distal with the saw. The notch
  is necessary to allow the final coronal cut to be made
  with a curved osteotome (TECH FIG 2C).

- Using extreme care, make the final cut in the hamate
  and complete the graft harvest.

- Gently advance an angled osteotome from proximal
  to distal, aiming to complete the cut through the
  distal hamate articular surface at the predetermined
  depth.

- Protect the metacarpal articular surfaces with an
  elevator.

- Take slightly more bone than needed. It is easier to
  trim excess than to deal with a graft that is too small.

- Keep the graft protected in a moist saline sponge during
  wound closure.

- After the wound is irrigated, securely close the capsule
  over the fourth and fifth CMC joints with a 4-0 braided,
  nonabsorbable suture. Close the skin in layers.

**TECH FIG 2** • A. Exposure of the fourth and fifth metacarpal–hamate joints. Through a transverse skin incision and
longitudinal capsular incision, as demonstrated in this cadaver dissection, expose the distal hamate articular surface
and mark the graft dimensions. B. Use an oscillating saw or, as depicted in this cadaver dissection, K-wire holes and
an osteotome, to make the cortical cuts in the dorsal surface of the hamate. C. Making the final hamate cut. A
curved osteotome is used to make the final coronal cut that separates the graft from the hamate. It is necessary to
make a back cut in the proximal hamate cortex to allow the osteotome to approach the cut at the proper angle.
(A–C: wrist is to the left and fingers are to the right.)

**GRAFT FIXATION**

- “Shotgun” the PIP joint open to expose the fracture site.

- Carefully trim the graft with a rongeur or oscillating saw
  so that it fits precisely into the prepared defect at the
  middle phalanx base.

- It is very important to tailor the graft so that it restores
  the cup-shaped contour of the middle phalanx base.
  Joint stability will be restored only by restoring a concave
  middle phalanx articular surface that includes a stout
  palmar lip (TECH FIG 3A–C).

- A common error is to set the graft at an angle that cre-
  ates a dorsal–proximal to palmar–distal slope. This car-
  pentry error fails to restore joint stability and encourages
  the dorsal migration of the middle phalanx on the prox-
  imal phalangeal head (TECH FIG 3D,E).

- Temporarily fix the graft with a centrally placed 0.028-
  inch K-wire.

- Lag 1.0- or 1.3-mm screws on either side of the provi-
  sional K-wire.

- If the graft is large enough, augment the fixation with a
  third screw placed into the hole that remains once the K-
  wire is removed (TECH FIG 3F).

- Relocate the middle phalanx on the proximal phalanx,
  and assess the joint for stability and alignment.

- The joint should remain in position throughout a full
  ROM. Dorsal subluxation suggests that the graft has
  been set too flat, failing to restore a concave articular
  surface.
- The joint should exhibit neutral alignment. Varus or valgus angulation suggests that the graft has not been set perpendicular to the long axis of the middle phalanx.
- Assess screw length and graft placement with fluoroscopy. The hamate articular cartilage is thicker than the middle phalanx cartilage. This discrepancy creates the illusion that the hamate has not been set flush with the middle phalanx, but a lack of step-off already has been confirmed by direct inspection of the joint surface (TECH FIG 3G).
- Often, the distal edge of the graft protrudes beyond the volar cortex of the middle phalanx fracture defect. Shave the graft edge to smooth the transition from graft to middle phalanx.

**TECH FIG 3**  
**A.** This lateral preoperative radiograph demonstrates a chronic, unstable PIP fracture-dislocation in a 19-year-old woman. Joint flexion occurs as the middle phalanx hinges at the palmar fracture margin and the proximal phalanx falls into the fracture defect.  
**B.** The graft has been inset to recreate a middle phalanx articular surface that is concave and matches the curvature of the proximal phalanx head.  
**C.** The graft must be contoured and set into the middle phalanx in a manner that restores the cup-shaped geometry of the middle phalanx base. Failure to restore a concave joint surface creates a flat surface (D) that encourages dorsal subluxation of the middle phalanx (E).  
**F.** Relocation of the joint. The joint has been relocated and stability confirmed by taking the joint through a full range of motion and ensuring that subluxation does not occur. Note how nicely the hamate graft recreates the palmar lip of the middle phalanx.  
**G.** Lateral radiograph of the graft. The lateral radiograph gives the false appearance that a step-off exists between the graft and the remaining middle phalangeal articular cartilage.

**CLOSURE**
- Repair the palmar plate and palmar margin of the middle phalanx. It may be necessary to secure the sutures through small drill holes.
- Repair the collateral ligaments to the stumps that were left on the middle phalanx during the approach.
- Interpose the flexor tendon sheath flap under the flexor tendons and over the PIP joint.
- Obtain hemostasis after the tourniquet is deflated.
- Close the skin.
- Apply a bulky dressing and splint holding the PIP joint in slight flexion.

POSTOPERATIVE CARE

- The goal of hemi-hamate arthroplasty is to operatively restore osseous PIP stability. Assuming that this goal has been attained and confirmed with lateral radiographs in extension that demonstrate concentric reduction, ROM is begun within the first week.
- Apply a postoperative dressing that controls edema and supports the PIP joint in a slightly flexed posture.
- Within the first week, begin active PIP flexion within an extension block splint that prevents extension past 20 degrees. The therapists may choose to fabricate a hand-based dorsal extension block splint if swelling is excessive, but a figure-eight splint is preferable.
- Encourage full active and passive motion at the MP and DIP. If a concomitant mallet injury is being treated, splint the DIP joint in full extension, but do not inhibit motion at the other joints.
- If the radiographs at 3 weeks show concentric joint reduction and solid graft fixation, begin gentle active assisted ROM.
- At 6 weeks postoperatively, again confirm solid graft fixation and concentric joint reduction radiographically, discontinue figure-eight splinting, and then begin passive ROM into flexion and correction of an excessive PIP flexion contracture with dynamic extension splinting.

OUTCOMES

- We have previously reported the outcome of 13 patients with unstable PIP dorsal fracture-dislocations treated with hemi-hamate autograft. The original results were extremely encouraging, and our long-term results have not dampened our enthusiasm for the procedure.
- Eleven of the 13 patients returned for examination and final radiographs, one patient’s results were assessed by chart review, and one patient was lost to follow-up.
- Pain
  - Pain in the injured digit was minimal, and was rated at an average of 1.3. Two patients had regular pain, and six noted occasional aching discomfort.
  - Graft donor site aching discomfort was noted only rarely in three patients. The remaining patients were asymptomatic.
- Motion
  - ROM in the PIP averaged 85 degrees (range 65 degrees to 100 degrees).
  - Most patients had a slight PIP flexion contracture that averaged 9 degrees (range 0 degrees to 25 degrees).
  - The ROM of the MP joint averaged 90 degrees (range 75 degrees to 100 degrees), and the motion at the DIP joint averaged 60 degrees (range 35 degrees to 80 degrees).
- Stability
  - Two of 12 patients demonstrated slight dorsal subluxation on the lateral radiograph, but neither patient had symptoms or functional problems.
  - One of the two patients with dorsal subluxation also demonstrated 20 degrees of ulnar instability, but she was not symptomatic from this abnormality.
- Radiographs
  - An apparent articular surface step-off between the graft and native middle phalanx cartilage commonly is observed. This phenomenon is caused by the greater thickness of the cartilage on the graft compared to the middle phalanx cartilage.
  - All grafts united, as demonstrated by bridging trabeculae.
  - None of the grafts demonstrated sclerosis that suggested osteonecrosis.
  - Graft reabsorption was not observed.
- Long-term outcome
  - Our experience with PIP hemi-hamate arthroplasty is too short to definitively determine the ultimate fate of the transferred articular cartilage.
  - Early results do not suggest that autograft will lead to excessive rates of cartilage degeneration causing symptomatic posttraumatic changes.

COMPLICATIONS

- The complication rate in our original patient cohort was low. No patients developed infection, and no patients required subsequent surgery.
- Dorsal subluxation was noted in 2 of 12 patients. One was believed to have been caused by an incompetent palmar plate. The other case of dorsal subluxation was attributed to a graft that was not appropriately contoured to restore the cup-shaped geometry of the middle phalanx base.
- Donor site morbidity has not occurred. To date, no patient has had instability or significant pain at the fourth or fifth CMC joints.
- We have maintained an acceptably low complication rate in our subsequent experience.

REFERENCES

DEFINITION
- Injuries about the distal interphalangeal joint (DIP) consist of avulsion injuries of the terminal extensor tendon or the flexor digitorum profundus (FDP) tendon, or isolated dislocations of the DIP joint.
- Isolated dislocations of the DIP joint are rare injuries in which the distal phalanx is dislocated either dorsal or volar relative to the middle phalanx.
- A “bony” mallet finger (ie, mallet fracture) is an intra-articular bony avulsion at the insertion site of the terminal extensor tendon on the dorsal base of the distal phalanx that results in inability to actively extend the DIP joint.
- A “non-bony” mallet finger is an injury to the extensor mechanism at or near the insertion onto the distal phalanx that typically results in inability to actively extend the DIP joint.
- “Jersey finger” is an avulsion of the FDP tendon, with or without its bony attachment, from the volar base of the distal phalanx. It typically results in inability to actively flex the DIP joint.

ANATOMY
- The DIP joint is stabilized by the radial and ulnar collateral ligaments, the volar plate, and the firm insertions of the FDP and terminal tendons of the extensor mechanism.
- The extensor mechanism terminates with the confluence of the lateral bands into a single terminal tendon, which inserts on the dorsal base of the distal phalanx. The terminal tendon is a strong, flat, thin segment that averages 10.1 mm in length and 5.6 mm in width.
- The terminal tendon insertion, on average, is 1.4 mm proximal to the germinal matrix of the fingernail.
- The volar surface of the terminal tendon usually is adherent to the dorsal capsule of the DIP joint.
- The FDP tendon inserts on the volar surface of the base of the distal phalanx. It is surrounded by the flexor tendon sheath. The A4, A5, and C3 pulleys secure the FDP tendon around the level of the DIP joint.
- The vinculum longus profundus and vinculum brevis profundus are thin mesenteries providing vascular supply to the distal portion of the FDP tendon. They also provide a weak attachment of the FDP tendon to the flexor tendon sheath.

PATHOGENESIS
- Mallet finger injuries are the result of a disruption to the extensor mechanism at or near the insertion to the base of the distal phalanx. Such disruptions can occur as a result of a laceration or a sudden flexion force to an extended DIP joint. The disruption of the extensor mechanism leaves the pull of the FDP unopposed, leaving the DIP joint in a flexed posture.
- Dislocations of the DIP joint are rare due to the inherent stability provided by the collateral ligaments, the volar plate, and the flexor and extensor tendon insertions. However, when a dislocation does occur, the distal end of the middle phalanx usually “buttonholes” through these structures, making reduction more difficult.
- “Jersey finger” injuries occur as a result of disruption to the FDP, from either a laceration or a sudden extension force applied to a flexed DIP joint, causing an eccentric contraction. The disruption of the FDP tendon leaves the pull of the extensor mechanism unopposed, resulting in an extended posture of the DIP joint.

NATURAL HISTORY
- Mallet finger injuries can occur in any finger, but most commonly are seen in the three most ulnar digits.
- Left untreated, a mallet finger injury can progress to a secondary “swan neck” deformity.
- With the disruption of the extensor mechanism at the DIP joint, the pull of the lateral bands adds to the extension force of the central slip at the PIP joint, thereby creating an imbalance in forces at the PIP joint and a hyperextension deformity at that joint.
- Despite treatment, residual deformity, usually in the form of a dorsal prominence, can be seen in up to 80% of cases.
- About 75% of cases of FDP avulsions involve the ring finger. Although some researchers hypothesize that this happens because the ring finger protrudes the farthest when the hand is held in a flexed position, this theory has never been proven.
- Leddy and Packard proposed the classification system that is still widely used today for FDP avulsion injuries, based on the level of retraction of the tendon. Other authors since have made modifications, including the addition of a fourth type of injury.
- Type I FDP avulsions retract into the palm, thereby disrupting the vincular system and leading to poor blood supply. Surgery should be performed within 7 to 10 days.
- Type II injuries retract to the level of the PIP joint or distal A2 pulley. An associated small bony fleck often is seen on the lateral radiograph. Because the proximal blood supply is preserved through the long vincula, these injuries can be successfully treated as late as 6 weeks from the time of injury.
- Type III injuries usually are associated with a bony avulsion, and as a result, do not retract proximal to the A4 pulley. These injuries are treated as bony injuries with open reduction and internal fixation and can be treated late if required.
- Type IV injuries are bony avulsion injuries in which the tendon also has separated from the avulsed bony fragment. Time to treatment depends on the level of tendon retraction.
PATIENT HISTORY AND PHYSICAL FINDINGS
- As with all hand injuries, patients should be questioned about their hand dominance and occupational requirements so the surgeon can better understand individual needs and goals.
- The following examinations should be performed to determine possible injuries:
  - FDP function
    - Inability to flex at the DIP joint implies disruption of the FDP tendon.
    - Limited, weak, or painful flexion may indicate a partial injury or a complete disruption with intact vinculae or pseudotendon.
  - DIP joint extensor mechanism function
    - Inability to extend at the DIP joint implies disruption of the terminal extensor tendon. Weak extension implies a partial or less severe injury. Loss of passive extension indicates a possible fracture or dislocation.
  - Axial injuries to an extended DIP joint often are the culprit in mallet finger injuries.
    - The history often reveals an axial blow to the fingertip, such as when catching a ball.
    - The patient will be unable to actively extend at the DIP joint.
  - “Jersey finger” injuries often are the result of a sudden extension force on a flexed DIP joint, such as when grabbing for another player’s shirt while playing football.
    - These patients will be unable to actively flex through the DIP joint.
    - Active PIP flexion will be present but may be moderately diminished due to pain or stiffness.
  - Most dislocations of the DIP joint are the result of sporting injuries.7,8

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs of the affected hand (PA, lateral, and oblique) and dedicated views of the affected finger (PA, lateral, and oblique) should be obtained, and usually are sufficient for making the diagnosis in association with a thorough clinical examination.
  - Mallet finger injuries can be associated with a bony avulsion. Any joint subluxation should be noted, and the size of the avulsed fragment should be estimated (FIG 1).
  - In FDP avulsion injuries, the location of the retracted flexor tendon often can be appreciated by finding a bony fragment on the lateral radiograph of the affected digit (FIG 2A).

FIG 1 • Lateral radiographs usually are the most helpful in identifying a mallet fracture. Note that in this image, the avulsed fragment includes more than 50% of the articular surface. There is no significant volar subluxation in this case.

FIG 2 • A. Flexor digitorum profundus (FDP) avulsion in which a bony fragment has been caught up at the A4 pulley. B. Lateral radiograph of a finger demonstrates chronic dorsal dislocation of the DIP joint, with associated arthrosis. C. Axial cut MRI at the level of the proximal phalanx shows both FDP and flexor digitorum superficialis (FDS) tendons are present. D. At the level of the middle phalanx, only the FDS tendon can be seen. (B–D: Copyright Thomas R. Hunt III, MD.)
Ultrasound sometimes can be helpful in determining continuity of the flexor tendon or identifying the location of the retracted proximal flexor tendon stump.

MRI also is valuable in determining flexor tendon continuity and level of tendon retraction (FIG 2C,D).

**DIFFERENTIAL DIAGNOSIS**

- Osteoarthritis
- Inflammatory arthropathy
- FDP rupture
- FDP laceration
- Terminal extensor tendon rupture (mallet finger)
- Mallet fracture

**NONOPERATIVE MANAGEMENT**

- For tendinous mallet fingers and mallet fractures involving less than one third of the articular surface and without joint subluxation, a variety of splints are available.
- We prefer immobilizing the DIP joint with a prefabricated polyethylene extension splint.
- Casting of the DIP joint also has been described.
- Full-time splinting in extension is recommended for 6 weeks, followed by 6 weeks of part-time splinting. During this second 6 weeks, we advise our patients to wear the splint for any heavy activity and at night, and we emphasize the inclusion of gentle DIP joint flexion, not exceeding 20 degrees in the first 2 weeks, and then gradually increasing to full flexion over the course of 6 weeks. If any loss of extension is experienced during this time, we advise the patient to return immediately to full-time splinting and to follow up in our clinic.
- Nonoperative treatment of acute FDP lacerations or ruptures at the DIP joint is not recommended unless the patient is unwilling to comply with postoperative splinting or rehabilitation.
- In subacute and chronic FDP lacerations or avulsions, the functional necessity of DIP joint motion should be carefully considered, and nonoperative treatment should be considered.
- Literature directing treatment in cases of delayed diagnosis is scarce.
- If the patient does not have any functional limitations as a result of the injury, we prefer to defer surgical management.
- If the patient is troubled by a tender mass in the palm but the hand is functional, we recommend excision of the tendon alone.
- Instability and weakness of pinch can become problematic. In such cases, we recommend tenodesis or arthrodesis.
- Only if the function of the DIP is crucial to the performance of daily activities do we recommend a staged reconstruction of the flexor tendon.

Closed reduction of isolated DIP joint dislocations can be attempted under a digital block.

- For dorsal dislocations, the FDP tendon or the volar plate can be interposed, blocking the reduction as the head of the middle phalanx buttonholes through the interval between the FDP tendon and the collateral ligament.8
- For dorsal dislocations, gentle traction and extension through the DIP joint can assist in reducing the interposed volar plate.
- In volar dislocations, the head of the middle phalanx can buttonhole through the interval between the terminal extensor tendon and the collateral ligament.7
- For volar dislocations, gentle traction can be used while guiding the condyle of the middle phalanx back through the interval between the terminal extensor tendon and the collateral ligament.
- In either case, a gentle reduction maneuver should be attempted, keeping in mind the structures that are likely to be interposed in the joint. Care should be taken to avoid excessive traction, which may tighten the tendon and ligament, preventing reduction.

**SURGICAL MANAGEMENT**

- Surgical treatment of mallet fractures is reserved for those fractures associated with joint subluxation.
- Operative treatment is recommended for all acute flexor tendon avulsions at the DIP joint and selected subacute or chronic cases.
- The level of retraction of the tendon on the flexor side determines the urgency with which the injury needs to be addressed (see Table 1). Although Type I and II injuries can be treated up to 6 weeks with good results, we recommend treating these injuries sooner when possible to optimize recovery and function.
- For isolated dislocations of the DIP joint, surgical management is indicated in those cases where closed reduction is unsuccessful. Generally, no surgical stabilization is required.

**Preoperative Planning**

- All images should be reviewed.
- For isolated dislocations, a review of the relevant anatomy, including the volar plate, flexor and extensor tendons, and collateral ligaments, is essential to understand which structures might be interposed in the DIP joint.

**Positioning**

- The patient is placed supine on the operating room table with the affected arm outstretched on an arm board. When

treated a flexor tendon injury, a flexible aluminum hand-holder can be useful for positioning the hand during the exploration.

- A well-padded tourniquet is placed high on the arm.

**Approach**

- **Mallet fingers**
  - We prefer to treat mallet fingers with percutaneous techniques.
  - Percutaneous treatment is more likely to succeed if the injury is treated within the first 3 to 5 days after the injury, although we have successfully treated cases as late as 6 weeks.
  - If open treatment is to be attempted, a variety of incisions can be used, including straight longitudinal, lazy-S type, H-type, and Bruner incisions. Meticulous soft tissue handling is vital to minimize trauma to the skin. Great care must be taken to avoid injury to the germinal matrix proximal to the nail fold.
  - “Jersey fingers”
  - A volar Bruner incision is used and is extended proximal enough to identify or retrieve the proximal tendon stump.
  - In type I injuries, one oblique limb of the Bruner incision over the A1 pulley region often is used to retrieve the retracted tendon.
  - Care is taken to preserve the A2 and A4 pulleys.
  - For open reduction of isolated DIP dislocations, the approach is dictated by the direction of the dislocation.
  - Dorsal dislocations are approached volarly, and volar dislocations are approached dorsally.

**TREATMENT OF MALLET FINGERS**

**Extension-Block Pinning of Mallet Fractures**

- The DIP joint is flexed initially, pulling the avulsed fragment volarly.
- A dorsal block pin is inserted obliquely from distal to proximal under fluoroscopy. A 0.045-inch K-wire usually is ideal, although 0.035-inch K-wires are sometimes preferred if the finger is small.
- The pin should enter at the dorsal edge of the articular surface of the middle phalanx, and bicortical purchase should be obtained (TECH FIG 1A,B). The dorsal blocking pin should not actually engage the fracture fragment, because this may result in comminution of the bone.
- Anteroposterior and lateral views on fluoroscopy should be obtained to ensure appropriate positioning (TECH FIG 1C).
- The distal phalanx is then extended, reducing and compressing the fracture.
- A second K-wire is inserted in a retrograde manner from the distal tip of the distal phalanx to the level of the DIP joint (TECH FIG 1D).
- While holding the digit extended with the fracture and DIP joint reduced, the second smooth K-wire is advanced retrograde across the DIP joint into the middle phalanx (TECH FIG 1E,F).
- The K-wires are cut, and protective plastic caps are placed over the exposed ends.
- The finger is then placed in a protective dressing.

**TECH FIG 1**

**A** With the DIP joint flexed, a K-wire is inserted at the dorsal edge of the articular surface of the middle phalanx. **B.** Bicortical purchase is obtained. **C.** PA fluoroscopic image confirms good bony purchase in both the dorsal and volar phalanx. **D.** With the DIP joint extended, a retrograde K-wire is introduced through the tip of the distal phalanx. **E.** Once reduction is confirmed, this retrograde pin is advanced into the middle phalanx. **F.** A final PA image confirms good placement of pins.
Pinning of Non-Bony Mallet Fingers
- For patients whose compliance is in doubt, or to assist with occupational requirements, a single 0.045- or 0.062-inch K-wire can be inserted in a retrograde manner through an extended DIP joint.
- The pin can be left either protruding through the skin and covered with a pin cap, or under the skin.

Pull-Through Button Technique for Flexor Digitorum Profundus Avulsions
- The fingers are held in an extended position using an aluminum hand.
- The volar surface of the injured finger is exposed through a Bruner incision, and the edges of the avulsed tendon are identified (TECH FIG 2A).
- The proximal segment of the tendon is retrieved, pulled out to length, and secured using a small-gauge needle directed transversely across the tendon (TECH FIG 2B).
- Using a 2-0 monofilament nonabsorbable suture (or other permanent suture appropriate for tendon repair), the proximal segment of the avulsed tendon is captured using a Krakow or Bunnell suture technique (TECH FIG 2C).
- The proximal segment of tendon is then threaded through the flexor pulley system.
- The volar base of the distal phalanx is prepared with a rongeur to expose bleeding bone.
- Two straight Keith needles are introduced into the volar wound and, using a wire driver, driven from the volar base of the distal phalanx, through the nailbed, and exiting through the center of the fingernail on the dorsal side (TECH FIG 2D,E).
- A small square of sterile felt and a plastic sterile button are placed over the exposed tips of the Keith needles (TECH FIG 2F).
- The two free ends of suture are threaded through the eyelets of the Keith needles, and the needles are advanced through the nailbed, felt, and button.
- The distal end of the avulsed tendon is pulled into its prepared footprint at the volar base of the distal phalanx, and the suture is then carefully tied over the button (TECH FIG 2G,H).
- Additional fixation is obtained by securing the tendon to tendon remnants at the insertion site.
- As an alternative to tying over the nail and a button, the Keith needles may be advanced through the proximal portion of the distal phalanx, avoiding the germinal matrix. A 3-mm transverse incision is then made over the exiting Keith needles, and the suture is tied down on bone.
- The wound is closed in standard fashion, and the hand is secured in a dorsal extension blocking splint (TECH FIG 2I).

Suture Anchor Technique for Flexor Digitorum Profundus Avulsions
- The approach, identification, and suture of the avulsed profundus tendon are the same as in the pull-through button technique.
- Two small suture anchors are introduced into the volar base of the distal phalanx in a trajectory from proximal-volar to distal-dorsal, or, as recently described by McAllister et al., may be placed in a distal-volar to proximal-dorsal trajectory.

TECH FIG 2 • A. A volar Bruner incision is planned. B. The avulsed tendon is identified and held in the wound with a small-gauge needle. C. The avulsed tendon is captured with a Krakow technique. D. Keith needles are advanced through the volar wound to exit in the center of the fingernail. (continued)
direction, taking special care not to violate the dorsal cortex. This placement ensures maximum bony purchase in the thickest portion of the distal phalanx and ensures maximum pullout strength.

- Fluoroscopic imaging can be used to ensure proper anchor placement and document that the suture anchors have not violated the dorsal cortex or the joint.
- A modified Kessler pattern of suturing can then be used to secure the FDP tendon in place at the base of the distal phalanx.
- The wound is closed and the splint applied in the manner described.

**Treatment Technique for Flexor Digitorum Profundus Disruption With Bony Avulsion**

- If the avulsed fragment is large enough, some authors recommend open reduction and internal fixation using small screws or wires.
- It is recommended that the fragment have a diameter at least 2½ times the diameter of the screw to avoid comminution of the bony fragment.\(^5\)
- Intraoperative radiographs are imperative to confirm reduction.

**TECH FIG 2 • (continued)**

**E.** A side view shows the Keith needles exiting through the fingernail. **F.** Sterile felt and a plastic button are threaded over the needles. **G.** The finger is flexed down, and the sutures are pulled through. **H.** The suture is securely tied over the button. **I.** The patient is immobilized initially in an extension block splint.
PEAKS AND PITFALLS

| Prevent proximal pin migration in nonbony mallet fingers | For cases in which we bury the pin, we prefer to make a small 90-degree bend in the distal end of the wire to prevent proximal migration of the pin into the phalanges. |
| Tendon retrieval in FDP avulsions | It is helpful to use a "milking" technique from proximal to distal in the forearm and palm, with the wrist in a flexed position, to deliver the proximal end of the tendon. Doing so can often decrease the length of the incision that is required for the repair. |
| Skin irritation with use of button | It is recommended to place a small piece of felt between the patient’s nail and the button to decrease irritation (see Tech Fig 2F,G). |
| PIP flexion contracture | Delayed treatment of a type I FDP avulsion can result in a PIP flexion contracture. If nearly full passive joint extension is not obtainable following tendon reinsertion, the repair should be abandoned. |
| Extension block pinning | Full DIP extension is not required to achieve reduction of the fracture. Avoid multiple attempts at K-wire placement. Avoid forced extension of the DIP joint, which may result in fracture at the entrance site of the dorsal block K-wire. Early treatment is easier and more effective. |

POSTOPERATIVE CARE

- Mallet fractures
  - The patient is allowed nearly full activity immediately postoperatively, including PIP joint and MCP joint motion.
  - An antibiotic ointment may be applied to the pin sites twice daily.
  - The patient should be counseled thoroughly on keeping pin sites clean.
  - The patient is seen for follow-up around postoperative day 10, and as needed for 4 weeks.
  - Pins are removed in the office setting when there is no tenderness to palpation at the fracture site and there is evidence of bridging trapezialis at the fracture site (usually about 4 to 5 weeks).

- FDP avulsions/lacerations
  - The patient is evaluated 3 to 5 days postoperatively, and if a strong repair has been accomplished and the patient is deemed compliant, a forearm-based dorsal extension block splint is fitted and the patient is enrolled into a directed hand therapy rehabilitation protocol with immediate edema control.
  - In the compliant patient, place-and-hold exercises, initially in the splint and then with the wrist in slight extension, are started between postoperative days 5 and 7.
  - Further progression is based on the protocol described by Cannon and Strickland, and typically includes tendon glides and wrist tenodesis activities at 5 weeks, and progressive strengthening at 7 to 8 weeks.

OUTCOMES

- For extension block pinning of mallet fractures, one study by the primary author reported average time to bony union of 35 days.
  - An average follow-up time of 74 weeks, range of motion averaged 4 to 78 degrees. For isolated dislocations of the DIP joint, case studies suggest that active range of motion at the DIP joint from 0 to 65 degrees is regained by 4 to 12 months postreduction. Most patients with FDP avulsions treated acutely are able to work between 8 and 18 weeks after the surgery, with some studies suggesting that an earlier return to work is seen with a suture anchor repair.
  - An 8- to 10-degree flexion contracture and a similar lack of terminal flexion at the DIP joint often are encountered.

COMPLICATIONS

- Pin tract infection
- Migration of pins
- Loss of reduction
- Nail deformity
- Dorsal skin necrosis from splinting
- Joint stiffness
- Loss of grip strength
- Tendon adherence
- Tendon rupture

REFERENCES

DEFINITION
- **Malunion** results when a fracture fragment heals in incorrect anatomic alignment.

ANATOMY
- Metacarpals and phalanges are tubular structures with a smooth dorsal surface covered by the extensor tendon and its expansions.
- Metacarpals are triangular in cross section. The medial and lateral surfaces meet at the volar ridge, providing attachment to the intermetacarpal ligaments proximally and distally help splint fractured bones, making functionally significant malunions of the ring and small metacarpals less common.
- Phalanges are bean-shaped in cross section. The volar aspects of the proximal and middle phalanges are in intimate relation to the flexor digitorum profundus (FDP) and superficialis (FDS) tendons, particularly in the region of the annular pulleys (FIG 1).
  - As a result, the tendons are vulnerable to damage from drills and screws used in a dorsovolar direction. This problem is especially significant in the region of the annular pulleys, where the tendons are strapped against the volar cortex, rendering them vulnerable to damage.

PATHOGENESIS
- Malunions most often occur secondary to lack of treatment or inadequate nonoperative care.
  - Malunion following internal fixation is uncommon, but when present usually results from inadequate stability or poor patient compliance.
  - Extra-articular malunions (EAM) often are multiplanar, but usually there is one major component to the deformity that causes the functional deficit.
  - The more proximal the malunion, the greater the deformity.
  - Just 1 degree of rotation at the fracture site may translate to 5 degrees at the finger tip.
  - 5 degrees of fracture malrotation can cause 1.5 cm of digital overlap when the fingers are flexed.
  - Soft tissue pathology such as neurovascular deficits, trophic changes, joint contractures, and tendon adhesions can coexist.
  - Results of corrective osteotomy are significantly poorer in the presence of such complicating factors.

NATURAL HISTORY
- Significant EAM can cause crossing or scissoring of fingers, pain due to distortion of joints, disturbance of muscle/tendon balance, and reduction of grip strength.
- EAMs associated with shortening can lead to an extension lag proportional to the degree of shortening. The effect is more pronounced in proximal phalanges compared to metacarpals.
- Intra-articular malunion (IAM) with a significant step (0.5 mm) or gap (1 mm) may cause joint surface incongruity, synovitis, capsular loosening or stiffness, and, ultimately, painful posttraumatic arthrosis.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The value of a good history and physical examination cannot be overemphasized. The decision as to whether surgical treatment is to be offered depends almost entirely on a history suggestive of a significant functional impairment or pain.
  - Injury specifics
    - The original injury and method(s) of treatment
    - Location
      - Phalanx versus metacarpal
      - Extra-articular versus intra-articular versus combined deformities
    - History of complicating factors, eg, infection and chronic mediated pain syndrome
    - Duration of malunion, particularly relevant in deciding surgical strategy (reducing the fracture vs osteotomy)
    - Associated injuries such as soft tissue defects and neurovascular injuries
  - Specific patient characteristics
    - Skeletal maturity
    - Hand dominance
    - Degree of deformity, swelling, stiffness, weakness of grip, and pain
    - Occupation and avocational pursuits as well as patient expectations and goals
    - Ability to cooperate with postoperative therapy regimen

FIG 1 Structures on the volar aspect of the metacarpals and phalanges. The flexor digitorum profundus (FDP) and flexor digitorum superficialis (FDS) tendons are intimately associated with the volar aspect of the phalanges and, to a lesser extent, the metacarpals. This dissected specimen also depicts the vinculae (V) and the A-1 and A-2 annular pulleys. (From http://www.turntillburn.ch.)
IMAGING AND OTHER DIAGNOSTIC STUDIES

- Good-quality radiographs taken in three precise planes (anteroposterior, lateral, and oblique) are sufficient for simple EAMs.
- Radiographs of the opposite hand are helpful in preoperative planning for complex EAMs.
- IAMs and combined malunions may require CT scans with three-dimensional reconstruction.

DIFFERENTIAL DIAGNOSIS

- Fibrous nonunion
- Nonunion with soft tissue contracture
- Sequelae of epiphyseal injury or growth arrest
- Erosive arthritis

NONOPERATIVE MANAGEMENT

- Hand therapy is directed toward maximizing the range of motion (ROM) of the digits, promoting optimal tendon excursion, and improving the grip strength.
- In less dramatic deformities, physical therapy is the first line treatment. Many patients will gain enough functional improvement that they decide to “live with” the deformity.
- Initiation of therapy allows the opportunity to assess the patient’s personality with respect to compliance and realistic expectations.

SURGICAL MANAGEMENT

Timing of Correction

- Treatment of nascent malunions results in improved outcomes.
- IAMs must be corrected as soon as possible if there is a significant articular step and no overwhelming technical difficulties are anticipated.1
- In the case of an EAM, after 6 to 8 weeks from the injury, a “wait and watch” policy before osteotomy is advisable to see whether the malunion causes significant functional or cosmetic problems.

Location of Correction

- At or near the apex of the deformity for angular and complex EAMs
- In the proximal metaphysis of the malunited bone for rotational EAMs. With improved osteotomy techniques and fixation implants, a proximal metacarpal osteotomy is no longer recommended for treatment of a P-1 rotational malunion.5

Type of Osteotomy

- For angular EAMs, a closing wedge osteotomy is preferable, especially in the setting of intrinsic tightness. This approach is most commonly used for dorsal apex metacarpal malunions. An opening wedge osteotomy is best in the setting of an extension lag and pseudoclaw deformity, which are more commonly seen in apex volar phalangeal malunions. An incomplete osteotomy may be used for either of these cases.
- For rotational and combined rotational/angular EAM correction, a complete osteotomy is required.4 Metacarpal neck EAM from a previous Boxer’s fracture without significant shortening may be corrected with a pivot osteotomy.5
- Condylar advancement osteotomy4 is suitable for IAM correction in many cases.

Severity of Deformity

- Malunion does not always mandate a corrective osteotomy. Patients possess a significant capacity to adapt to minor deformities. For instance, slight overlap of adjacent digits due to rotational malunion may be unsettling and unsightly, but it is consistent with good hand function.3 Similarly, a proximal diaphyseal malunion of the small-finger metacarpal can contribute to tendon imbalance and flexion contracture of the proximal interphalangeal joint, but the hand may function effectively.7
- Multifragment IAMs and those with established posttraumatic arthritis are best treated by arthrodesis or arthroplasty rather than repositioning osteotomy.

Preoperative Planning

- In addition to precise evaluation of the bony deformity, careful assessment of the soft tissue envelope, gliding capacity of the flexor and extensor tendons, joint mobility, and neurovascular status is critical.
- Plan for adjunct procedures (eg, tenolysis, capsulotomy) that may be required.
- Determine the optimal location for placement of internal fixation.
- Decide on opening or closing wedge osteotomy. In the presence of an extension lag, an opening wedge is preferred, whereas, in the presence of intrinsic tightness, a closing wedge is preferred.
- Provide for soft tissue coverage as needed.
- Preoperative templates are created for bony correction.
- The proximal and distal fragments are each outlined then superimposed over an outline of the contralateral uninjured bone.
- The type and location of the osteotomy, the size of the bone graft needed (in the case of an opening wedge osteotomy), as well as the method of fixation are determined.
- In the rare cases requiring large corticocancellous interposition grafts, iliac crest bone graft harvest is planned.

Positioning

- The patient is positioned supine with the shoulder abducted to 90 degrees, elbow extended, and the extremity on an arm table.
- Place a proximal arm, non-sterile tourniquet.
- If required, prep for ipsilateral iliac crest graft harvest.
- Perform an examination under anesthesia to determine joint ROM and stability.

Approach

- A dorsal approach through a dorsal skin incision in the intermetacarpal space is used for the second through fourth metacarpals (FIG 2A).
- A midaxial approach through a midaxial skin incision at the junction of the wrinkled dorsal and smooth volar skin is used for the fifth metacarpal and the proximal and middle phalanges (FIG 2B).
- Coronal plane correction is best accomplished with a lateral buttress plate placed over the bone graft (FIG 2C,D).
- Dorsal plates should be avoided in the phalanges due to extensor tendon adhesions and resulting loss of motion.
**INCOMPLETE OSTEOTOMY FOR ANGULAR CORRECTION**

**Metacarpal Closing Wedge Osteotomy**

- Make a dorsal incision in the interval between either the index–long or ring–small metacarpals, depending on the bone to be treated (see Fig 2A).
  - An incision at the junction of the glabrous skin often is appropriate for small metacarpal malunion correction (see Fig 2B).
- Retract the extensor tendon to expose the metacarpal (TECH FIG 1A).
- Make a dorsolateral incision through the metacarpal's periosteum, and carefully free this layer from the dorsum of the metacarpal with a no. 15 blade (TECH FIG 1B).
  - At completion of the operation, this periosteal and muscle layer will be closed, serving to protect the extensor tendons from the underlying internal fixation.
- Subperiosteally expose the circumference of the bone at the planned osteotomy site.
- Pass two small Hohmann retractors, one radially and one ulnarily, to protect the tendons and neurovascular structures.
  - Take care not to put undue tension on these structures.
- Precisely identify the apex of the deformity by determining the intersection between the true anatomic axis of both the proximal and distal fragments.
  - Place a 0.35-mm K-wire parallel to the proximal fragment and under radiographic guidance mark the anatomic axis using diathermy or a marking pen.
  - Mark the distal fragment in a similar manner.
- Design the osteotomy around the intersection of these two marks (TECH FIG 1C).
  - Plan the cuts perpendicular to the long axis of each fragment.
  - The size of the bone wedge to be removed is determined based on preoperative templates and intraoperative measurements.
  - Center and apply a six- or seven-hole 2.0- to 2.7-mm compression plate to the dorsum of one fragment using two screws.
  - Moderately tighten the screws.
  - Plan for six cortices of fixation proximal and distal to the osteotomy if possible.
  - Juxta-articular osteotomies are best stabilized using condylar plates, T-plates, or Y-plates. Locking plates also may be of value in these cases.
  - Remove one screw and rotate the plate away from the osteotomy site.
  - Create an incomplete osteotomy, starting on the dorsal convex surface and using a water-cooled sagittal saw or sharp osteotome.
    - Complete the distal bone cut before making the proximal bone cut.
    - An elastic pillar of bone is left intact volarly on the concave side to act as a hinge.
    - In some cases, complete correction and osteotomy reduction can be obtained only if the volar cortex is cut and only the volar periosteum is left intact as the hinge.
    - Correction is adequate when the true anatomic axes of the proximal and distal fragments are parallel (TECH FIG 1D).
  - The dorsal plate often will serve as a guide to reduction when it sits flat on the dorsum of both fragments.
Chapter 40  CORRECTIVE OSTEOTOMY FOR METACARPAL AND PHALANGEAL MALUNION

**TECHNIQUES**

**TECH FIG 1 • A.** Extensor tendons have been retracted to expose the dorsal surface of the metacarpal sagittal plane malunion. **B.** The deep subtendinous layer of the metacarpal is demonstrated. Note that the periosteum is still intact. This layer is repaired covering the implant to prevent tendon adhesions. **C,D.** Method of using K-wires to determine the apex of the deformity. After removing a wedge, the size of which is determined by preoperative templating (**C**), deformity correction is confirmed when the K-wire markings are observed to be parallel (**D**). **E.** Dorsally applied T-plate with three screws distal and three screws proximal to the osteotomy.

- Re-apply the plate, tightening the two screws. Reduce the osteotomy, and secure the other fragment by applying the other side of the plate in compression (**TECH FIG 1E**).
- Insert the remaining screws and assess reduction clinically and radiographically.
- Close the periosteal and muscle layer between the plate and the extensor tendons with absorbable suture, and close the skin in the usual manner.
- Place a forearm-based splint with the wrist mildly extended and the metacarpophalangeal (MP) joints immobilized in 60 to 70 degrees of flexion. The proximal interphalangeal (PIP) joints are left free.

**Phalangeal Opening Wedge Osteotomy**

- Make a mid-axial skin incision (**TECH FIG 2A**).
- Protect against injury to the dorsal sensory nerve branch (**TECH FIG 2B**).
- Incise the lateral band as required (**TECH FIG 2C**), and expose the circumference of the bone subperiosteally at the site of the planned osteotomy.
- Use a “no touch” technique with the extensors and insert small Hohmann retractors to visualize the bone and the deformity.
- Apply K-wires to precisely locate the site of the deformity and serve as a guide for correction in the manner detailed earlier (**TECH FIG 2D,E**).
- Make an incomplete osteotomy on the concave side at the apex of the deformity perpendicular to the distal fragment.
- Contouring of the bone graft is simplified if the osteotomy is made perpendicular to the distal fragment. This leaves only the proximal portion of the graft irregular.
- Provisionally stabilize the fragments with a longitudinal K-wire and assess clinically and radiographically.

**TECH FIG 2 • A.** Lateral incision for proximal phalangeal osteotomy. **B.** Dorsal cutaneous nerve. **C.** Lateral approach to the proximal phalanx. The sagittal band has been cut and elevated to expose the proximal phalanx. (continued)
Hand Fractures and Dislocations

TECHNIQUES

Harvest either a corticocancellous wedge of bone or cancellous bone from the dorsal distal radius just proximal and ulnar to Lister’s tubercle.
- The size of the graft is determined by preoperative templating and intraoperative measurement.
- Contour the graft using a water-cooled sagittal saw.
- Insert the graft to correct the deformity and apply a lateral six-or seven-hole 1.5- to 2.0-mm compression plate (TECH FIG 2F).
- Plan for six cortices of fixation proximal and distal to the osteotomy, if possible.

Juxta-articular osteotomies are best stabilized using condylar plates, T-plates, or Y-plates. Locking plates also may be of value.
- If possible, close the thin periosteal layer between the plate and the extensor tendons with absorbable suture, and close the skin in the usual manner.
- Do not repair the lateral band. Check the correction clinically and compare with the preoperative pictures.
- Place a forearm-based splint with the wrist mildly extended and the MP joints immobilized in 60 to 70 degrees of flexion. The IP joints are immobilized in full extension.

COMPLETE OSTEOTOMY FOR ROTATIONAL AND COMBINED ROTATIONAL/ANGULAR MALUNIONS

- Perform a dorsal approach for malunions of the second through fourth metacarpals and a lateral approach for the fifth metacarpal and phalangeal malunions, as detailed earlier.
- Identify and mark the true anatomic axis of the proximal and distal fragments using 0.35-mm K-wires under radiographic guidance in the manner already reviewed. Define the apex of the angular deformity (see Tech Figs 1C and 2D,E).
- Insert one K-wire proximal and one distal to the malunion, perpendicular to the long axis and in a true dorsal-volar direction. This defines the rotational deformity.
- In the manner detailed previously, perform the osteotomy (opening vs closing) needed to correct the angular portion of the malunion using a water-cooled sagittal saw or a sharp osteotome.
- Insert a longitudinal K-wire to temporarily stabilize the fragments.
- Early correction of the angular malunion aids in plate contouring and placement.

Select a suitable plate (1.5 to 2 mm for P-1 and 2.0 to 2.7 mm for metacarpals), contour it to the lateral bony surface of the proximal fragment, align it to the anatomic axis, and insert screws through the plate fixing it to that fragment.
- Harvest, contour, and insert bone graft if required.
- Remove the longitudinal K-wire and correct the rotational portion of the malunion by bringing the dorsal-volar K-wires into a parallel position while still maintaining angular correction (TECH FIG 3A).
- Secure the distal fragment to the plate in a compression mode.
- Fine-tune the rotational alignment while maintaining the angular correction by using a gliding hole rotation plate (TECH FIG 3B,C).
- Check the correction and range of motion clinically (TECH FIG 3D).
- Close the wound and splint as previously discussed.
TECH FIG 3 • A. K-wires previously were inserted in the dorsovolar plane, perpendicular to the dorsal surface of the proximal and distal fragments. The position of these K-wires defines the degree of rotational malunion. After correction of the sagittal plane deformity, the K-wires are manipulated into a parallel position to achieve rotational correction. B, C. Use of the rotation plates (in this case, VariAx Hand Locking Plate Module [Stryker]). The screw in the perpendicular gliding hole is positioned (but not tightened) ulnar or radial, depending on the direction of the rotational correction desired. The osteotomy is compressed, and the screws in the parallel oblong holes are tightened first. The rotational correction is then obtained, and the gliding hole screw is tightened to obtain controlled correction. D. View after correction of a combined rotational and angular malunion of the fifth metacarpal. (B, C: Courtesy of Stryker Osteosynthesis.)

CONDYLAR ADVANCEMENT OSTEOTOMY

- Condylar advancement osteotomy avoids the problem of handling a small condylar malunion (TECH FIG 4A), which is difficult to fix securely and is susceptible to osteonecrosis.9
- Make a sweeping dorsal, curved skin incision over the involved MP or PIP joint.
  - MP: Incise the sagittal band and then the capsule.
  - PIP: Enter the interval between the lateral band and the central slip and incise the capsule.
  - Protect the origin of the collateral ligament and its accompanying vascularity.
- Carefully dissect the extensor tendon gently off the bone over the region of the proposed osteotomy.
- Evaluate the condition of the joint. If significant arthrosis is present, consider a salvage procedure rather than a repositioning osteotomy.
- Resect a wedge of bone between the condyles with a water-cooled sagittal saw (TECH FIG 4B).
- Make a counter-cut in the diaphysis and advance the mal-united condyle distally to restore articular congruity (TECH FIG 4C).
- Stabilize the mobilized fragment using interfragmentary screws (TECH FIG 4D).
  - Insert the first screw parallel with the joint to ensure precise joint reduction.

TECH FIG 4 • Condylar advancement osteotomy for unicondylar malunion.
PELALS AND PITFALLS

Indications
- Define the goals of treatment with the patient, and ensure that they are realistic.
- In the case of an intra-articular malunion, consider a salvage procedure rather than a repositioning osteotomy in the face of arthrosis.

Preoperative assessment
- Understand the “personality” of the malunion as well as the patient. Bony as well as soft tissue aspects of the deformity must be understood.

Operative planning
- The plane of the deformity and the different components of the deformity, as well as the true extent of the deformity, must be factored in planning the location, orientation, and extent of the osteotomy.

Operative technique
- Atraumatic bone and soft tissue handling is critical, especially in regard to the extensor mechanism overlying P-1. An oscillating power saw with a thin blade and a field of excursion similar to the diameter of the bone is needed. Copious saline irrigation is used to prevent thermal necrosis.
- Accurate plate and screw placement is essential. A screw offset of 1 mm can cause as much as 10 degrees of rotation.

Implants
- Stable fixation is needed to allow early range of motion.
- Consider using implants a size larger than used for acute fractures, particularly if extensive soft tissue release has been performed.
- Newer-generation locking plates and screws are valuable when fixation in the metaphysis is required.

Postoperative
- Institute early postoperative therapy.

POSTOPERATIVE CARE
- If adequate stability is obtained at the time of surgery, remove the postoperative splint 3 to 5 days after surgery and initiate protected motion.
  - Initiate an early active and active assisted ROM program.
  - When not performing ROM exercises, rest the hand in a volar splint in a functional position (MP joints flexed to 60–70 degrees and IP joints fully extended), apply a compression bandage, and elevate.
  - Progress to passive ROM exercises, and use reverse blocking exercises to strengthen and rebalance the extensors.
  - If needed, and if healing is progressing appropriately, use static or dynamic splints to address pending joint contractures.
  - Encourage functional use of the hand long before the radiographs show complete bony consolidation.

OUTCOMES
- Encouraging results have been reported. In the largest reported series of 59 osteotomies Buchler et al reported the following:
  - A 100% union rate
  - Satisfactory correction of the deformity in 76% of cases
  - A net gain in active ROM in 89% of the patients
  - Excellent and good functional results in 96% of patients requiring bony corrections only and 64% for those requiring bony and soft tissue correction

COMPLICATIONS
- Incomplete or inadequate correction (up to 24% of patients)
- Iatrogenic damage to soft tissues (up to 4% of patients)
- Residual stiffness

REFERENCES
DEFINITION
- Scapholunate and lunotriquetral interosseous ligament tears are common wrist injuries occurring in isolation or as part of the perilunate injury pattern.
- Interosseous ligament injuries are being diagnosed with an increased frequency as a result of recent advances in imaging and arthroscopy.
- Management of these injuries has proven to be a difficult clinical problem. Surgical management has been more reliable in pain relief than in altering the natural history.

ANATOMY
- The scapholunate complex is subject to significant loads, since the scaphoid is the only carpal bone to span from the proximal to the distal carpal row.
- The proximal carpal row flexes with radial deviation and extends with ulnar deviation.
  - The scaphoid “wants” to flex and the triquetrum “wants” to extend.
  - The lunate (the intercalated segment) is tethered between the scaphoid and triquetrum. A large amount of potential energy exists in the proximal carpal row.
- Stability is provided to the scapholunate complex by the intrinsic scapholunate interosseous ligament (SLIL) as well as extrinsic capsular ligaments, especially the dorsal radiocarpal (DRC), dorsal intercarpal (DIC) ligament, and volar radioscaphocapitate (RSC) and scaphotrapezial-trapezoid (STT) ligaments.
- The SLIL is a C-shaped structure consisting of a stronger dorsal ligamentous portion (2 to 3 mm thick), a volar ligamentous portion (1 mm thick), and a proximal fibrocartilaginous (membranous) portion.2
- Isolated injuries to the SLIL appear to be associated with dynamic instability, whereas static instability usually indicates additional injury to the secondary ligamentous stabilizers, including the DIC ligament.16
- The lunotriquetral complex is also stabilized by an intrinsic lunotriquetral ligament (LTIL) and extrinsic (volar and dorsal) capsular ligaments.
- The LTIL is C-shaped, analogous to the SLIL, consisting of dorsal and volar ligamentous portions and a membranous proximal portion. In contrast to the SLIL, the volar ligamentous portion of the LTIL is stronger and more significant functionally.12
- As with the scapholunate complex, isolated injuries to the LTIL are usually insufficient for the development of static instability. Presence of a static deformity indicates additional injury to extrinsic ligamentous structures (volar lunotriquetral, ulnolunate, and ulnocapitate ligaments or the dorsal radio-carpal and intercarpal ligaments).7,20

PATHOGENESIS
- Mayfield et al7 postulated that scapholunate disruption is the initial component of the lesser arc perilunate injury pattern, which occurs when force is applied to the thenar area with the wrist in extension, supination, and ulnar deviation.
  - Depending on the amount of kinetic energy involved, the injury may or may not extend to the ulnar side of the wrist.
- SLIL injuries can be sprains, partial tears, or complete tears (with or without injury to the extrinsic ligament stabilizers).
  - With complete SLIL tears the scaphoid flexes and the lunate is pulled by the triquetrum into extension (dorsal intercalated segment instability [DISI] pattern).
  - With complete SLIL tears the ligament usually fails at the bone-ligament interface off the scaphoid.
- Arthroscopic evaluation has revealed associated SLIL injuries in up to 30% of intra-articular distal radius fractures.3
- LTIL disruption may be traumatic or atraumatic in origin.
  - Traumatic LTIL rupture may occur as the final component of a greater or lesser arc perilunate injury pattern.9
  - Isolated LTIL tears may result from a fall on an outstretched hand in extension, pronation, and radial deviation (reverse perilunate injury)11 or from a dorsally applied force on a flexed wrist.25
  - Atraumatic ruptures of the LTIL may occur secondary to inflammatory arthritis or ulnar impaction syndrome.18

NATURAL HISTORY
- Tears of the SLIL or LTIL, with or without extrinsic ligamentous injury, may lead to various degrees of carpal instability (predynamic, dynamic, or static), alteration of normal carpal mechanics and kinematics, and early degenerative changes in the radiocarpal and midcarpal joints.
- A complete SLIL tear is associated with the development of a DISI deformity, which may be dynamic or static (indicates additional injury to the extrinsic ligaments).
  - As a DISI deformity forms, abnormal radiocarpal contact loading occurs as the proximal carpal bones shift in position and lose congruency.
  - Abnormal flexion and hypermobility of the scaphoid over time leads to degenerative changes of the radioscaphoid and capitulunate joints and ultimately collapse, termed scapholunate advanced collapse (SLAC) wrist degeneration.22,23
- These degenerative changes have been documented to begin as early as 3 months after injury.
A complete LTIL tear is associated with the development of a volar intercalated segment instability (VISI) deformity. The natural history of partial tears of the SLIL or LTIL is at present poorly defined. Partial scapholunate and LT injuries may cause chronic, activity-related wrist pain in the absence of radiologic findings.23 Predynamic or dynamic instability may cause attenuation of extrinsic ligaments with progressive development of further instability and static changes.29,30 There is evidence that this process typically requires many years.10

**PATIENT HISTORY AND PHYSICAL FINDINGS**

Dorsoradial or ulnar-sided wrist pain with a history of a fall, sudden loading, or twisting of the wrist should raise suspicion for a SLIL or LTIL tear, respectively. However, it is not uncommon for the patient to deny any significant injury. Patients frequently complain of weakness, swelling, and loss of range of motion of the wrist. A sensation of instability or “giving way” is often reported, occasionally associated with a painful clunk. A detailed physical examination of the wrist may provide significant information for the diagnosis of ligamentous injuries and help to rule out other wrist pathology. Examination of the wrist begins with evaluation for any deformity or swelling and determination of wrist range of motion. Key tests and maneuvers specifically evaluating the scapholunate and lunotriquetral ligaments are as follows:

- **Grip strength and pain:** Diminished grip strength correlates with wrist pathology.
- **The presence of pain at the central aspect of the wrist with attempted grip has also been associated with scapholunate ligament pathology.**
- **Deep palpation of scapholunate interval:** Point tenderness indicates SLIL injury, scaphoid injury, or ganglion cyst.
- **Watson’s scaphoid shift test:** Pain with or without a clunk or catch sensation is highly suggestive of scapholunate instability.
- **Scaphoid ballottement test:** Pain and increased anteroposterior laxity are highly suggestive of scapholunate instability.
- **Deep palpation of lunotriquetral interval:** Point tenderness indicates LTIL injury or triangular fibrocartilage complex (TFCC) pathology.
- **Ulnar wrist loading:** A painful snap indicates lunotriquetral instability, midcarpal instability, or TFCC complex pathology. This maneuver will also be painful if ulnar impaction is present.
- **Triquetrum ballottement test:** Pain and increased anteroposterior laxity are highly suggestive of lunotriquetral instability.
- “**Ulnar sniffbox**” tenderness: Pain with or without crepitus indicates lunotriquetral instability, TFCC complex pathology, or triquetrohamate pathology.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Initial imaging of the wrist should always include AP and lateral radiographs, combined with special views depending on the suspected pathology. If scapholunate pathology is suspected, a bilateral pronated grip anteroposterior (Mayo Clinic) view should be obtained for comparison to the contralateral side. Abnormal findings in static scapholunate instability include:

- **AP view:** increased scapholunate interval (3 mm or more; comparison to contralateral wrist), scaphoid cortical “ring sign,” and triangular appearance of lunate.
- **Lateral view:** flexion of scaphoid and dorsiflexion of lunate, as determined by increased scapholunate angle (more than 60 degrees) and increased lunocapitate angle (over 10 degrees) with dorsal translation of capitate.
- **Radiographic findings in patients with lunotriquetral tears are often normal. Abnormal findings in static lunotriquetral instability include:**
  - **AP view:** proximal translation of triquetrum or lunotriquetral overlap without gapping, and interruption of Gilula’s arc.
  - **Lateral view:** flexion of scaphoid and lunate, as determined by normal or decreased scapholunate angle (less than 45 degrees), increased lunocapitate angle (more than 10 degrees) with volar translation of capitate, and a negative lunotriquetral angle.
  - **Provocative views (radial-ulnar deviation, flexion-extension views) or videofluoroscopy may demonstrate asynchronous scapholunate motion (dynamic scapholunate instability) in cases with suspected SLIL injury and normal standard views. Increased, synchronous mobility of the scapholunate complex with diminished motion of the triquetrum indicate an LTIL injury.**
  - **Wrist arthrography has a sensitivity of only 60% compared to arthroscopy and cannot determine the extent of any tear present.**26
  - **MRI (with or without arthrography) has limited value in evaluating interosseous ligament injuries. Reported sensitivity rates for SLIL injuries range from 40% to 65% compared to arthroscopy.17 MRI is even less reliable in diagnosing LTIL injuries.**
  - **Arthroscopy (radiocarpal, midcarpal with probing) remains the gold standard in evaluation of SLIL and LTIL injuries.**

**DIFFERENTIAL DIAGNOSIS**

- **Differential diagnosis of scapholunate injuries and radial-sided wrist pain**21
  - Scaphoid fracture or nonunion
  - Scaphotrapezial arthritis
  - Radiocarpal arthritis
  - De Quervain’s tenosynovitis
  - Dorsal ganglion cyst
  - Dorsal wrist impaction syndrome
  - Perilunate instability
  - Isolated DRC ligament tear
- **Differential diagnosis of lunotriquetral injuries and ulnar-sided wrist pain**18
  - TFCC injury
  - Distal radioulnar joint (DRUJ) instability or arthritis
  - Ulnar impaction syndrome or chondromalacia
  - Ulnar styloid impingement syndrome
  - Extensor carpi ulnaris (ECU) tendon subluxation
  - Psotriquetral arthritis
  - Triquetrohamate instability
NONOPERATIVE MANAGEMENT

- SLIL and lunotriquetral injuries associated with dynamic instability may respond to initial nonoperative treatment for 6 to 12 weeks.
- Conservative management typically includes a combination of the following:
  - Splinting
  - Nonsteroidal anti-inflammatories
  - Intra-articular (radiocarpal) corticosteroid injections
  - Occupational therapy and work restrictions
  - Re-education of wrist proprioception with flexor carpi radialis strengthening

SURGICAL MANAGEMENT

- The selection of surgical treatment for SLIL and LTIL injuries is based on the severity of symptoms, the degree of instability (dynamic or static), chronicity (acute, subacute, or chronic), arthroscopic findings (Geissler grade; see TECH FIG 1), and reparability of the ligament.
- Dynamic instability (based on positive physical findings with provocative maneuvers, abnormal stress radiographs, arthroscopic findings) that has failed to respond to nonoperative treatment may be treated arthroscopically.
  - Arthroscopic options include simple débridement, débridement with thermal shrinkage, and débridement (with or without shrinkage) with percutaneous pinning.
  - Static instability and severe dynamic instability are indications for open surgery.
  - Surgical options include open repair or augmentation (especially of acute or subacute injuries), capsulodesis, and tenodesis.
- Patients developing carpal collapse with arthritic changes require salvage procedures such as radial styloidectomy, proximal row carpectomy, and limited wrist fusions (eg, STT, scaphocapitate, scaphoidectomy plus four-corner fusion, reduction-association scapholunate [RASL] procedure, lunotriquetral fusion).
- The focus of this chapter is on arthroscopic procedures described for management of dynamic scapholunate or lunotriquetral instability. Newer arthroscopic alternatives advocated for management of more advanced pathology are also described.

Arthroscopic Procedures

- Arthroscopic débridement of SLIL and LTIL injuries
  - Indications: Predynamic or dynamic instability; arthroscopic findings of a partial ligament tear with an unstable tissue flap (Geissler grade II); with or without synovitis
  - The ideal patient for this technique is one with mechanical symptoms (pain with crepitation or clicking) attributable to impingement of unstable tissue flaps and resulting synovitis.
- Arthroscopic débridement and thermal shrinkage of SLIL and LTIL disruptions
  - Indications: Predynamic or dynamic instability; arthroscopic finding of a partial ligament tear (Geissler grade I or II). The dorsal segment of the SLIL should be intact for this procedure.
  - This technique provides an option for the management of lax, redundant ligaments with no frank tear (Geissler grade I) where simple débridement is not an option.
  - Thermal shrinkage is performed in an attempt to increase stability and improve long-term outcome compared to simple débridement.
  - Radiofrequency probes use a high-frequency alternating current to generate heat. This leads to denaturation (uncoiling) of the collagen triple helix with reduction in overall ligament length.
  - Use of this device is contraindicated in patients with pacemakers or other implantable electronic devices.
- Arthroscopic débridement and percutaneous pinning of SLIL and LTIL disruptions
  - Indications: Acute or subacute dynamic instability (Geissler grades II and III)
  - This technique aims to induce the formation of fibrous union between the two involved carpal bones.
- Arthroscopic radial styloidectomy
  - Indications: Early (stage I) scapholunate advanced collapse (SLAC) wrist (ie, radial styloid–scaphoid impingement or arthritis) with focal and reproducible clinical findings of radial styloid pain exacerbated by wrist flexion and radial deviation
  - This procedure may provide significant pain relief until a salvage procedure (proximal row carpectomy, scaphoid excision, four-corner fusion) becomes necessary.
- Arthroscopic RASL procedure (see Chap. HA-46) and lunotriquetral fusion
  - Indications: Static instability (Geissler grade IV); lunotriquetral arthritis
  - Early (stage I) SLAC wrist is not a contraindication.
  - The RASL procedure aims to achieve fibrous union while maintaining mild rotation at the scapholunate joint, thus approximating normal wrist kinematics. On the other hand, bony fusion is the goal in the lunotriquetral joint.

Preoperative Planning

- A careful review of the patient’s history, physical findings, as well as static and stress radiographs may provide the surgeon with a reasonable impression of what will be required.
- In most cases, however, a decision on the type of procedure to be performed is made intraoperatively based on the arthroscopic findings and associated pathology.
- Consideration must therefore be given to have the following available: radiofrequency probes, mini C-arm, drills, Kirschner wires of various widths, and headless compression screws.

Positioning

- The patient is placed in the supine position with the extremity on a hand table.
- Any possible donor site for ligament reconstruction or augmentation should also be prepared and draped in a sterile fashion.
- The extremity is placed in a tower distraction device with 10 to 12 lb (5 to 6 kg) of distraction and 12 to 15 degrees of wrist flexion (FIG 1).
- The arthroscope monitor is placed on the opposite side of the hand table from the surgeon.
If percutaneous pinning or use of other implants is anticipated, a small fluoroscopy unit is placed adjacent to the head of the operating table.

**Approach**

- Arthroscopic evaluation and management of scapholunate and lunotriquetral injuries can typically be performed through standard dorsal wrist portals (3–4, 4–5, 6R, midcarpal).
- The additional use of a radial volar portal through the flexor carpi radialis (FCR) sheath has been advocated for better visualization of the volar portions of the SLIL and LTIL, as well as the DRC and DIC ligaments.\(^1\,\!^{19}\)

**Fig 1** A. Positioning for arthroscopy of the wrist. B. The monitor should be visible to the surgeon. If use of fluoroscopy is anticipated, the C-arm is placed adjacent to the head of the operating table.

**Arthroscopic Evaluation**

- An 18-gauge needle is used to distend the radiocarpal joint with 7 to 10 mL of normal saline.
- A 2.7-mm, 30-degree arthroscope is preferred for wrist arthroscopy.
- Typical working portals include the 3–4, 4–5, 6R, and midcarpal portals. Outflow is established through the 6U or 6R portal.
- The entire radiocarpal joint is evaluated in a systematic manner, usually from radial to ulnar.
- The SLIL is best visualized through the 3–4 portal with probe insertion through the 4–5 or 6R portal. The 4–5 portal is used for instrumentation.
- Occasionally the avulsed portion of the SLIL may make visualization through the 3–4 portal difficult. In this situation, the arthroscope is transferred to the 6R portal and directed radially.
- The proximal portion of the SLIL is easily visualized by following the radiocapitate ligament (ligament of...
Testut) to its insertion. The volar radioscapholunate and long radiolunate ligaments (wider) are visualized radially, and the short radiolunate is located ulnar to the ligament of Testut.

- The LTIL is best visualized through the 4–5 or 6R portal, with use of the 3–4 and 6R for instrumentation.
- Both ligaments should be evaluated in their entirety (dorsal, proximal, and volar portions).
  - If visualization of the volar portions of the SLIL and LTIL is inadequate, an additional volar portal through the FCR sheath may be used, but this has rarely been necessary in our experience.
- In patients with gross scapholunate instability, the arthroscope is finally turned toward the dorsum of the scaphoid and lunate to identify possible avulsion of the DIC or DRC ligament.

ARTHROSCOPIC DÉBRIDEMENT

- A thorough diagnostic arthroscopy (radiocarpal plus midcarpal) is performed to verify the diagnosis and rule out instability or other associated pathology.
- The inflamed synovium is excised with a 2.5- or 2.7-mm full-radius resector.
- Any unstable tissue flaps are resected with a suction punch or synovial resector.
- Redundant tissue is then resected to a stable rim with the synovial resector or bipolar radiofrequency probe.

ARTHROSCOPIC DÉBRIDEMENT AND THERMAL SHRINKAGE

- Diagnostic arthroscopy is performed as previously described.
- Geissler grade II tears are débrided with a synovial resector to a stable rim (TECH FIG 2A). Thermal shrinkage of the intact portion of the ligament is then performed with a 2.3-mm bipolar radiofrequency probe.
- Attenuated ligaments (Geissler grade I) are treated with thermal shrinkage alone.
- Thermal shrinkage is performed by applying the radiofrequency probe in a paintbrush fashion (2.3-mm radiofrequency probe [Mitek VAPR®, Westwood, MA]) (TECH FIG 2B). The goal is to evenly distribute the thermal energy throughout the ligament.

Techniques

- A probe is then inserted through the 4–5 or 6R portal to reassess stability from both the radiocarpal and midcarpal joint.
- Débride-ment should generally be limited to the proximal membranous portion of the SLIL or LTIL.
- Unwarranted débride-ment of the dorsal (SLIL) or volar (LTIL) portions of the ligamentous complex may lead to further instability.
- Carpal stability should be assessed both before and after débride-ment.
ARThROSCOPIC DÉBRIDEMENT AND PERCUTANEOUS PINNING

- Diagnostic arthroscopy is performed as previously described.
- All residual tissue of the torn ligament (SLIL or LTIL) is débrided with a 2.5- or 2.7-mm full-radius resector.
- The cartilage of the apposing surfaces of the involved carpal bones is then débrided to bleeding bone with a 2.5- or 2.7-mm aggressive full-radius resector and a 2.9-mm barrel abrader (TECH FIG 3A).
- The extremity is then removed from the distraction tower.
- If necessary, congruity of the joint is improved by external (pressure on the distal pole of scaphoid) or internal maneuvers (percutaneous Kirschner wires used as joysticks).

- The joint is stabilized by percutaneously inserting three or four 0.045-inch (1.1-mm) Kirschner wires under fluoroscopic control.
- The scapholunate joint is typically stabilized with two Kirschner wires across the scapholunate joint (radial to ulnar) followed by one or two Kirschner wires across the scaphocapitate joint (TECH FIG 3B).
- The lunotriquetral joint is similarly stabilized with two Kirschner wires across the lunotriquetral joint (ulnar to radial) followed by one or two Kirschner wires across the lunocapitate joint.
- The pins are then cut subcutaneously or bent outside the skin per surgeon preference.

ARThROSCOPIC RADIAL STYLOIDECTOMY

- Diagnostic arthroscopy is initially performed to delineate the chondral lesions and accurately stage the SLAC wrist.
- The arthroscope is placed in the 3–4 or 4–5 portal.
- Excision of the radial styloid is performed through the 1–2 (or 3–4) portal with a side-cutting 3.5-mm sheathed burr.
- Arthroscopic evaluation of articular cartilage and intra-operative radiographs should be used to determine the extent of resection.
- The origin of the radioscapophocapitate ligament is visualized and preserved during bone resection.
- Although the tendency is to overestimate the amount of bone resected, excision of more than 4 mm may jeopardize the ligament and result in ulnar carpal dislocation.

ARThROSCOPIC RASL PROCEDURE AND LUNOTRIQUETRAL FUSION

- Diagnostic arthroscopy with evaluation of chondral lesions is performed as described previously.
- The apposing surfaces of the joint to be fused are débrided to bleeding bone with a 2.5- or 2.7-mm aggressive full-radius resector and a 2.9-mm barrel abrader.
- Complete decortication is verified from both the radiocarpal and midcarpal joints.
- In the case of the RASL procedure, a side-cutting 3.5-mm sheathed burr is then used to perform an arthroscopic radial styloidectomy through the 1–2 (or 3–4) portal as described previously.
- Kirschner wires (0.062 inch or 1.6 mm) are then inserted percutaneously from the dorsum into the involved carpal bones (distal scaphoid-lunate or lunate-triquetrum). Positioning of the wires should be slightly eccentric to allow for subsequent placement of the screw centrally. The Kirschner wires are used as joysticks to reduce the joint under fluoroscopic (with or without arthroscopic) control.
- It is essential to verify adequate reduction of the capitotrapezial joint on the lateral view.
- A Köcher clamp may be placed across the Kirschner wires to maintain reduction.
■ An additional 0.045-inch (1.1-mm) Kirschner wire may be inserted through the dorsal rim of the distal radius into the lunate for provisional stabilization of the lunate.

■ A 0.035-inch (0.9-mm) guidewire is then placed across the joint (scapholunate or lunotriquetral) under fluoroscopic control.

■ In the case of the RASL procedure, the guidewire should be placed through the 1–2 portal, across the scaphoid waist toward the proximal-ulnar corner of the lunate, thus approximating the normal axis of rotation of the scapholunate joint (TECH FIG 4).

■ A cannulated headless compression screw is then placed across the joint. Length measurement should be reduced by about 4 mm to accommodate for joint compression and to ensure that the screw is completely countersunk into bone.

■ After satisfactory reduction and fixation are verified, the wrist capsule incision is repaired.

■ In patients with lunotriquetral instability as a result of ulnar impaction syndrome, fusion of the lunotriquetral joint must be combined with an arthroscopic wafer procedure or an open lunotriquetral arthrodesis.

---

**PEARLS AND PITFALLS**

| Diagnosis | ■ Meticulous examination and arthroscopy of the entire wrist are necessary to ensure diagnosis and treatment of concomitant pathology.

| Indications | ■ Arthroscopic débridement with or without thermal shrinkage is not adequate management for static scapholunate or lunotriquetral instability.

| Contraindications | ■ Use of radiofrequency probes for débridement or thermal shrinkage is contraindicated in patients with pacemakers or implantable electronic devices.

| Surgical technique | ■ Wrist arthroscopy for evaluation of SLIL or LTIL tears must include arthroscopy of the midcarpal joint.

■ Carpal stability should be assessed both before and after any débridement of the SLIL or LTIL.

■ Débridement of functionally significant portions of the SLIL (dorsal) or LTIL (volar) should be kept to a minimum to prevent further destabilization.

■ Thermal shrinkage should be performed with specially designed radiofrequency probes. Otherwise, the probe should be applied in a paintbrush fashion for only a few seconds at a time with adequate outflow to avoid reaching ablation temperatures.

| Rehabilitation | ■ If thermal shrinkage is performed, the wrist should be immobilized for at least 2 weeks postoperatively and protected for an additional 4 weeks to allow healing of treated tissue.

---

**POSTOPERATIVE CARE**

■ Patients treated with arthroscopic débridement alone are placed in a cock-up wrist splint postoperatively and instructed to initiate range-of-motion exercises at 48 hours.

■ Patients treated with arthroscopic débridement and thermal shrinkage are placed in a full-time short-arm splint postoperatively. Range-of-motion exercises are initiated at 2 to 4 weeks, with use of a removable cock-up splint between sessions. Strengthening exercises are initiated at 4 to 6 weeks.

■ Patients treated with arthroscopic débridement and percutaneous pinning are placed in a short-arm splint, changed to a short-arm cast after suture removal. The cast is maintained until pin removal, which is performed at 8 to 10 weeks for the scapholunate and at 4 to 6 weeks for the lunotriquetral joint. Range-of-motion exercises are then initiated, with progression to strengthening as tolerated.

■ Patients treated with an arthroscopic RASL procedure are placed in a short-arm splint for only 2 or 3 weeks. Range-of-motion exercises are then initiated, with progression to strengthening as tolerated. Conversely, patients treated with arthroscopic fusion of the lunotriquetral joint are immobilized until radiographic fusion is obtained.

**OUTCOMES**

■ Ruch and Poehling15 reported excellent results with arthroscopic débridement alone in 14 patients with partial SLIL or lunotriquetral tears, or both, and predominantly mechanical symptoms. At a minimum follow-up of 2 years, all patients reported complete relief of their mechanical symptoms, while pain was significantly reduced and grip strength was restored.

■ Weiss et al27 have treated both partial and complete SLIL and lunotriquetral tears with arthroscopic débridement alone
in an attempt to elicit scar formation with some degree of stabili-zation. Excellent pain relief and increased strength were achieved in 17 of 19 patients with partial tears, but only in 17 of 24 patients with complete tears. No radiologic progression was noted at 27 months follow-up.

Darlis et al\(^6\) reported substantial pain relief in 14 of 16 pa-tients with Geissler grade I or II SLIL tears treated with arthro-scopic débridement and thermal shrinkage. Wrist motion was main-tained and there was no radiologic evidence of instability at 19 months of follow-up.

Hirsh et al\(^6\) reported excellent results in 9 of 10 patients with Geissler grade II SLIL tears treated with arthroscopic débridement and thermal shrinkage at 28 months of follow-up.

Whipple\(^28\) reported his results with percutaneous pinning in patients with scapholunate instability. Symptom duration of more than 3 months and a side-to-side gap difference of more than 3 mm were associated with poor outcomes. Pain relief was satisfactory in only 53% of patients with both of these factors.

Darlis et al\(^3\) reported management of chronic (longer than 3 months) dynamic scapholunate instability (Geissler grades III, IV) with arthroscopic débridement and percutaneous pinning in patients who did not wish to undergo open surgery. Results were suboptimal, with significant pain relief and improved grip strength in 6 of 11 patients. At 33 months of follow-up there was no radiologic evidence of progression to static instability, but three patients required additional surgery to address persistent pain.

Clinical experience with the arthroscopic RASL procedure and lunotriquetral fusion is limited. Rosenwasser et al\(^14\) reported excellent results using the open RASL technique in 20 patients with static instability. At 54 months of follow-up, patients had achieved 91% of their normal wrist motion and 87% of contralateral grip strength. The authors noted that the procedure may be performed arthroscopically, but thought that experience with the open technique should first be obtained.

COMPLICATIONS

- Injury to branches of superficial radial sensory nerve (espe-cially with use of 1–2 portal) or dorsal branch of ulnar nerve (6R, 6U portals)
- Injury to radial artery (radial volar portal). This portal should be established through the floor of the FCR sheath.
- Persistent pain or instability
- Need for additional surgery (ligament reconstruction, capsulodesis, tenodesis, proximal row carpectomy, partial or complete wrist fusion)

REFERENCES

DEFINITION

- Scapholunate instability is the most common form of carpal instability.
- Scapholunate interosseous ligament (SLIL) injury can result in a predictable pattern of arthritis over time: scapholunate advanced collapse (SLAC).12
- Acute tears (<6 weeks from injury) versus chronic tears (>6 weeks from injury)
  - Acute tears tend to be amenable to primary ligament repair.
  - Chronic tears tend to require ligament reconstruction procedures.
- Static or dynamic instability
  - Static instability: any or all of the five characteristic changes on standard plain radiographs (see below)
  - Dynamic instability: normal plain radiographs; however, with loaded (grip view) plain radiographs, any or all of the five characteristic changes may become present.10
- Fixed versus reducible deformity
  - Fixed deformity: the static radiographic changes are not passively correctible
  - Reducible deformity: the static radiographic changes are passively correctible
  - This distinction can be determined preoperatively by noting improvement in the static changes on plain radiographs of the wrist in radial deviation compared with AP views of the wrist.

ANATOMY, PATHOGENESIS, AND NATURAL HISTORY

- See Chapter HA-41.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Typical presentation follows a fall on an outstretched hand with acute onset of wrist pain and mild dorsal wrist swelling.
- Key physical examination findings are reviewed in Chapter HA-41.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs may reveal five characteristic findings suggestive of SLIL pathology (FIG 1).
  - Terry Thomas sign: gap between the scaphoid and lunate of more than 3 mm on posteroanterior (PA) radiograph
  - Cortical ring sign: Cortical hyperdensity is seen on PA radiograph as the scaphoid moves into increasing flexion.1
  - Angular changes in the carpal rows
    - Scapholunate angle: Normal is 30 to 60 degrees (mean 46 degrees); with SLIL injury, more than 60 degrees6
    - Capitolumate angle: Normal is −15 to 15 degrees (mean 0 degrees); with SLIL injury, more than 15 degrees
  - Radiolunate angle: Normal is −10 to 10 degrees (mean 0 degrees); with SLIL injury, more than 10 degrees
  - Quadrangular lunate: As the lunate moves into extension it assumes a rectangular appearance on PA radiograph.
  - Disruption of Gilula’s lines: Gentle concentric arcs follow the proximal and midcarpal rows. These lines are disrupted with SLIL tears as the relationship of the proximal row is lost.
- Arthrography: sensitivity 56%, specificity 83%, accuracy 60%13
  - False-positive results have been documented with communication of contrast shown in asymptomatic patients.1
- CT arthrography: sensitivity 86% to 100% (100% sensitive in the detection of dorsal ligament tears), specificity 50% to 79% (79% specific in the detection of dorsal ligament tears), accuracy 78% to 83%7
- MRI: sensitivity 25% to 60%, specificity 77% to 100%, accuracy 64% to 78%8
  - Specifically, palmar tears of the SLIL were identified with a sensitivity of 60% and specificity of 77% in a cadaveric study. However, the more important stabilizing dorsal portion tears were seen in 0 of 9 specimens.7
  - Ultrasound: sensitivity 46%, specificity 100%, accuracy 89%2
- A negative result with various imaging studies does not prove an absence of ligamentous injury. Arthroscopy has become the gold standard for the diagnosis of SLIL tears.

DIFFERENTIAL DIAGNOSIS

- Dynamic SLIL instability or partial SLIL tear
- Radiocarpal arthritis
- Scaphoid fracture
- Keinböck or Preiser disease

FIG 1 • AP and lateral plain radiographs of a patient with scapholunate ligament tear.
NONOPERATIVE MANAGEMENT
- Nonoperative methods are unsuccessful in treating dynamic or static acute scapholunate ligament injuries.
  - 0 of 19 patients with dynamic instability treated with immobilization, nonsteroidal anti-inflammatories, and activity modification had substantial reduction in symptoms even up to 12 weeks into treatment.*

SURGICAL MANAGEMENT
- Indications
  - Wrist pain with an acute tear (<6 weeks)
    - These patients may or may not have static radiographic changes.
  - Should static radiographic changes be present, plain radiographs in radial deviation can show if the radiographic changes are fixed (and therefore are not amenable to soft tissue repairs) or correct in radial deviation (and therefore are amenable to soft tissue repairs).
  - Wrist pain with dynamic instability
  - We advocate diagnostic arthroscopy before open treatment.

Preoperative Planning
- General or regional anesthesia
- Equipment
  - Mini suture anchors (1.8 mm)
  - Kirschner wire driver and smooth wires (0.045 and 0.062 inch)
  - Arthroscopic equipment (see Chap. HA-41)
  - Mini C-arm

Positioning
- The patient is positioned supine with a hand table.
- The bed is turned such that the hand table faces the corner opposite anesthesia.
- Fluoroscopy can then move in and out from the opposite corner perpendicular to the patient.
- An upper arm nonsterile tourniquet should be placed.
- The operative arm is prepared and draped. Slack is left in the armboard portion of the drape to allow the sterile wrist traction tower to slide under the arm above the elbow.
- The operative wrist is suspended in a wrist traction tower.

Approach
- A preoperative examination of both wrists is performed and documented, noting passive range of motion, swelling, and the Watson scaphoid shift test.
- Arthroscopy is recommended before open reconstruction because of the lack of diagnostic accuracy of available imaging modalities.
- Wrist arthroscopy is considered the gold standard for diagnosis of SLIL pathology and can confirm the diagnosis and degree of instability before making a larger skin incision.
- Geissler staging of SLIL tears is covered in Chapter HA-41.

DIRECT SLIL REPAIR
- Specific indications for direct SLIL repair with or without dorsal capsulodesis
  - Geissler III or IV complete SLIL tear
  - Injury less than 6 weeks old
    - It is rare that a repairable ligament is available more than 3 months after injury.
  - Minimal degenerative changes in the radiocarpal and midcarpal joints
  - Static radiographic changes that are not fixed
  - Adequate SLIL tissue
- Make a standard longitudinal dorsal incision just ulnar to the tubercle of Lister and dissect to the extensor retinaculum.
- Raise flaps at the level of the extensor retinaculum, exposing the retinacular edges proximally and distally.
  - Superficial radial and ulnar dorsal cutaneous nerve branches will be within these flaps.
- Incise the extensor retinaculum over the third extensor compartment and transpose the extensor pollicis longus (EPL) tendon into the radial subcutaneous space.
- Arthroscopic equipment (see Chap. HA-41)
- Mini C-arm

Expose the dorsal capsule and dorsal extrinsic radiocarpal ligaments (dorsal radiocarpal [DRC] and dorsal intercarpal [DIC] ligaments).
- Incise the dorsal capsule, leaving a 1- to 1.5-cm ulnar-based flap (TECH FIG 1A).
  - Leaving the capsule attached ulnarily provides a capsular flap available for capsulodesis or augmentation of a repair if desired.
- This flap of tissue will parallel the DIC and include the capsule and portions of the DIC and DRC.
- With the scaphoid, SLIL, and lunate exposed, note any arthritic changes, the location of the SLIL disruption (typically it avulses off the scaphoid) (TECH FIG 1B,C), and any injury to the DIC ligament.
- In cases of high energy the DIC may avulse off its scaphoid and lunate attachment.
- Place joystick Kirschner wires (0.062 inch) into the scaphoid and the lunate.
- The SLIL is probed in the radiocarpal and midcarpal joints.
  - A 1-mm arthroscopic probe passable in the scapholunate interval and rotated 360 degrees is indicative of a grade III Geissler lesion.
  - A “drive-through” sign with a 2.7-mm arthroscope is indicative of a grade IV Geissler lesion.
- Midcarpal arthroscopy most effectively reveals the degree of instability.

TECHNIQUES

DIAGNOSTIC WRIST ARTHROSCOPY
- See Chapter HA-41.
- The 3-4 portal is used for viewing.
- The 6U portal is used for outflow (typically an 18-gauge needle with sterile IV tubing).
- The 4-5 is used for placement of instruments.

DIRECT SLIL REPAIR
- Specific indications for direct SLIL repair with or without dorsal capsulodesis
  - Geissler III or IV complete SLIL tear
  - Injury less than 6 weeks old
    - It is rare that a repairable ligament is available more than 3 months after injury.
  - Minimal degenerative changes in the radiocarpal and midcarpal joints
  - Static radiographic changes that are not fixed
  - Adequate SLIL tissue
- Make a standard longitudinal dorsal incision just ulnar to the tubercle of Lister and dissect to the extensor retinaculum.
- Raise flaps at the level of the extensor retinaculum, exposing the retinacular edges proximally and distally.
  - Superficial radial and ulnar dorsal cutaneous nerve branches will be within these flaps.
- Incise the extensor retinaculum over the third extensor compartment and transpose the extensor pollicis longus (EPL) tendon into the radial subcutaneous space.
- Arthroscopic equipment (see Chap. HA-41)
- Mini C-arm

Expose the dorsal capsule and dorsal extrinsic radiocarpal ligaments (dorsal radiocarpal [DRC] and dorsal intercarpal [DIC] ligaments).
- Incise the dorsal capsule, leaving a 1- to 1.5-cm ulnar-based flap (TECH FIG 1A).
  - Leaving the capsule attached ulnarily provides a capsular flap available for capsulodesis or augmentation of a repair if desired.
- This flap of tissue will parallel the DIC and include the capsule and portions of the DIC and DRC.
- With the scaphoid, SLIL, and lunate exposed, note any arthritic changes, the location of the SLIL disruption (typically it avulses off the scaphoid) (TECH FIG 1B,C), and any injury to the DIC ligament.
- In cases of high energy the DIC may avulse off its scaphoid and lunate attachment.
- Place joystick Kirschner wires (0.062 inch) into the scaphoid and the lunate.
TECH FIG 1 • A. Intraoperative photo demonstrating the exposure and location of the dorsal capsular ulnar-based flap. The DIC parallels the more distal transverse limb of the flap. S, scaphoid; L, lunate; T, triquetrum. B. Intraoperative photo demonstrating the flexed scaphoid (S), the capitate (C), and the extended lunate (L). A complete disruption of the scapholunate interosseous ligament (SLIL) is noted. The arrow points at the ulnar-based capsular flap. C. Intraoperative photo showing the scaphoid on the left and the SLIL still attached to the lunate on the right (held by forceps). The capitate head is seen distal to the lunate at the top of the photo. D. Intraoperative photo after suture anchor placement into the scaphoid at the dorsal SLIL footprint on the left, then passed through the SLIL shown on the right. The joystick Kirschner wires are placed into the scaphoid and the lunate in such a manner that when they are brought together, the dorsal intercalated segment instability (DISI) deformity will be corrected and the joint reduced. E. Intraoperative photo after reduction of the joint and DISI deformity using the joystick Kirschner wires and suture repair of the avulsed SLIL. The Kirschner wires in the scaphoid and in the lunate have been brought together from their divergent positions and are now in the same plane, correcting the DISI deformity. The two Kirschner wires have been placed from radial to ulnar (seen on the left of the image), passing through the scapholunate interval and scaphocapitate interval. F,G. AP and lateral intraoperative fluoroscopic images demonstrating Kirschner wire placement across the scaphocapitate joint and the reduced scapholunate joint. Suture anchors can be seen in the scaphoid at the dorsal SLIL footprint. This example shows a third, more distal suture anchor at the scaphoid that was used for dorsal capsule augmentation.
TECHNIQUES

■ Place these wires parallel to the scapholunate joint about 5 mm from the articular surface.
■ The scaphoid joystick should angle proximally and the lunate joystick should angle distally (TECH FIG 1D).
■ The Kirschner wire joysticks are brought together, taking the scaphoid out of flexion and the lunate out of extension to correct any dorsal intercalated segmental instability deformity and reduce the joint.
■ Preliminarily reduce the scapholunate joint and identify the anatomic insertion site for the SLIL.
■ Roughen the SLIL footprint to bleeding bone on the dorsal ulnar portion of the scaphoid and insert one or more mini suture anchors (2.0 or 2.5 mm).
■ Pass the sutures from the suture anchor through the SLIL stump but do not tie them (TECH FIG 1D).
■ With the joint reduced via the joysticks, drive two 0.045-inch smooth Kirschner wires from the scaphoid into the lunate across the reduced scapholunate joint and drive one or two 0.045-inch Kirschner wires through the waist of the scaphoid into the capitate (TECH FIG 1E–G).
■ Secure the SLIL to the prepared site by tying the suture anchor sutures.
■ Remove the joystick Kirschner wires and cut the remainder of the Kirschner wires below the skin.
■ Suture anchors are placed at the DIC footprint on the dorsal more distal scaphoid should it be avulsed and need repair or should capsular flap augmentation be desired (see Direct SLIL Repair with Dorsal Capsulodesis).
■ Close the capsule with 3–0 absorbable suture.
■ Transpose the EPL tendon subcutaneously and repair the extensor retinaculum with 3–0 absorbable suture.

DIRECT SLIL REPAIR WITH DORSAL CAPSULODESIS

■ Indications
  ■ Tenuous SLIL repair
  ■ Chronic scapholunate dissociation (>6 weeks) without arthritis
    ▪ The deformity must be reducible and not fixed.
  ■ Should capsulodesis be required for augmentation, perform the SLIL repair as described above, making the same ulnar-based dorsal capsular incision.
  ■ After the SLIL is repaired, swing the ulnarly based capsular flap over the scapholunate interval and plan the location for its attachment to the scaphoid waist.
  ■ Plan to secure the flap under tension to further stabilize the scapholunate joint.
  ■ Place one or two mini suture anchors (1.8 or 2.0 mm) into the scaphoid at the determined location and another mini suture anchor dorsal-central into the lunate.
  ■ With the capsular flap pulled taut, pass the scaphoid suture anchor sutures through the flap. Then pass the lunate sutures through the central aspect of the flap, estimating suture location to maximize stabilization of the scapholunate joint.
  ■ Once all sutures from the scaphoid and the lunate are placed through the capsular flap, tie them down (TECH FIG 2).

PEARLS AND PITFALLS

| Fluoroscopy | By moving the fluoroscopy unit perpendicular to the patient with the C-arm parallel to the floor and locking all the joints but the most distal fulcrum, the amount of “fighting” with the fluoroscopy unit is minimized. |
| Buried Kirschner wires | Buried Kirschner wires require removal in the operating room but minimize the risk of pin tract infection. |
| Posterior interosseous nerve neurectomy | Consider performing a posterior interosseous nerve neurectomy during the procedure. Identify the nerve on the floor of the fourth extensor compartment, cauterize it and its accompanying vessel, then resect a segment. |
| Joystick placement during reduction of the scapholunate joint | Place the scaphoid Kirschner wire distal in the scaphoid, angling proximally. Remember the scaphoid is flexed and most of the cartilage you will see initially is the radiocarpal articular portion of the scaphoid. Similarly, place the lunate Kirschner wire proximally, angling in a distal direction to correct its extended position. |
POSTOPERATIVE CARE
- The wrist is immobilized in a short-arm thumb spica splint immediately after surgery.
- Sutures are removed at 2 weeks and the wrist is placed into a short-arm thumb spica cast for 8 weeks.
- Radiographs are obtained at 2 and 4 weeks to evaluate reduction and any pin migration.
- Pins are removed at 8 weeks and the wrist is placed back into a short-arm thumb spica splint.
- Gentle active range-of-motion exercises are allowed at 8 weeks, out of the splint for exercises only.
- Immobilization is discontinued at 12 weeks.
- Full activities are allowed at 4 to 6 months.
- Forced hyperextension (push-ups) and axial loading are especially restricted during the 4- to 6-month postoperative period.

OUTCOMES
- Results following direct SLIL repair with capsulodesis are highly variable.
- By not crossing the radiocarpal joint with the capsulodesis, theoretically wrist motion will be maximized.
- Szabo et al. showed mean loss of wrist flexion of 10 degrees, extension of 15 degrees, radial deviation of 20 degrees, and ulnar deviation of 11 degrees at 2 years of follow-up for chronic (>6 weeks) SLIL tears treated with DIC capsulodesis.
- Grip strength was unchanged from the preoperative assessment (mean 41).
- Results of the procedure typically do not hold over time radiographically.
- Minimum 5-year follow-up for chronic SLIL tears treated with DIC capsulodesis showed:
  - Immediate postoperative scapholunate angle of 56 degrees at 5 years increased to 62 degrees
  - Immediate postoperative scapholunate gap of 2.6 mm at 5 years increased to 3.5 mm
  - Also, 50% of wrists show arthritic changes at 5 years.
- Radiographic changes have not correlated with clinical results over time.
- Wrist flexion decreased 19 degrees at 5-year follow-up compared with preoperative values.
- Extension and radial and ulnar deviation remained unchanged at 5 years from the immediate postoperative values shown above.
- Grip strength remained unchanged at 5 years (mean 43).
- Outcome instrument scores at 5 years (Mayo Wrist Score):
  - 38% excellent, 19% good, 31% fair, 12% poor outcomes
- No correlation between subjective pain scores and radiographic changes has been shown at 5 years.

COMPlications
- Pin tract infections (this risk is minimized with buried pins)
- Superficial radial nerve injury
- The surgeon should keep skin flaps thick when dissecting on top of the extensor retinaculum (this keeps the superficial radial nerve branches within the flaps).
- The surgeon should make a small stab incision to bluntly dissect down to bone to minimize risk of nerve injury during pin placement.
- Loss of scapholunate reduction
- Arthritic changes in the radiocarpal and midcarpal joints

REFERENCES
DEFINITION
- Scapholunate dissociation (SLD) is the rupture of the anatomic linkage between the scaphoid and lunate and its subsequent progressive dysfunction, with or without carpal malalignment.
- Classical radiographic signs occur only when there is permanent carpal malalignment. This is preceded by complete scapholunate disruption together with failure of the secondary scaphoid stabilizers, namely the scaphotrapezial-trapezoid ligament (STT), the scaphocapitate (SC) ligament, and the radioscapohamate (RSH) ligament.
- However, in many cases, only partial tears or ligament sprains occur and do not produce positive radiologic signs. These injuries are often seen only arthroscopically.
- Dorsal capsulodesis of the radioscapohamate joint was first described by Blatt.2 Now it is one of the most commonly used techniques in the treatment of carpal instability. This procedure involves the creation of a dorsal capsular flap.

ANATOMY
- Scapholunate ligaments are divided into three fibrous structures:
  - Dorsal ligament
  - Volar ligament
  - Thin proximal membrane
- Anatomically, the dorsal scapholunate ligament is the thickest and shortest of the fibrous structures, measuring 2 to 3 mm thick and 2 to 5 mm long. Biomechanically, it is the strongest and most resistant to failure under load (FIG 1A).1 The radioscapohamate (Testut) ligament is only a path for vascularization and innervation of the scaphoid and lunate.
- Scaphoid position and relationship with lunate and distal carpal row is maintained by the scapholunate ligaments and by the secondary stabilizers (STT, SC, and RSH ligaments), which prevent excessive scaphoid flexion. These are called secondary stabilizers (FIG 1B).
- The flexor carpi radialis tendon is closely related to the scapholunate joint and acts as a crucial dynamic stabilizer of the scaphoid, preventing it from going into excessive flexion and pronation during a firm grip of an object (FIG 1C).

PATHOGENESIS
- Injury to the scapholunate ligaments occurs when the wrist is hyperextended, ulnarly deviated, and supinated during a fall on an outstretched hand. Because of the osseous configuration and disposition of the bones of the proximal carpal row, when the hand hits the floor, the tubercle of the scaphoid is pushed dorsally and extended. The lunate is held in position by the volar radiolunate (RL) ligaments and resists the tendency to extension transmitted by the scaphoid. The impact of the hand on the floor also pushes the pisiform against the triquetrum and because of the configuration of the joint between the triquetrum and the hamate, the former turns into flexion. If forces exceed the ligaments’ resistance, they will rupture.
- The sequence of failure of the ligaments is from palmar to dorsal. The first to tear is the volar scapholunate ligament, the weaker of the two scapholunate ligaments, followed by the dorsal scapholunate ligament.3
- The participation of the dorsal intercarpal ligament (DICL) in scapholunate instability has been recently supported by the studies of Mitsuyasu et al.8

NATURAL HISTORY
- Most SLDs present as the initial stage of a progressive carpal destabilization. The mechanism of injury produces a spectrum of injuries, ranging from mild scapholunate sprains to complete perilunar dislocations, all being different stages of the same progressive perilunar destabilization process as described by Mayfield et al.9
- If only the palmar scapholunate ligament and the proximal membrane are disrupted, minor kinematic alterations result in predynamic instability. There is no gross carpal malalignment but because there is an increased motion between the scaphoid and lunate causing shear stress, these injuries may be sufficient to promote painful synovial inflammation.
- Complete disruption of the scapholunate ligament complex leads to substantial alteration in kinematic and force transmission parameters (demonstrated in cadaver specimens), but not necessarily static carpal malalignment.8,13 This results in a dynamic instability. The scaphoid is unconstrained at the proximal end, resulting in increased radiolunate motion and correspondingly decreased radioscapoid motion. This is accentuated in a loaded wrist.
- When the secondary stabilizers start to attenuate after repeated use of the wrist, carpal malalignment develops, eventually resulting in static instability. Initially the scaphoid is still reducible, but over time it becomes permanently flexed and pronated (see “Imaging and Other Diagnostic Studies”).
- If the alteration in the motion of the scaphoid persists, the cartilage degenerates and arthrosis develops. This pattern of degeneration is known as scapholunate advanced collapse (SLAC).
- Once arthrosis is present, surgical techniques directed at replacing or reconstructing the injured ligaments are no longer options.
- SLD is a progressive entity. Therefore, reconstruction is advocated as soon as it is diagnosed.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Almost always, patients present after a fall on their outstretched hand. The patient complains of dorsal hand and wrist pain when loading the affected wrist, such as when standing up from a chair.
Predynamic and dynamic stages of SLD are often missed or overlooked. The injury usually is the result of isolated trauma, which the patient does not clearly remember, or is masked by other more severe or obvious injuries (eg, fractured scaphoid and distal radius). A high index of suspicion is required.

- Weakness of grip strength, occasional swelling over the dorsoradial wrist, point tenderness over the scapholunate interval (more pronounced with gripping), and radial-sided wrist pain after excessive or heavy use are common but subtle physical examination findings.
  - The examiner should palpate the scapholunate interval dorsally (1 cm distal to the tubercle of Lister) with the wrist in 30 to 50 degrees of flexion.
  - On palpation of the anatomic snuffbox and palmar scaphoid tubercle, tenderness may also be present, suggesting ligament involvement, synovitis, or an occult ganglion.
  - Provocative tests such as the Watson scaphoid shift test and resisted finger extension test reinforce the possibility of the diagnosis.
  - Watson scaphoid shift test: The scaphoid flexes as the wrist goes from ulnar to radial deviation. The examiner’s thumb prevents the scaphoid from flexing and if the scapholunate ligament is torn or incompetent, the proximal pole subluxates dorsally out of the scaphoid fossa, causing pain. When the thumb pressure is released, there may be a snap, signifying spontaneous reduction of the scaphoid back into the scaphoid fossa. This test is not highly specific and may signify synovitis, an occult ganglia, or radioscaphoid impingement.
  - Sharp pain on the resisted finger extension test has low specificity but high sensitivity.

### IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographs
  - Posteroanterior (PA) view
    - Elbow flexed at 90 degrees, neutral prono-supination, and the middle finger aligned with the forearm axis. The palm of the hand is in full contact on the film case.
    - Scapholunate gap greater than 3 mm or wider than the contralateral normal side and a cortical “ring” sign suggest static scapholunate dissociation.
    - Decreased space between the radius and the scaphoid signifies cartilage loss and arthrosis.
  - Anteroposterior (AP) view
    - Forearm is in maximal supination.
    - This projection puts the scapholunate interval aligned with the beam of the ray.
  - Lateral view
    - Elbow at 90 degrees of flexion, middle finger aligned with the forearm, and wrist at 0 degrees of extension or flexion
    - This projection allows measurement of the scapholunate angle. An angle greater than 60 degrees indicates disruption of the scapholunate ligaments and often corresponds with widening on the PA and AP views.
    - Clenched-fist AP view demonstrates a widened scapholunate gap compared to the normal side (FIG 2A).
    - Cineradiography reveals abnormal movements between the scaphoid and lunate and an increase in the scapholunate gap as the wrist moves from radial to ulnar deviation.

---

**FIG 1**

- **A.** The elements that maintain the scaphoid in its normal position.
- **B.** Volar view of secondary stabilizers.
- **C.** The dynamic stabilizer of the scaphoid.
**DIFFERENTIAL DIAGNOSIS**
- Occult ganglia
- Synovitis
- Scaphoid fracture, nonunion, and avascular necrosis
- Radiocarpal arthrosis
- Radioscaphoid impingement

**NONOPERATIVE MANAGEMENT**
- Initial conservative management aims at resting the injured limb and decreasing edema. Adequate immobilization with casting or splinting is advocated.
  - This immobilization is frequently therapeutic for patients with predynamic SLD.
  - Elevation of the limb and active finger motion minimize edema.
  - Anti-inflammatory medications can be given for pain relief.
- Physiotherapy may have a role if a Geissler grade 1 is diagnosed by arthroscopy. As the ligaments have not lost their integrity, a period of short immobilization (2 weeks), followed by proprioception re-education of the flexor carpi radialis (FCR), as dynamic stabilizer of the scaphoid, is suggested.
- Nonoperative treatment is seldom indicated when a significant disruption is diagnosed.

**SURGICAL MANAGEMENT**
- Capsulodesis is part of the surgical armamentarium for the treatment of SLD. It is indicated for predynamic SLD, resulting from an isolated partial tear of the scapholunate ligament, and for dynamic SLD when the following criteria are fulfilled:
  - Complete disruption of all scapholunate components (palmar and dorsal)
  - Technically repairable dorsal ligament that has good healing potential
  - Intact secondary stabilizers
  - No cartilage degeneration
- Capsulodesis is not indicated when static SLD is present.

**Arthrologic (Geissler) Grading of Interosseous Ligament Tears**

<table>
<thead>
<tr>
<th>Grade</th>
<th>Description</th>

See also Chap. HA-41.
Capsulodesis is used either as an isolated procedure together with Kirschner wire stabilization of the scapholunate joint in predynamic cases, or in combination to augment a direct repair of the dorsal scapholunate ligament in dynamic cases. Due to its structure and position within the wrist, the scaphoid has an inherent tendency to flex and pronate, especially when the wrist is in flexion and radial deviation. The capsular flap created during dorsal capsulodesis acts as a checkrein to tether the scaphoid, preventing it from going into excessive flexion and pronation.

Preoperative Planning
- All preoperative radiographs and diagnostic studies, especially arthroscopic findings, are reviewed.

Positioning
- The patient is under anesthesia and in the supine position with hips and knees flexed at 30 degrees for low back comfort. The arm is exsanguinated and the tourniquet inflated at 250 mm Hg.
- The arm is on the hand table in pronation, presenting the dorsal aspect of the wrist.

BLATT CAPSULODESIS

Exposure
- The tubercle of Lister and the radial styloid are identified by palpation.
- An oblique skin incision is made following a line from a point 1 cm distal and ulnar with respect to the tubercle of Lister, to a point 1 cm distal to the radial styloid (TECH FIG 1).
- Veins are coagulated or ligated.
- Care is taken to identify the branches of the superficial radial nerve and mobilize and retract them with the subcutaneous tissue. This is accomplished taking all the fat with the skin as a flap.
- Communicating vessels from the superficial layers to the deep arches are divided and coagulated.
- The extensor retinaculum overlying the fourth dorsal extensor compartment is incised. The extensor retinaculum is then raised as two flaps, radially and ulnarly based, to free the extensor tendons from the second to fourth compartments.
- A neurectomy of the posterior interosseous nerve can be performed at this point.
- The extensor digitorum communis (EDC) is retracted ulnarily and the extensor pollicis longus (EPL) and extensor carpi radialis brevis (ECRB) radially to expose the dorsal capsule.

Creation of the Capsular Flap
- A rectangular capsular flap, 25 mm long and 10 mm wide, is created by making a transverse capsular incision just proximal to the vascular dorsal carpal arch and elevating the tissue in a distal to proximal direction, leaving the proximal end still attached to the dorsal rim of the distal radius (TECH FIG 2A).
- As the flap is elevated, the scaphoid is exposed (TECH FIG 2B).
- At the dorsum of the scaphoid, a trough is created at a point distal to the axis of rotation of the scaphoid (scaphoid neck) (TECH FIG 2C).

Reducing the Instability
- If the instability is acute, a primary repair of the scapholunate ligament is performed.
- The space between scaphoid and lunate is reduced, using a 1.1-mm Kirschner wire inserted in the scaphoid as a joystick, and then another Kirschner wire is placed in the scaphoid and fixed to the lunate.
- This step should be performed under radiologic guidance. The scapholunate angle in which these bones are fixed should be 45 ± 5 degrees.
- When fixing the scaphoid to the lunate, ensure that the lunate is in a neutral position.
If the capsulodesis is being performed for predynamic instability, the scaphoid is fixed to the lunate in its normal alignment. This is also accomplished by means of a Kirschner wire as described earlier.

Another Kirschner wire is passed from the scaphoid into the capitate to avoid flexion and pronation (TECH FIG 3).

### Securing the Capsular Flap and Wound Closure

- The flap is tightly inserted into the notch created on the dorsum of the scaphoid.
- There are two ways of securing the proximally based capsular flap to the scaphoid:
  - The flap is secured through holes created in the notch and transosseous sutures that are tied on the volar surface of the scaphoid tubercle.
  - The flap is secured to the sutures of a bone anchor (authors’ preferred method) (TECH FIG 4).
- The dorsal capsule is left in situ. The extensor retinaculum is closed with resorbable sutures.
- Layered closure of the wound and skin is performed.

**TECH FIG 2 • (continued)**

B. Capsular flap is elevated, allowing visualization of the scaphoid, lunate, and head of the capitate. C. Intraoperative photo showing the scaphoid (S), the capitate (C), and the dorsal scapholunate ligament (SL). A bone trough has been created in the distal scaphoid for insertion of the capsular flap. KW, Kirschner wire in the lunate. (C: Courtesy of A. Lluch, Institut Kaplan.)

---

**TECH FIG 3 • Orientation of the Kirschner wires recommended to stabilize the joints and protect the capsulodesis.**

---

**TECH FIG 4 • A. Placement of two bone anchors in the distal dorsal scaphoid. B. The proximally based capsular flap is prepared for insertion. (continued)**
This method is very similar to Blatt’s technique, the difference being that the capsular flap is distally based. There is no clear advantage to this technique over that described by Blatt.

The same approach is used and the same capsular flap created except that the tissue is left attached to the distal third of the scaphoid. The flap is incised at the radiocarpal joint, tensioned proximally, and anchored to the dorsal radius using a suture anchor. This force extends the distal pole of the scaphoid, reducing the scapholunate joint (TECH FIG 5).

The same approach is used and the same capsular flap created except that the tissue is left attached to the distal third of the scaphoid.

This elevated flap includes the proximal half of the DICL. Separate this portion of the DICL from the capsular tissue in an ulnar to radial direction, maintaining the radial insertion of the ligament.

Transfer this strip of ligament to the dorsum of the lunate into a prepared cancellous trough (TECH FIG 6). This will create a link between scaphoid and lunate, preventing scaphoid flexion and pronation.

The ligament is secured by tying to the suture anchor(s) in the lunate.

This technique represents a variation of a previous version described by Taleisnik and Linscheid\(^{15,17}\) in which the flap was attached to the dorsum of the distal radius.

**HERBERT TECHNIQUE**

- This method is very similar to Blatt’s technique, the difference being that the capsular flap is distally based.
- There is no clear advantage to this technique over that described by Blatt.

**BERGER CAPSULODESIS**

- Use the same approach and exposure as described for the Blatt capsulodesis.
- Raise a rectangular, radially based, capsular flap to allow exposure of the carpus. Its ulnar margin is the radiotriquetral ligament, its proximal margin is the radius, and its distal margin is the midsurface of the DICL.
- This elevated flap includes the proximal half of the DICL. Separate this portion of the DICL from the capsular tissue in an ulnar to radial direction, maintaining the radial insertion of the ligament.
- Transfer this strip of ligament to the dorsum of the lunate into a prepared cancellous trough (TECH FIG 6).
- This will create a link between scaphoid and lunate, preventing scaphoid flexion and pronation.
- The ligament is secured by tying to the suture anchor(s) in the lunate.
- This technique represents a variation of a previous version described by Taleisnik and Linscheid\(^{15,17}\) in which the flap was attached to the dorsum of the distal radius.
**POSTOPERATIVE CARE**

- Blatt recommended wearing a thumb spica cast for 2 months, after which active range-of-motion exercises were begun. The Kirschner wires were left in place for another month before removal, allowing intercarpal motion at 3 months postoperatively. Forceful stress was discouraged for up to 6 months postoperatively.

- We prefer 6 weeks of immobilization in a rigid splint, avoiding extreme motions for one additional month. Kirschner wires can be removed at 8 weeks from the time of surgery.

**OUTCOMES**

- A number of clinical series have reported good results with these procedures.\(^2\)\(^{-}\)\(^4\)\(^,\)\(^6\)\(^,\)\(^7\)\(^,\)\(^10\)\(^-\)\(^12\)\(^,\)\(^14\)\(^,\)\(^16\)\(^,\)\(^18\)\(^,\)\(^19\) The agreement of these series is that tensioning or augmenting the dorsal radioscaphoid capsule offers less surgical morbidity than other alternatives.

- Forceful stress was discouraged for up to 6 months postoperatively.

- The Kirschner wires were left in place for another month before removal, allowing intercarpal motion at 3 months postoperatively.

**OUTCOMES**

- A number of clinical series have reported good results with these procedures.\(^2\)\(^^{-}\)\(^4\)\(^,\)\(^6\)\(^,\)\(^7\)\(^,\)\(^10\)\(^-\)\(^12\)\(^,\)\(^14\)\(^,\)\(^16\)\(^,\)\(^18\)\(^,\)\(^19\) The agreement of these series is that tensioning or augmenting the dorsal radioscaphoid capsule offers less surgical morbidity than other alternatives.

- The radial insertion is incised at the level of the trapezium, trapezoid, and distal third of the scaphoid and then transferred to the scaphoid at the level of the scapholunate ligament insertion.

- The transferred ligament may also be integrated into the scapholunate ligament repair more proximally.

- The transferred ligament is secured using suture anchor(s) into a cancellous trough in the scaphoid.

- Like the Berger capsulodesis, this technique does not specifically limit wrist flexion as it does not cross the radiocarpal joint.\(^14\)

**TZABO TECHNIQUE**

- The DICL is used to stabilize the scapholunate interval as above except the ligamentous tissue is ulnarily based and is inserted into the scaphoid rather than the lunate (TECH FIG 7).

- Typically a longitudinal capsular incision is used to expose the carpus.

- Care is taken to avoid incising the DICL.

- The DICL is defined and its proximal half separated.

- The radial insertion is incised at the level of the trapezium, trapezoid, and distal third of the scaphoid and then transferred to the scaphoid at the level of the scapholunate ligament insertion.

- The transferred ligament may also be integrated into the scapholunate ligament repair more proximally.

- The transferred ligament is secured using suture anchor(s) into a cancellous trough in the scaphoid.

- Like the Berger capsulodesis, this technique does not specifically limit wrist flexion as it does not cross the radiocarpal joint.\(^14\)

---

**TECH FIG 7** • Szabo’s technique involves transfer of the distal half of the dorsal intercarpal ligament from its attachment to the trapezium and trapezoid (x) to the distal third of the dorsum of the scaphoid (y).
COMPLICATIONS

- Reduction of wrist flexion (FIG 3)
- Failure
- Progression of SLD

REFERENCES

DEFINITION

- Scapholunate dissociation (SLD) is a symptomatic wrist dysfunction that results from partial or total rupture of the scapholunate ligamentous complex, with or without carpal malalignment.
- It may appear either as an isolated injury, or associated with distal radius fractures or displaced scaphoid fractures. Usually the result of trauma (hyperextension and ulnar deviation injury to the wrist), SLD may also result from a chronic inflammatory arthropathy (rheumatoid arthritis, chondrocalcinosis).

ANATOMY

- Under load the scaphoid is inherently unstable owing to its oblique alignment relative to the direction of axial forces being transmitted across the wrist. The amount of instability depends on the following factors:
  - The geometry of the radioscapoid joint (the deeper the scaphoid fossa, the less unstable)
  - The stabilizing efficacy of the periscaphoid ligaments (proximal scapholunate intersosseous ligament complex, dorsal scaphotriquetral [STq], palmar scaphocapitate [SC] and lateral scapho-trapezial-trapezoidal [STT] ligaments)
  - The indirect action of the flexor carpi radialis (FCR) muscle
  - The scapholunate interosseous ligament complex consists of three structures: the two scapholunate ligaments (palmar and dorsal) and the proximal fibrocartilaginous membrane.
  - The proximal membrane connects the two adjacent convex borders of the two bones from dorsal to palmar, separating the radiocarpal and midcarpal joint spaces (FIG 1).
  - The dorsal scapholunate ligament is formed by dense, slightly oblique connective fibers that link the dorsal aspects of the scaphoid and lunate bones.
  - The palmar scapholunate ligament has longer, more obliquely oriented fibers, allowing substantial rotation of the scaphoid relative to the lunate.
  - The dorsal scapholunate ligament has the greatest yield strength (260 Newtons [N] on average), followed by the palmar scapholunate ligament (118 N) and the proximal membrane (63 N).2
  - The proximal portion of the membrane often appears perforated in middle-aged and older individuals, which does not cause instability.

PATHOGENESIS

- When axially loaded, the three proximal bones do not react equally in terms of direction of rotation. The scaphoid tends to rotate into flexion and pronation while the triquetrum is pulled into extension by the dorsally subluxing hamate bone (FIG 2A).
  - If both the palmar and dorsal scapholunate and lunotriquetral (LTq) ligaments are intact, such differences in reactive motion generate increasing torques at both scapholunate and LTq levels, resulting in an increasing coaptation of these joints. Such an increased coaptation further contributes to the proximal carpal row stability (FIG 2B).
  - If the scapholunate ligaments are completely torn, the scaphoid no longer appears constrained by the rest of the proximal row, and tends to collapse into an abnormally flexed and pronated posture (“rotatory subluxation of the scaphoid”).
  - By contrast, the lunate and triquetrum translate ulnarly while rotating abnormally into extension, a pattern of carpal malalignment known as a dorsal intercalated segment instability (DISI) (FIG 2C).

NATURAL HISTORY

- Partial scapholunate ligament injury may not be radiologically demonstrable and may not produce symptoms unless the wrist is overloaded (predynamic instability).
  - If left untreated, a partial scapholunate tear may progress toward a more complete disruption of all three elements of the scapholunate joint, in which case a symptomatic dysfunction usually appears.
  - Radiographically, a gap between the scaphoid and lunate may be seen. This, however, is visible only under certain loading conditions (dynamic instability).
With time, the secondary stabilizers (STT and SC ligaments) may stretch out and become inefficient. In such circumstances, the wrist may progress toward permanent malalignment (static instability) (FIG 3A, B).

- The wrist moves abnormally, with the lunate decreasing its range while progressively adopting an extended position (DISI).
- Conversely, the scaphoid adopts a flexed collapsed position, with its proximal pole subluxing dorsoradially over the edge of the radioscapoid fossa (FIG 3C).

- The abnormal joint contact between radius and scaphoid may cause cartilage deterioration of the proximal pole of the scaphoid and the reactive formation of an osteophyte at the tip of the radial styloid. This condition is known as scapholunate advanced collapse (SLAC), stage 1.
- If untreated, SLAC stage 1 may progress toward a more extended cartilage loss involving the entire scaphoid fossa (SLAC stage 2).
- As the lunate becomes fixed in DISI, the dorsally subluxing capitate may present with cartilage deterioration progressing...
from radial to ulnar until it involves the entire capitoluminate joint (SLAC stage 3).

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Two clinical situations lead to a diagnosis of SLD. One is the patient who presents following violent trauma, such as a fall from a height or a motorcycle accident, who is likely to have a major carpal derangement. Another is the patient who may not recall specific trauma and yet presents with symptoms.
- In the first case, the diagnosis of a major SLD may be obvious.
- In the second case, identification of the true nature of dysfunction may require a high index of suspicion, careful examination, and appropriate diagnostic tools.
- Not uncommonly, arthroscopy is the only way to fully assess the extent of ligament derangement (see Chap. HA-41).
- In both dynamic and static SLD, swelling may be moderate. In acute cases, range of motion may be limited by pain, whereas it may be normal in chronic cases.
- Scapholunate point tenderness: If sharp pain is elicited by pressing this area, the probability of localized synovitis is high. Not all synovitis represents an injury to the scapholunate joint. Occult ganglia may present with a similar type of pain on palpation.
- The resisted finger extension test\(^9\) has low specificity but excellent sensitivity. In the presence of scapholunate injury, sharp pain is elicited at the scapholunate area, representing dorsal subluxation of the scaphoid.
- Scaphoid shift test\(^8\): If the scapholunate ligaments are completely torn, the proximal pole may sublux dorsally out of the radius, inducing pain on the dorsoradial aspect of the wrist. This test has low specificity: occult ganglia, hyperlaxity, or radioscaphoid degenerative arthritis may produce similar symptoms.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Posteroanterior radiographic view of the neutral positioned wrist
  - Increased scapholunate joint space compared with the contralateral side (Terry Thomas sign) suggests static SLD.
  - A foreshortened appearance of the scaphoid with the scaphoid tuberosity projected in the form of a ring over the distal two thirds of the scaphoid (ring sign) indicates rotatory subluxation of the scaphoid. The ring sign is not specific for SLD; it may also be present in static LTq dissociations.
- Lateral radiographic view
  - Increased scapholunate angle compared with the contralateral side. For this to be significant, the wrist needs to be in strict neutral alignment and neutral pronosupination.
  - Arthroscopy is the gold standard technique in the diagnosis of SLD. It is also useful in describing the degree of injury to the interosseous ligaments.\(^4\)
- Magnetic resonance imaging may provide useful information regarding ligament integrity, bone vascularity, presence of local synovitis, and other soft tissue status.

**STAGING**

- **SLD stage 1**: Partial scapholunate ligament injury. Normal wrist alignment. Usually diagnosed by arthroscopy. No abnormal scapholunate gap (Table 1).\(^4,5\)

- **SLD stage 2**: Complete scapholunate ligament injury, reparable. Complete disruption of scapholunate ligaments, the dorsal one being still repairable, with good healing potential. Normal wrist alignment.
- **SLD stage 3**: Complete scapholunate ligament injury, non-reparable, normally aligned scaphoid. Dorsal scapholunate ligament with poor healing capability. Normal carpal alignment.
- **SLD stage 4**: Complete scapholunate ligament injury, non-reparable, reducible rotary subluxation of the scaphoid. Complete SLD plus detachment of the dorsal LTq ligament off the distal margin of the lunate, plus insufficiency of the distal scaphoid stabilizers (STT and SC ligaments). Rotary subluxation of the scaphoid. Radioscaphoid angle greater than 45 degrees. The lunate may appear abnormally ulnarly translated and in DSI.
- **SLD stage 5**: Complete scapholunate ligament injury with irreducible malalignment, but normal cartilage. Fixed, irreducible long-lasting malalignment, without cartilage degeneration.
- **SLD stage 6**: Complete scapholunate ligament injury with irreducible malalignment and cartilage degeneration. Chronic dysfunctional wrists with cartilage degeneration (SLAC).

**NONOPERATIVE MANAGEMENT**

- Acute, minimally dysfunctional SLD, stage 1, may respond well to a period of 3 to 5 weeks of wrist immobilization, anti-inflammatory medication, and subsequent physical rehabilitation.
- Re-education of the dynamic scaphoid stabilizing capability of the FCR muscle may be helpful in minimal scapholunate dysfunctions. The FCR uses the scaphoid tuberosity as a hinge toward its distal insertion into the second metacarpal base. Its contraction generates a dorsally directed vector to the unstable scaphoid that prevents its collapse into flexion. Optimization of the time response of the FCR muscle to wrist loading may prevent progression of scapholunate ligament disruption (FIG 4).\(^4\)

**SURGICAL MANAGEMENT**

- Partial ligament injuries may create discomfort from joint irritation by the ligament remnants. Arthroscopic débridement of these fragments may solve this problem.
- Electrothermal shrinkage of stretched scapholunate ligaments has been shown to be beneficial in selected cases of dynamic
instability. Careful control of intra-articular fluid temperature is mandatory. Burns are not rare if lasers are carelessly applied.4

- Tendon reconstruction of the scapholunate linkage is recommended only in SLD stages 3 or 4—that is, when there is a nonreparable complete scapholunate ligament injury causing carpal malalignment. For this to be successful, however, it is very important that:
  - The malalignment is easily reducible, and
  - The periscaphoid cartilages are completely normal
  - No soft tissue reconstruction can achieve effective carpal stability if the malalignment cannot be reduced with minimal force.
  - Intra-articular fibrosis is the most common cause of irreducibility.
  - Heavy manual workers are not good candidates for this treatment modality; they may require a more solid form of stabilization, such as a partial fusion.
  - Tendon reconstruction cannot solve the loss of protective capsular proprioception, and therefore tenodeses are likely to deteriorate with time if chronically overstressed.

**Preoperative Planning**
- A complete set of plain radiographic views and stress views are mandatory.
- Arthroscans (tomograms taken after three-compartment injection of dye) are very useful to assess cartilage status.
- Best-quality magnetic resonance imaging may provide useful accessory information regarding bone vascularity, synovitis effects, and soft tissue status.
- Arthroscopy is by far the best tool for preoperative planning.

**Positioning**
- An axillary block is used. The patient is in the supine position. The arm is exsanguinated.

**Approach**
- An 8-cm dorsal zigzag, lazy S, or longitudinal incision of the skin and subcutaneous tissue is centered on the tubercle of Lister.
- The dorsal sensory branches of the radial and ulnar nerves are identified and protected.
- The extensor retinaculum is divided along the third compart- ment and the extensor pollicis longus tendon is retracted radially.
- The retinacular septa between compartments II and V are sectioned and the two retinacular flaps so created are retracted. Most septa contain intraseptal vertical vessels that need to be carefully coagulated (FIG 5).

**TECHNIQUES DORSAL LIGAMENT-SPLITTING CAPSULOTOMY (BERGER ET AL1)**

- The first incision is made along the dorsal rim of the radius to the center of the lunate fossa.
- The second incision is made from the end of the first incision following the fibers of the dorsal radiotriquetral ligament to its distal insertion onto the dorsal ridge of the triquetrum (TECH FIG 1A).
- The third incision is made from the STT joint progressing medially along the dorsal intercarpal ligament to its insertion onto the dorsum of the triquetrum.
- By connecting the last two incisions, a radially based capsular flap is created. This flap is carefully elevated by sectioning its connections to the dorsal edge of the three bones of the proximal row (TECH FIG 1B).
- It is important to leave enough dorsal RTq ligament attached to the triquetrum in order to facilitate later ten- sioning of the tendon reconstruction.

**FIG 4** The flexor carpi radialis (FCR) tendon is in close relationship to the scaphoid tuberosity. Based on this, the scaphoid flexion tendency that appears when the bone is unstable can be effectively compensated by the dynamic action of the FCR muscle. Indeed, proprioception re-education of this muscle may be useful in stage 1 scapholunate dissociation.

**FIG 5** Dorsal approach to the wrist through a longitudinal incision. The extensor retinaculum has been divided along the third compartment and retracted in the form of two flaps, radial and ulnar. Extensor tendons are uncovered.
TECH FIG 1 • A. A radially based capsular flap is created by incising the dorsal capsule along the fibers of both the dorsal radiotriquetral ligament and the dorsal intercarpal ligament. B. Once the capsular flap is retracted radially, the scapholunate injury can be inspected (arrow) and a final therapeutic decision can be made.

PALMAR SCAPHOTRAPEZOID PLUS DORSAL RADIOSCAPHOID TENODESIS (BRUNELLI AND BRUNELLI)\(^3\)

- Beginning at the level of the distal pole of the scaphoid, using small transverse palmar incisions along the course of the FCR, a strip of the FCR tendon is obtained.
- The strip is incised at the musculotendinous junction and left attached distally.
- The size of graft harvested depends on the size of the scaphoid and bone tunnel created.
- A 2.7- to 3.2-mm drill hole is started volarly at the distal pole of the scaphoid, entering at the front of the scaphoid tuberosity to emerge dorsally at the level of the scaphoid neck.
- Using a tendon passer or a wire loop, the tendon strip is passed through the bone tunnel.
- While maintaining the proximal pole of the scaphoid reduced on its fossa, two Kirschner wires are passed across the scaphocapitate joint.
- Fluoroscopic assessment of reduction is important. Slight overreduction (radioscaphoid angle of about 60 degrees) is recommended.
- Later stretch of the tenodesis is likely, in which case the scaphoid will recover its ideal alignment of 45 degrees.
- While the wrist is maintained in neutral position, the tendon is tightly anchored to the area of the tubercle of Lister using transosseous nonabsorbable sutures or metal suture anchors (TECH FIG 2).
- The extensor retinaculum is repaired, leaving subretinacular drains. The extensor pollicis longus is usually left superficial to the extensor retinaculum.
- The capsular flap is passed underneath the tenodesis and reattached to its origins by absorbable sutures.

THREE-LIGAMENT TENODESIS (MODIFIED BRUNELLI’S TENODESIS\(^5,8\))

- The transscaphoid tunnel is not transverse across the distal scaphoid (as detailed above), but oblique along the longitudinal axis of bone, from dorsal to palmar, entering at the level of the original insertion site of the dorsal scapholunate ligament, aiming at the palmar tuberosity (TECH FIG 3A).
- So as not to damage the medial or lateral articular surfaces of the scaphoid, we recommend using a 2.7- to 3.2-mm cannulated drill over a Kirschner wire preset under fluoroscopy control.
- The FCR tendon strip is passed through the oblique scaphoid tunnel using a wire loop or a tendon passer (TECH FIG 3B).
- A transverse trough or channel is then made over the dorsum of the lunate with a rongeur. This trough needs to uncover cancellous bone, the only tissue able to generate proper healing of the tendon into bone (TECH FIG 3C).
- To obtain intimate contact between the tendon strip and the lunate cancellous bone, a small anchor suture is placed into the floor of the trough.
The distal end of the dorsal radiotriquetral ligament is then localized. By its insertion on the bone, a slit is created through which the tendon strip is passed volar to dorsal (TECH FIG 3D).

- The dorsal radiotriquetral ligament is used as a pulley to tension the ligament strip.

- The scaphoid, lunate, and capitate are reduced and stabilized with two 1.5-mm Kirschner wires prior to tensioning the tendon graft. One wire is placed across the scapholunate joint and one across the SC joint.

- It is critical to ensure reduction of the scaphoid and the lunate, elimination of any DISI deformity, and proper placement of the wires using fluoroscopy.

- Radially directed tension is applied to the tendon graft already placed around and through the dorsal radiotriquetral ligament (TECH FIG 3E).

- The tendon graft is secured tightly into the cancellous bone channel created in the lunate using the suture anchor (TECH FIG 3F).

- The end of the tendon strip is sutured onto itself with nonabsorbable 3-0 sutures (TECH FIG 3G,H).

- The capsular flap is brought back, over the tendon reconstruction, to its original position by suturing side-by-side the split fibers of the two ligaments involved in the capsulotomy. Some sutures are also placed connecting the capsule and the tendon loop to re-establish the normal capsular attachment to the dorsum of the scapholunate joint.

- The extensor retinaculum is finally reconstructed, drains are placed, and the skin is closed.

TECH FIG 3 • A. A 2.7-mm drill is used to create an oblique tunnel that enters the scaphoid beginning at the site where the dorsal scapholunate ligament originally inserted. The drill exits the scaphoid at the palmar scaphoid tubercle. B. With a tendon passer or a wire loop, the strip of FCR tendon is brought through the bone tunnel exiting dorsally. C. The strip of FCR tendon has been passed through the scaphoid tunnel. A trough has been carved onto the dorsal cortex of the lunate and a suture anchor inserted at that location. A slit has been developed along the fibers of the dorsal radiotriquetral ligament. D. The strip of FCR tendon has been passed through the ligament rent created along the fibers of the dorsal radiotriquetral ligament. E. The strip of FCR tendon is tensioned in a radial direction using the dorsal radiotriquetral ligament as a pulley. (continued)
PEARLS AND PITFALLS

**Indications**
- Never perform a tenodesis if the malalignment is not easily reducible, or if there is cartilage wear at the periscaphoid joints.

**Scaphoid tunnel placement**
- Drill a Kirschner wire from dorsal to palmar and from proximal to distal, aiming at the tuberosity. After fluoroscopy control, use a cannulated 2.7- or 3.2-mm drill depending on the size of the tendon strip obtained. It is best to have a tighter fit rather than a looser fit in the tunnel so that there is less "slop" in the system and potentially less likelihood of loss of reduction. The bone tunnel size, therefore, depends on the tendon graft thickness and also on the size of the scaphoid.

**Pin stabilization**
- One 1.5-mm Kirschner wire enters from the dorsoradial corner of the scaphoid across the scaphoid, aiming at the hook of the hamate.
- A second Kirschner wire enters from the palmar-radial corner of the scaphoid tuberosity, aiming at the lunate.
- Avoid Kirschner wires across the anatomic snuffbox (radial artery at risk).

**Fixation of the split tendon to the lunate**
- The anchor suture in the lunate is not to be used as anchor point for tendon tensioning, but only as a means to maintain the split tendon in full contact to cancellous bone. Tension of the tenodesis relies on the dorsal radiotriquetral ligament.

**Tensioning of the tenodesis**
- Avoid excessive reduction of the DISI by applying too much tension to the graft. A "volar intercalated segment instability" may be created, aside from affecting motion, or may even lead to necrosis.

POSTOPERATIVE CARE
- The wrist is immobilized in a well-padded splint including the metacarpophalangeal joint of the thumb for 10 days.
- After stitch removal, the wrist is maintained in a short-arm thumb spica cast for 5 more weeks.
- A protective removable splint is then fabricated. This will allow resting the joint between sessions of supervised physiotherapy. The splint is used for an additional 4 weeks.
- Before wire removal, at 8 weeks, therapy consists of only gentle radiocarpal mobilization. After pin removal, global active mobilization is emphasized. Aggressive passive mobilization is never recommended.
- Muscle strengthening exercises are not initiated until 10 weeks after surgery.
- Contact sports are to be avoided for 6 months after surgery.

OUTCOMES
- A recently published review of 38 patients with a symptomatic SLD who had a three-ligament tenodesis procedure, with a mean follow-up of 46 months, showed an average range of motion of about 75% of the contralateral side. Average grip strength was 65%. Pain relief at rest was obtained in 28 patients, with 8 complaining of mild discomfort during strenuous activity, and 2 having pain in most activities.
of daily life. Twenty-nine resumed their normal occupational-vocational activities. There were no signs of scaphoid necrosis. Recurrence of carpal collapse occurred in only two wrists. Nine patients showed mild signs of degenerative osteoarthritis at the tip of the radial styloid, but none had substantial symptoms.

COMPLICATIONS

- Recurrence of the malalignment and subsequent development of degenerative arthritis is common when the technique is used inappropriately, in cases with a poorly reducible SLD (stage 5), or when cartilage deterioration is already present (SLAC).
- When reducibility is in doubt, a more aggressive treatment (partial fusion or proximal row carpectomy) is recommended.

REFERENCES

DEFINITION

- Scapholunate ligament tears are the most common form of carpal instability.
- If left untreated, this injury will cause degenerative changes in the wrist.\(^3,6,8,13\)
- Complete tears of the scapholunate ligament exist, yet partial tears, or dynamic instability, occur as well. This diagnosis requires a high index of suspicion and specific imaging. Dynamic instability is defined as a wrist that maintains normal alignment at rest but will collapse with applied load. Consequently, stress radiographs or diagnostic arthroscopy is needed to make the diagnosis.\(^3,13\)
- Treatments of scapholunate ligament tears include primary repair, dorsal capsulodesis, tendon grafting, ligament reconstruction, proximal row carpectomy (PRC), and limited carpal arthrodesis.
  - Primary repair may not be possible if the remnant ligament is not amenable to repair.
  - Tendon weaves are technically challenging and do not recreate the unique motion between the scaphoid and lunate and thus may yield new problems. A PRC alters kinematics and may decrease grip strength.
  - Limited arthrodesis for the chronic scapholunate ligament tear with coincident radiocarpal arthrosis relieves pain but creates a decrease in range of motion and alters the mechanics of the wrist joint, potentially leading to degenerative changes in adjacent joints.\(^3,6,13\)

ANATOMY

- The scapholunate ligament is one of the many intrinsic ligaments of the wrist. It is intra-articular and is composed of collagen fascicles. It consists of three main parts: dorsal, membranous (or proximal), and volar (Fig 1).\(^1,11\)
- The dorsal portion is the strongest of the three. It is 2 to 3 mm thick and 3 to 5 mm long. Its collagen bundles are oriented transversely. It is most important in limiting dorsal–palmar translation. The most dorsal area always merges with the wrist articular capsule. More than 300 Newtons (N) of tensile stress is required for failure.
- The proximal or membranous portion is weak and thin. It is composed of mostly fibrocartilage and there are no neurovascular bundles within it (avascular). Only 25 N of stress will cause this portion of the scapholunate ligament to fail.
- The volar portion of the scapholunate ligament is only 1 mm thick and 4 to 5 mm long. Its collagen bundles are oriented obliquely. The volar and proximal portions are most important in limiting dorsal–palmar rotation. The volar and membranous portions of the scapholunate ligament are intersected by the loose radioscapholunate ligament (ligament of Testut). The amount of stress to failure here is 150 N.
- The scaphocapitate, scaphotrapezium–trapezoid (intrinsic), radioscaphocapitate, long and short radiolunate (volar extrinsic), dorsal radiocarpal, and dorsal intercarpal (dorsal extrinsic) ligaments also provide support and stability in this area.

PATHOGENESIS

- The mechanism of injury is often a fall on an outstretched hand. Mayfield et al\(^9\) described this injury occurring with an axial load in excessive dorsiflexion, ulnar deviation, and midcarpal supination. This position causes the capitate to separate the scaphoid (radial and dorsal) and lunate (ulnar and palmar).
- An ipsilateral distal radius fracture or scaphoid fracture can occur up to 30% of the time.\(^3,4\)
- The lunate will naturally flex with the scaphoid and extend with the triquetrum. In a patient with a scapholunate ligament injury, the connection to the scaphoid is lacking, the scaphoid will flex and rotate away from the lunate because of its other attachments, and the lunate will fall into a dorsal intercalated segment instability (DISI) pattern. For this rotational instability to occur, the dorsal capsular ligaments must be injured as well.
- An acute scapholunate injury may or may not coincide with an injury to the surrounding ligaments (ie, dorsal extrinsics). If it does, a DISI pattern may be noted soon after injury. If there is no injury to the surrounding structures, attenuation of these structures over time may occur and then subsequently cause a DISI pattern. When DISI does occur, this pattern of carpal instability must be corrected for any treatment of this injury to be successful.

NATURAL HISTORY

- The natural history of the wrist with a scapholunate ligament injury has been described by several authors. Pain and instability can result from a static injury. A DISI pattern deformity as described earlier will develop, and a very specific sequential pattern of wrist arthrosis will progress (scapholunate advanced collapse [SLAC]):
  - Stage IA: radial styloid with or without scaphoid arthrosis
  - Stage IB: radioscaphoid arthrosis
“complete” series to include a clenched-fist PA, a radial deviation PA, and flexion and extension lateral radiographs. It is helpful to compare the radiographs with the contralateral extremity.3,13

■ A static scapholunate ligament injury will reveal an increased space between the scaphoid and lunate on a PA radiograph. The normal scapholunate distance is less than 3 mm. If this interval is greater than 3 mm, the patient has what is known as the Terry Thomas sign. Additionally, as mentioned earlier, the scaphoid will collapse into flexion and the tuberosity will project in the coronal plane, revealing a scaphoid ring sign. The astute observer may also note the volar lip of the extended lunate overlapping with the capitate (FIG 2A–C).

■ The lateral radiograph may reveal an increased scapholunate angle. This angle is found by drawing lines through the longitudinal axes of the scaphoid and lunate and measuring the angle. Normally, it falls between 30 and 60 degrees. A radiolunate angle greater than 15 degrees indicates a DISI deformity (FIG 2D).

■ Flexion and extension lateral radiographs will show motion occurring at the lunocapitate joint and an uncoupling of the normally synchronous scapholunate motion.

■ Radial and ulnar deviation radiographs and a clenched-fist radiograph may portray a dynamic instability picture in that a static radiograph reveals no deformity (ie, normal scapholunate gap), but one of these views will reveal an abnormal scapholunate diastasis.

■ The chronic scapholunate injury may have evidence of arthritis on any of these views and the physician must recognize these findings, which indicate an old injury (FIG 2E,F).

■ Magnetic resonance imaging has become valuable in assessing acute or chronic scapholunate ligament tears (FIG 2G).

■ Arthroscopy is the imaging method of choice. It allows the experienced surgeon to diagnose most wrist pathology as well as affording the ability to possibly treat it (FIG 2H).

Geissler et al4 published four stages of scapholunate ligament tears based on arthroscopic examination (see Chap. HA-41).

DIFFERENTIAL DIAGNOSIS

■ Distal radius fracture
■ Scaphoid fracture
■ Radioscaphoid arthritis
■ Scaphotrapezial arthritis

DIFFERENTIAL DIAGNOSIS

Stage II: capitulonate arthrosis
Stage III: pan-arthritis
The radiolunate joint is typically spared.14,15

PATIENT HISTORY AND PHYSICAL FINDINGS

■ Commonly, the patient will describe radial-sided wrist pain, pain with loading activities, and weakness.
■ Physical examination methods include the following:
  ■ Observation and palpation of gross edema
  ■ Wrist range of motion in extension, flexion, ulnar, and radial directions. Decreased range of motion or pain with extremes of motion will be evident.
  ■ Palpation just distal to the tubercle of Lister to assess for scapholunate interval tenderness
  ■ Ballottement test: Pain or instability here is concerning for a scapholunate ligament tear
  ■ Watson test: Pressure on the scaphoid tuberosity during ulnar-to-radial deviation of the wrist prevents the scaphoid from normally flexing. In a wrist with a scapholunate ligament tear, the proximal pole of the scaphoid will dorsally subluxate out of the scaphoid fossa with this maneuver, causing a clunk. A palpable clunk is indicative of instability.
  ■ Grip strength weakness is sensitive but not specific for scapholunate ligament disruption.

■ A complete examination of the wrist should also include evaluation of associated injuries and ruling out differential diagnoses. This includes but is not limited to the following:
  ■ Lunatotriquetral tears: pain with “shuck” of the lunate and triquetrum
  ■ Masses: examine carefully for any cysts or masses that may be causing pain
  ■ Distal radius or scaphoid fracture: tenderness at the distal end of the radius or the snuffbox as well as a fracture noted on radiographs
  ■ Triangular fibrocartilage complex (TFCC) tears: pain with a TFCC stress test, which is an axially applied load via ulnar deviation while moving the wrist through a flexion–extension arc

IMAGING AND OTHER DIAGNOSTIC STUDIES

■ Plain radiographs include posteroanterior (PA), lateral, and scaphoid views, although some authors will advocate the
Part 6  HAND, WRIST, AND FOREARM  •  Section V  WRIST INSTABILITIES

**NONOPERATIVE MANAGEMENT**

- deQuervain tenosynovitis
- Dorsal wrist impaction syndrome
- Dorsal ganglion cyst
- Lunatotriquetral instability
- Midcarpal instability

**SURGICAL MANAGEMENT**

- Less invasive surgical procedures are used for partial scapholunate ligament tears and the wrist with dynamic instability. This can consist of thermal shrinkage through the arthroscope, arthroscopic débridement, and percutaneous pinning of the scaphoid and lunate in a reduced position. A capsulodesis may be considered.
- The surgical treatment of complete scapholunate ligament tears depends on the chronicity of the injury and the presence of joint arthrosis. Ligament injuries older than 3 weeks have a lower rate of healing because of the ligament’s lack of vascularity. In these more subacute or chronic injuries, it may be difficult to obtain a good outcome when performing a primary direct repair of the ligament.\(^5\)
- In addition, repair or reconstruction of the scapholunate ligament is a futile exercise in those joints with SLAC arthrosis, demonstrated by imaging studies preoperatively or arthroscopic findings intraoperatively. These procedures will not address arthritic pain.
- Our algorithm is given in Table 1.
- The purpose of this chapter is to review the techniques for bone-ligament-bone reconstruction of the scapholunate ligament.
- The advantages of this technique compared to other techniques are a more anatomic reconstruction, better approximating carpal kinematics; bone-to-bone healing as opposed to tendon-to-bone healing; and local availability.

### Table 1  Algorithm for Treatment of Scapholunate Ligament Injuries

\(^5\) Intercarpal arthrodesis examples include scapho–trapezium–trapezoid, scaphocapitate, scapholunate, and scapholunate–capitate.
Preoperative Planning

- The surgeon should review radiographs for any evidence of arthrosis. MRI is reviewed for pathology.
- Associated fractures or other soft tissue pathology should be addressed.
- Any evidence of joint arthrosis should indicate to the surgeon that a salvage procedure should be performed rather than a ligament reconstruction.
- A Watson shift test is performed while the patient is under anesthesia. The examiner may better appreciate a clunk while the patient is under anesthesia in contrast to the awake patient where pain may be present, making it difficult for the examiner to perform this maneuver well.

Positioning

- Often, a diagnostic wrist arthroscopy is performed initially.
- The patient is positioned supine. A hand table is appropriately positioned. A nonsterile tourniquet (set to 250 mm Hg) is placed on the upper arm.
- After preparation and draping, the wrist is placed in the arthroscopic tower. About 10 to 15 pounds of traction is used to distract the joint for the arthroscopy.
- Arthroscopy aids in evaluating the extent of the injury to the scapholunate ligament, assessing the quality of tissue remaining, and diagnosing concomitant injuries (FIG 3).

Once the diagnostic arthroscopy is completed and the decision to perform a reconstruction is made, the wrist is taken out of the tower and placed pronated on the hand table.

Approach

- There are several dorsal approaches to the wrist. Some prefer a trans-fourth compartment approach. We prefer an approach between the second and fourth compartments while transposing the extensor pollicis longus.
- Another decision to be made is where to obtain the bone–ligament–bone graft. We prefer local tissue, such as the capitohamate ligament, while some would advocate autograft from the foot. Autograft from the foot creates two operative sites and thus a second potential site of morbidity. In addition, there have been no clinical studies at this point verifying its merit; however, biomechanical studies are encouraging.\(^2,12\)

**FIG 3** • Arthroscopic setup. The arthroscopic tower uses plastic hook-and-eye straps and finger traps. About 10 to 15 lb of traction is used to distract the joint for the diagnostic arthroscopy.

**APPROACH TO THE DORSAL WRIST**

- An incision of about 6 to 8 cm is made just ulnar to the tubercle of Lister, extending distally to include the third metacarpal (TECH FIG 1A).
- The extensor pollicis longus sheath is incised and the tendon is transposed in a radial direction (TECH FIG 1B).
- The interval continues between the second and fourth compartment.
- The posterior interosseous nerve is excised to decrease residual pain.
- A ligament-splitting dorsal wrist capsulotomy described is made through the dorsal intercarpal and dorsal radiocarpal ligaments (TECH FIG 1C).\(^1,3,13\)
- Direct visual inspection and probing allows the surgeon to further assess the scapholunate ligament for direct primary repair versus reconstruction.

**TECH FIG 1** • Approach. A. A 6- to 8-cm incision is made ulnar to the tubercle of Lister, extending distally. B. The third extensor compartment is incised and the tendon is radialized. C. A ligament-splitting incision is made in the capsule.
GRAFT HARVESTING

- Fluoroscopy and an 18-gauge needle can help identify the capitohamate ligament.
- Using a quarter-inch osteotome, a portion of the ligament with bone blocks (10 x 5 x 5 mm) is taken. This concept is quite similar to a bone–patellar tendon–bone autograft for anterior cruciate ligament reconstructions (TECH FIG 2A,B).
- Other ligaments from the upper extremity that can be used include the third metacarpal–capitate ligament, the capito–trapezoid ligament, the second metacarpal–trapezoid ligament, and the dorsal extensor retinaculum bone block. This last choice was the weakest of all in a biomechanical study.

The dorsal tarsometatarsal ligaments between the lateral cuneiform and the third metatarsal or the ligament between the navicular and the first cuneiform of the foot have also been shown to be both geometrically and biomechanically similar to the scapholunate ligament, and they remain an option for grafting.

- If the surgeon prefers this dorsal foot graft, a longitudinal incision is made over the base of the third metatarsal. Sharp dissection is used for exposure to the joint. An osteotome is used to harvest the ligament with large bone blocks as close to the size of the scapholunate recipient site as possible—typically no greater than a 5- to 8-mm-wide section. The remainder of the dorsal ligament as well as the plantar ligament remains in place, ensuring maintained stability for the foot (TECH FIG 2C).

- Fluoroscopy and an 18-gauge needle can help identify the capitohamate ligament.
- Using a quarter-inch osteotome, a portion of the ligament with bone blocks (10 x 5 x 5 mm) is taken. This concept is quite similar to a bone–patellar tendon–bone autograft for anterior cruciate ligament reconstructions (TECH FIG 2A,B).
- Other ligaments from the upper extremity that can be used include the third metacarpal–capitate ligament, the capito–trapezoid ligament, the second metacarpal–trapezoid ligament, and the dorsal extensor retinaculum bone block. This last choice was the weakest of all in a biomechanical study.

The dorsal tarsometatarsal ligaments between the lateral cuneiform and the third metatarsal or the ligament between the navicular and the first cuneiform of the foot have also been shown to be both geometrically and biomechanically similar to the scapholunate ligament, and they remain an option for grafting.

- If the surgeon prefers this dorsal foot graft, a longitudinal incision is made over the base of the third metatarsal. Sharp dissection is used for exposure to the joint. An osteotome is used to harvest the ligament with large bone blocks as close to the size of the scapholunate recipient site as possible—typically no greater than a 5- to 8-mm-wide section. The remainder of the dorsal ligament as well as the plantar ligament remains in place, ensuring maintained stability for the foot (TECH FIG 2C).

PREPARATION OF THE RECIPIENT SITE AND FIXATION

- Using fluoroscopic guidance, 0.062 Kirschner wires are used to reduce the DISI (ie, joystick) and hold the scaphoid and lunate in position (TECH FIG 3A).
- Two Kirschner wires from scaphoid to lunate and, if required, one from scaphoid to capitate to stabilize the reduced scapholunate interval (TECH FIG 3B). More recently, we have been using a cannulated scapholunate screw for fixation.
- A trough is cut in the dorsal aspect of the scaphoid and lunate using an osteotome (TECH FIG 3C). The trough must be large enough to accept the bone blocks of the bone–ligament–bone autograft. We aim to make the trough as equal to the bone blocks as possible.

- The bone blocks are placed into the trough with digital pressure and they are held with a 1.5-mm screw in each bone. It is important to ensure that full flexion and extension of the wrist is still possible after fixation (TECH FIG 3D–F).
- Another option would be to acquire a “press fit” with the bone blocks, thereby bypassing the need for screws. This will decrease the possibility of fragmenting the bone block with the screws. However, we prefer obtaining a larger bone block autograft and using screws for added stability.
- A dorsal capsulodesis (see Chap. HA-43) can be performed for added stability. We prefer using a portion of the dorsal intercarpal ligament. This technique is described elsewhere in this part.
We prefer to deflate the tourniquet and obtain hemostasis before closure. Once hemostasis is achieved, the capsule and extensor retinaculum are closed.

The extensor pollicis longus tendon is left out of its sheath so swelling will not cause any attenuation and possible attritional rupture in its watershed area.

The skin is closed. Kirschner wires are cut under the skin to prevent pin tract infection.

Final radiographs should demonstrate screws to be adequately placed and the scaphoid and lunate to be in good position by noting a decreased scapholunate interval, a reduced scapholunate angle, and no evidence of DISI. The wrist is splinted in neutral or 30 degrees of extension; theoretically, the dorsal rim of the radius buttresses the graft for additional support in this slightly extended position.

PEARLS AND PITFALLS

**Indications**
- Carefully review the history for assessment of chronicity of the injury to determine whether a repair versus a reconstruction is needed.
- Carefully review all imaging studies preoperatively to assess for any arthritic changes that may preclude bone–ligament–bone reconstruction.

**Approach**
- It is helpful to transpose the extensor pollicis longus.

**Donor graft**
- The bone blocks should be large enough to accommodate a 1.5-mm screw without the risk of fragment fracture.

**Recipient site**
- The trough should be large enough to accept the bone blocks without being so large that the scaphoid or lunate would lose their dimensions.
- The scaphoid and lunate must be reduced and pinned before stabilization of the graft; otherwise the graft will be tensioned incorrectly.

**Postoperative care**
- A good outcome will be predicated on supervised postoperative therapy after healing.
POSTOPERATIVE CARE

- The wrist is strictly immobilized for 8 weeks. Finger and elbow range of motion is encouraged.
- Pins are removed at 8 weeks and gentle active range-of-motion exercises are started. A removable splint is still worn when not exercising for an additional 4 weeks.
- Passive range of motion begins at 12 weeks, followed by strengthening.

OUTCOMES

- Patients with a partial tear or dynamic component and patients with a shorter time from injury to treatment have a better outcome.
- Weiss\textsuperscript{16} reported excellent results at a minimum of 2 years of follow-up in 13 of 14 patients with scapholunate gaps of less than 8 mm using a bone–retinaculum–bone autograft, even though it has been shown to be biomechanically weaker than the native scapholunate ligament. This may be due to graft remodeling or hypertrophy in vivo.
- Lutz\textsuperscript{18} used a periosteal flap of iliac crest as the autograft. With an average follow-up of 29 months, they reported 6 of 11 patients to be clinically excellent or good and 5 as fair. Average radiographic parameters improved.
- Hanel\textsuperscript{5} reported that all 39 of his patients treated with the bone-ligament-bone reconstruction outlined in this chapter returned to work, but some had difficulty with return to some sports. All patients would have the surgery again as it had helped their day-to-day activities.
- Although there are no long-term clinical outcome studies in the literature on bone-ligament–bone reconstruction, short-term results are promising. A larger number of patients with a longer follow-up is required to fully recommend this technique for most scapholunate injuries.

COMPLICATIONS

- Fragmentation of the bone block intraoperatively or postoperatively
- Failure of graft to incorporate if the trough made in the scaphoid or lunate is not deep enough to cause punctate bleeding for the incorporation of the graft
- Pin tract infections (which are treated with oral antibiotics)
- Failure to achieve normal carpal alignment

REFERENCES

DEFINITION
- Scapholunate instability occurs as a result of injury to the scapholunate interosseous ligament (SLIL).
- Instability can be categorized based on physical and radiographic findings.
  - Static instability: abnormal alignment of the scaphoid and lunate evident on routine radiographs
  - Dynamic instability: abnormal alignment of the scaphoid and lunate present only on stress radiographs
  - Predynamic instability: no radiographic abnormalities present, but history and physical findings consistent with a SLIL injury
- Reduction and association of the scaphoid and the lunate (the RASL procedure) is used to correct scapholunate instability.

ANATOMY
- The SLIL can be divided into three components: dorsal, palmar, and proximal. Of these, the dorsal component is the thickest and contributes the most to scapholunate stability.¹
- Normally, the interval between the scaphoid and the lunate measures less than 3 mm, but this can vary between patients. The interval should be compared to the contralateral wrist (FIG 1A).

The normal angle between the scaphoid and the lunate measures 46 degrees with the wrist in neutral position (FIG 1B).⁵
- With wrist flexion and extension, there is 25 degrees of obligatory rotation motion between the scaphoid and the lunate. With radial and ulnar deviation, there is 10 degrees of normal motion.⁷

PATHOGENESIS
- SLIL injury typically occurs after a fall onto an extended wrist. The combination of axial load, wrist extension, intercarpal supination, and ulnar deviation leads to supraphysiologic loads across the SLIL.
- Injury can also occur in association with other injuries, such as the constellation seen in perilunate dislocations and distal radius fractures.

NATURAL HISTORY
- The motion of the scaphoid and that of the lunate are linked, such that both bones flex with wrist flexion and radial deviation and extend with wrist extension and ulnar deviation.² After SLIL injury, the synchronous movement between the scaphoid and lunate is lost and the scaphoid flexes while the lunate extends.
- Increased scaphoid flexion leads to point stress at the radiostylo-scaphoid juncture. This is the path to scapholunate advanced collapse and osteoarthritis.
- Dorsal intercalated segment instability (DISI) occurs because of unlinked lunate extension, which creates a scapholunate diastasis and allows for descent and altered kinematics (FIG 2). This results in pain, weakness, and progressive osteoarthritis.
- Over time, a progressive pattern of degenerative arthritis termed scapholunate advanced collapse (SLAC) occurs.¹⁰
  - Arthritic changes first arise between the radial styloid and the scaphoid (stage 1), followed by progression of arthritis into the proximal scaphoid fossa (stage 2). Next, the midcarpal joint becomes involved (stage 3), in particular the capitolunate joint, and eventually pancarpal arthritis is the final result (stage 4).
PATIENT HISTORY AND PHYSICAL FINDINGS

- History should include details of prior wrist trauma, especially in regard to mechanism and timing.
- Acute injuries are those that have occurred within 3 weeks, subacute between 3 weeks and 3 months, and chronic greater than 3 months before presentation. Dates are unreliable, but radiographic changes suggest many are acute-on-chronic injuries.
- After acute trauma, there is usually a repairable scapholunate ligament, whereas in the setting of subacute or chronic injury, the ligament is resorbed or mechanically unsound. The presence of adequate ligament tissue for repair outweighs the reported time since injury.
- Instability may be the result of cumulative trauma, and the patient may present with a history of multiple wrist sprains that ultimately produce chronic wrist pain.
- Physical examination includes the following:
  - Direct palpation of the wrist: Tenderness in this region corresponds to scapholunate ligament injury. May also see fullness or thickness, corresponding to dorsal capsule synovitis.
  - Range of motion: Pain with range of motion may indicate instability, synovitis, and chondral wear.
  - Watson scaphoid shift test: Pain over the scaphoid tubercle with radial deviation indicates SLIL injury.
  - Assessment of both normal and aberrant motion
  - Provocative maneuvers
- Examination of the contralateral uninjured wrist is essential to assess radiographic findings of minimal diastasis or DISI, which may be part of a hyperlaxity syndrome.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs and stress views are critical in diagnosis and consist of:
  - Neutral posteroanterior (PA), lateral, and oblique views
  - PA views in ulnar and radial deviation
  - Clenched-fist PA view in pronation
  - Contralateral wrist films should always be taken for comparison.
- Radiographic evidence of SLIL injury includes:
  - Scapholunate diastasis greater than 3 mm. Comparison should be made with the contralateral side, as ligamentous laxity can produce a normal scapholunate interval of greater than 3 mm (FIG 3A). Scaphoid cortical ring sign, which occurs when the scaphoid is in a flexed posture and the distal tubercle aligns with the proximal scaphoid (FIG 3A).
  - Scapholunate angle greater than 60 degrees (FIG 3B). DISI deformity pattern with capitate dorsal translation and decreased carpal height measurements
- The accuracy of MRI is affected by the strength of the magnet and the use of dedicated wrist coils.
  - Sensitivity ranges from 63% to 92%.
  - Specificity ranges from 86% to 100%, depending on the degree of injury and the type of MRI used.

DIFFERENTIAL DIAGNOSIS

- Scaphoid fracture
- Capitulonate arthritis
- Scaphotrapeziotrapezoidal (STT) arthritis

FIG 3 • A. A widened scapholunate interval (>3 mm) and a scaphoid cortical ring sign are seen on an AP view of the wrist. B. An obtuse scapholunate angle (>60 degrees) is appreciated on a lateral view of the wrist.

NONOPERATIVE MANAGEMENT

- Normal clinical alignment with persistent wrist pain with or without a Watson sign is managed with resting splints until symptoms resolve.
- Occasionally intra-articular steroid injections are performed.

SURGICAL MANAGEMENT

Contraindications to RASL

- A repairable SLIL
- A primary ligament repair is preferable if a ligament of adequate tissue quality is present.
- This is most likely seen in acute injuries (less than 3 weeks) but may be possible in chronic injuries. For this reason, arthroscopy is recommended before performing a RASL procedure to evaluate the quality of the SLIL.
- Presence of significant capitulonate or pancarpal arthritis
- If significant midcarpal, radiolunate, or radioscapoid arthritis is present, a salvage procedure, such as a proximal row carpectomy or a limited wrist fusion, may be a better treatment option.
Focal arthritis between the scaphoid and radial styloid is not a contraindication since a radial styloidectomy is routinely performed during the RASL procedure.

**Positioning**
- The procedure is performed with the patient supine and the arm on a standard hand table.
- The operating table should be rotated 90 degrees to facilitate the use of the image intensifier during the procedure.

**Approach**
- The RASL procedure can be performed either arthroscopically or via an open dorsal approach.
- The arthroscopic RASL should be attempted only after obtaining experience with the open technique, or if already a master arthroscopist.
- The open technique is performed using a dorsal intercarpal ligament-sparing approach.

**DORSAL LIGAMENT–SPARING CAPSULOTOMY**

- Make a longitudinal incision on the dorsal wrist, staying just ulnar to the tubercle of Lister (TECH FIG 1A).
- Bluntly dissect the soft tissue down to the level of the extensor retinaculum, taking care to preserve any dorsal veins and cutaneous nerve branches wherever possible.
- Incise obliquely the extensor retinaculum parallel to the course of the extensor pollicis longus (EPL) tendon (TECH FIG 1B).
- This will open the third and fourth extensor compartments.
- The EPL is retracted radially and the fourth compartment tendons are retracted ulnarly.
- Make an oblique incision through the dorsal wrist capsule parallel and proximal to the dorsal intercarpal ligament (DIC) (TECH FIG 1C).
- The dorsal radiocarpal ligament (DRC) should also be identified and preserved.

**TECH FIG 1 • A.** A dorsal midline incision is made just ulnar to the tubercle of Lister. **B.** An oblique incision is made through the extensor retinaculum parallel to the extensor pollicis longus (EPL) tendon. The EPL is retracted radially and the fourth compartment tendons are retracted ulnarly. **C.** An oblique incision is made through the dorsal wrist capsule parallel and proximal to the dorsal intercarpal ligament. The dorsal radiocarpal ligament should also be identified and preserved.

**STYLOIDECTOMY**

- Once the capsulotomy is performed, identify the scapholunate interval and the SLIL and inspect the radiocarpal and intercarpal joints.
  - If significant arthritis is present in areas other than the radiostyloscapophoid articulation, a salvage procedure is indicated.
- Perform a second incision in the midaxial line over the first dorsal compartment (TECH FIG 2A).
  - The major branch of the superficial radial nerve should be seen and isolated with a vessel loupe.
- Release the first compartment retinaculum and retract the tendons dorsally.
- Incise the capsule longitudinally through the wrist capsule, thereby exposing the radial styloid (TECH FIG 2B).
- Elevate the periosteum overlying the radial styloid and use an osteotome to perform a radial styloidectomy.
  - Remove enough of the radial styloid that radial deviation of the wrist does not cause impingement of the scaphoid and radius.
  - Too aggressive of a radial styloidectomy will compromise the volar radioscaphocapitate ligament, which originates from the base of the radial styloid.
**PREPARATION AND REDUCTION OF THE SCAPHOLUNATE JOINT**

- Place a 0.062-inch Kirschner wire in the lunate and another in the scaphoid to serve as joysticks (TECH FIG 3A).
- To bring the lunate out of extension, place the Kirschner wire in the most proximal portion of the exposed dorsal surface, angled from proximal to distal.
- Similarly, to bring the scaphoid out of flexion, place the Kirschner wire in the most distal portion of the exposed dorsal surface, angled from distal to proximal.
- Keep in mind the eventual path of the Herbert screw when placing the Kirschner wires and try to avoid this area in both bones.

- Remove the articular cartilage of the scapholunate joint using a side-cutting burr (TECH FIG 3B).
- The joysticks can be used to separate the two bones to better visualize the articular surfaces.
- Remove the cartilage until cancellous bone and punctate bleeding are visualized.
- Reduce the scaphoid and lunate by flexing the lunate and extending the scaphoid (TECH FIG 3C).
- A Köcher clamp is used to hold the reduction (TECH FIG 3D).
- Verify the reduction with an image intensifier (TECH FIG 3E).

**TECH FIG 2** • A. A longitudinal incision is made over the first dorsal extensor compartment. B. The first compartment is released and a longitudinal incision is made down to the radial styloid.

**TECH FIG 3** • A. 0.062-inch Kirschner wires are placed in the lunate and scaphoid to serve as joysticks. B. A side-cutting burr is used to remove the cartilage within the scapholunate joint. C. The joysticks are used to extend the scaphoid and to flex the lunate. D. A Köcher clamp is used to hold the reduction. E. The reduction is verified with an image intensifier.
**HERBERT SCREW PLACEMENT**

- The path of the Herbert screw should be through the center of rotation of both the scaphoid and the lunate.
- Introduce the Herbert jig through the radial incision and place the insertion point of the jig on the scaphoid waist.
- Through the dorsal incision, introduce the end of the jig and rest it on the proximal ulnar corner of the lunate.
- Do not violate the lunotriquetral interosseous ligament.
- The insertion angle of the screw should be roughly parallel to the radial inclination of the distal radius, 20 degrees (TECH FIG 4A).
- Once the jig is in proper position and both bones are properly measured, drilled, and tapped, insert the Herbert screw.
- Countersink the screw into the scaphoid so that it is not palpable.
- Correct screw placement should be confirmed by fluoroscopy (TECH FIG 4B,C).
- Remove the Köcher clamp and the joystick wires.
- Take the wrist through a full range of motion to assess for any restrictions in motion and to confirm that the scaphoid and lunate remain reduced.

**WOUND CLOSURE**

- Release the tourniquet and achieve hemostasis using Bovie or bipolar electrocautery.
- Close the dorsal and radial capsular incisions and extensor retinaculum (once the EPL and fourth compartment tendons are placed back into their respective compartments) using 3-0 absorbable monofilament suture.
- Close the skin using 5-0 nylon suture and apply a sterile bulky dressing and volar thumb spica splint.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Indications</th>
<th>Pearls and Pitfalls</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dorsal and radial approaches</td>
<td>Carefully evaluate both radiographically and intraoperatively for the presence of significant arthrosis. Identify and protect all neurovascular structures, especially superficial radial sensory nerve branches through the radial incision. Identify the dorsal radial artery just distal to the screw insertion site before screw placement.</td>
</tr>
<tr>
<td>Radial styloidectomy</td>
<td>Avoid removing too much of the radial styloid since this may destabilize the radioscaphocapitate and long radiolunate volar ligaments. Remove just enough to prevent radioscaphoid impingement.</td>
</tr>
<tr>
<td>Kirschner wire joystick placement</td>
<td>Do not place the Kirschner wires in the centers of the scaphoid and lunate. Aim for the proximal ulnar corner of the lunate and the distal radial corner of the scaphoid to avoid interfering with the eventual path of the screw.</td>
</tr>
<tr>
<td>Bone preparation</td>
<td>When burring down the chondral surfaces of the scaphoid and lunate before screw placement, remove only the cartilage and dense subchondral bone. Removing too much bone will decrease the amount of bony contact between the scaphoid and lunate after reduction.</td>
</tr>
<tr>
<td>Screw placement</td>
<td>After placing the jig, inspect its position both visually and by fluoroscopy. The axis of the jig should cross the central portions of the scaphoid and lunate. The screw should be directed toward the proximal ulnar corner of the lunate.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE
- The wrist is kept immobilized for 4 to 6 weeks.
- After 4 to 6 weeks, the thumb spica splint is removed, a removable splint is applied, and range-of-motion therapy is initiated.
- Over time, therapy is advanced to strengthening exercises around 3 months postoperatively.

OUTCOMES
- Rosenwasser et al. reported on a series of 21 patients with a mean of 32 months of follow-up.
  - In this group, 95% of patients returned to their previous occupations. One-year postoperative scapholunate angles and intervals were corrected to within normal limits, with the scapholunate angle being corrected from 69 degrees preoperatively to 40 degrees postoperatively, and the scapholunate interval being corrected from 4.1 mm preoperatively to 1.4 mm postoperatively.
  - One patient was converted to a partial wrist fusion secondary to screw migration and failure of reduction. Another patient required removal of the screw 4 years postoperatively secondary to radial impingement and still demonstrated scapholunate stability after screw removal.

COMPICATIONS
- Residual instability
- Screw migration
- Superficial radial sensory nerve injury

REFERENCES
DEFINITION
- Isolated injury of the lunotriquetral interosseous ligament complex is less common and less well understood compared with the other proximal row ligament injury, scapholunate dissociation.
- Lunotriquetral ligament disruption can occur in isolation or in combination with other wrist pathology, such as a perilunate dislocation.
- It may result from acute trauma or chronic degenerative or inflammatory processes.
- Injuries to the lunotriquetral ligament occur in a spectrum of severity ranging from partial tears with dynamic dysfunction (most common) to complete dissociation with static collapse.
- Lunotriquetral instability can occur when the ligament complex is intact but incompetent or attenuated. If the ligament is stretched and attenuated from chronic or inflammatory degradation, instability can occur in the absence of ligament dissociation (complete disruption).

- When the lunotriquetral ligament is completely ruptured (both dorsal and volar regions), it is called a lunotriquetral dissociation.
- When the dorsal radiotriquetral ligament (and other secondary restraints) is also compromised and the entire ligament complex is disrupted, carpal collapse results. This deformity is termed volar intercalated segment instability (VISI). VISI carpal collapse cannot be reproduced by simply sectioning the dorsal and palmar subregions of the lunotriquetral ligament. Loss of integrity of the radiotriquetral ligament restraint is required to create static carpal instability (FIG 1).

ANATOMY AND KINEMATICS
- Like the scapholunate ligament, the lunotriquetral interosseous ligament is C-shaped, spanning the dorsal, proximal, and palmar edges of the joint surface.
- The palmar portion of the lunotriquetral ligament is the thickest and most biomechanically important region of the...
entire complex. In contrast, the dorsal component of the scapholunate ligament has been shown to be the strongest. The dorsal lunotriquetral ligament is important as a rotational constraint, while the palmar portion is the strongest and transmits the extension moment of the triquetrum as it engages the hamate. The membranous region has little effect on rotation, translation, or distraction. These findings illustrate the “balanced lunate” concept, which describes the lunate as torque suspended between the scaphoid and triquetrum. The scaphoid has a tendency to palmar flex, while the triquetrum has a tendency to extend. Through the lunotriquetral and scapholunate ligaments the two forces are balanced and the entire proximal carpal row is balanced about the lunate.

PATHOGENESIS

The exact mechanism of traumatic lunotriquetral ligament injuries is not fully understood. Many mechanisms may play a role.

Lunotriquetral ligament injuries can occur in Mayfield III and IV perilunate injuries (FIG 2A). An isolated traumatic lunotriquetral ligament injury may occur in a reverse perilunate injury (FIG 2B). In the absence of trauma, degenerative lunotriquetral instability can result from inflammatory arthritis. Positive ulnar variance may lead to lunotriquetral ligament degeneration by wear mechanisms or altered intercarpal kinematics (ulnar impaction syndrome).

NATURAL HISTORY

The natural history of these injuries has not been fully elucidated but they may lead to degenerative joint changes.

PATIENT HISTORY AND PHYSICAL FINDINGS

Lunotriquetral ligament injuries present as vague ulnar-sided wrist pain either acutely after trauma or as generalized ulnar-sided chronic wrist pain.
The examination should encompass the entire wrist, especially the ulnar side.
- Dorsal lunotriquetral joint tenderness should be elicited in lunotriquetral joint injuries.\(^8,11\)
- Ulnar deviation with pronation and axial compression may elicit dynamic instability with a painful snap “catch-up” clunk.
- A palpable wrist click is occasionally significant, particularly if painful and occurring with radioulnar deviation.
- Provocative tests that demonstrate lunotriquetral laxity, crepitus, and pain are helpful to accurately localize the site of pathology. Three useful tests to perform include:
  - Ballottement\(^11\): The test is positive if increased anteroposterior laxity and pain occur.
  - Compression: Pain with this maneuver may indicate pathology of the lunotriquetral or triquetral hamate joints.\(^1\)
  - Shear test\(^7\): Positive with pain, crepitance, and abnormal mobility of the lunotriquetral joint
- Other common findings on physical examination include limited range of motion and diminished grip strength.\(^8\)
- Comparison of findings with the contralateral wrist is essential.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain radiographs are often normal in lunotriquetral ligament injuries because the most common presentation is dynamic dysfunction that manifests only with loading or certain positions of the hand and wrist.
- Dissociation of the lunotriquetral ligament can lead to disruption of Gilula arcs I and II, demonstrating proximal translation of the triquetrum, with or without lunotriquetral overlap (FIG 3A,B). \(^6\)
- Often, no lunotriquetral gap occurs, in contrast to scapholunate injuries.
- A static VISI deformity indicates not only lunotriquetral interosseous ligament injury but also damage to the dorsal radiotriquetral ligament.
- Radial and ulnar deviation together with clenched-fist anteroposterior views are often helpful. Lunotriquetral dissociation leads to lessened triquetral motion and increased movement of the lunate, scaphoid, and distal row.\(^2\)

- Injection of local anesthetic into the midcarpal space can be useful to localize the cause of the patient’s pain.
- Addition of corticosteroid to the injection may provide temporary relief by decreasing local inflammation.
- Arthrographic dye pooling or leakage at the lunotriquetral interspace can indicate ligamentous injury (FIG 3C). However, age-dependent degenerative changes and asymptomatic lunotriquetral instability have been reported. Correlation with physical examination is required.
- Real-time videofluoroscopy can illustrate the site of a “clunk” that occurs with wrist deviation. This occurs in lunotriquetral injuries when the triquetrum “catches up” when the wrist is moved into maximal ulnar deviation.
- Technetium-99m diphosphate bone scan can aid in the localization of an acute injury but has been shown to be less specific than arthrography (FIG 3D).\(^6\)
- Magnetic resonance imaging is improving but is not yet reliable for imaging of lunotriquetral ligament injuries.

**DIFFERENTIAL DIAGNOSIS**
- The differential diagnosis of ulnar-sided wrist pain can be divided into six categories: osseous, ligamentous, tendinous, vascular, neurologic, and miscellaneous.
- Osseous injuries include the sequelae of fractures (ie, nonunion or malunion) and degenerative processes. Fracture nonunions can affect the hamate, pisiform, triquetrum, base of the fifth metacarpal, ulnar styloid process, and distal part of the ulna or radius.
- Degenerative processes at the pisotriquetral joint, midcarpal (triquetrohamate) articulation, fifth carpometacarpal joint, or distal radioulnar joint can also result in substantial ulnar-sided wrist pain. Ulnar impaction or abutment into the radius or carpus has been reported as well.
- Ligamentous injuries can occur in any of the ulnar-sided intrinsic (lunotriquetral or capitohamate) or extrinsic (ulnolunate, triquetrocapitate, or triquetrohamate) ligaments as well as the triangular fibrocartilage complex.
- Tendinopathy of the extensor carpi ulnaris or flexor carpi ulnaris
- Vascular lesions such as ulnar artery thrombosis or hemangiomas
- Neurologic processes such as entrapment of the ulnar nerve in Guyon’s canal, neuritis of the dorsal sensory branch of the ulnar nerve, and complex regional pain syndromes
- The miscellaneous group includes the very unusual etiologies such as tumors, including osteoid osteomas, chondroblastomas, and aneurysmal bone cysts.

**NONOPERATIVE MANAGEMENT**
- Initial care for most lunotriquetral ligament injuries is immobilization with a splint or cast with a pisiform lift. Initially the wrist is immobilized in a long-arm cast for 4 weeks and then a short-arm cast for an additional 4 weeks. Care should be taken to mold a pad underneath the pisiform (pisiform lift) to maintain optimal alignment as the ligament heals.
- Acute injuries without radiographic changes may be successfully treated nonoperatively.
- Symptoms of chronic injuries often improve with immobilization.
- Midcarpal injections with local anesthetic and corticosteroid often provide significant relief for a prolonged time.
If conservative management fails for either acute or chronic injuries, surgical treatment can be performed. A trial of nonoperative treatment does not seem to jeopardize the outcome of subsequent surgical intervention.

**SURGICAL MANAGEMENT**

- Operative management is indicated in acute or chronic injuries unresponsive to conservative treatment.
- The goal of surgery is to return rotational stability of the proximal carpal row and restore the natural alignment of the lunocapitate axis.
- Functional reconstruction of the lunotriquetral ligament can be accomplished with direct ligament repair, ligament reconstruction with a strip of extensor carpi ulnaris tendon graft, or arthrodesis.
- The choice of intervention should be discussed with the patient. Our preference, based on outcomes studies performed at our institution, is tendon repair or reconstruction.13
- Arthrodesis is avoided whenever possible secondary to higher complication rates and lower patient satisfaction.
- If significant degenerative changes have occurred in the lunotriquetral, radiocarpal, or midcarpal joints, partial or total carpal arthrodesis or proximal row carpectomy may be indicated.
- In the presence of significant VISI deformity that cannot be easily reduced (ie, static VISI), intercarpal arthrodesis is recommended.
- In cases of significant ulna-positive or ulna-negative variance, ulna shortening or lengthening may be indicated as well.

**DIRECT LUNOTRIQUETRAL LIGAMENT REPAIR**

**Incision and Dissection**

- A longitudinal incision is made over the third extensor compartment (TECH FIG 1).
- Alternatively, a curvilinear incision can be used.
- The dorsal sensory branch of the ulnar nerve is identified and protected.

**Preoperative Planning**

- The senior author’s preference is to perform diagnostic arthroscopy on patients with lunotriquetral ligament injuries to evaluate the articular surface and assess other intercarpal pathology.
- Anterior interosseous and posterior interosseous nerve neuroectomies can be performed at this time as well.
- The findings of the arthroscopy are discussed with the patient at a second meeting and a reconstructive or salvage procedure can then be performed 6 weeks later.
- Alternatively, a definitive surgical procedure can be performed at a single surgical setting following a thorough preoperative discussion with the patient.
- When a lunotriquetral dorsal ligament repair is planned, preparations should also be made to proceed with ligament reconstruction if the quality of the lunotriquetral ligament is poor.

**Positioning**

- The patient is positioned supine on a standard operating room table with the affected arm on a hand table.
- A long-acting axillary regional anesthetic block placed preoperatively is helpful with postoperative pain control.
- A nonsterile tourniquet is applied above the surgical drapes.
- Preoperative intravenous antibiotics are routinely administered before beginning the procedure.
- The hand and arm are prepared and draped in standard fashion.
- An examination under anesthesia is always performed initially to evaluate for “catch-up” intercarpal clunks and well as radioulnar clunks.

If not previously performed, a posterior interosseous neurectomy is performed to partially denervate the dorsal wrist capsule (TECH FIG 4).

The dorsal radiocarpal and intercarpal ligaments are identified and a ligament-splitting capsulotomy made as described by Berger and Bishop4 (TECH FIG 5A–D).

When elevating the capsule it is important not to dissect too deep over the region of the lunotriquetral area. The lunotriquetral ligament is intimately related to the radiotriquetral ligament and can be injured if attention is not paid during the capsulotomy.

The midcarpal and radiocarpal joint surfaces are exposed and examined for arthritic changes (TECH FIG 5E).

The scapholunate and lunotriquetral ligament are thoroughly examined.

The dorsal aspect of the lunotriquetral ligament is inspected to determine if it is suitable for repair. The midcarpal joint is also inspected.
The volar portion of the lunotriquetral joint is examined, and the integrity of the volar lunotriquetral ligament is indirectly inspected. If it is completely incompetent, then a direct repair of the dorsal lunotriquetral ligament is contraindicated and one should proceed to a ligament reconstruction as described later in this chapter.

Intra-articular step-off of the lunotriquetral articulation is also assessed, as well as the presence of a separate lunate facet (type II lunate).

Reattaching the Ligament

- The lunotriquetral ligament is reattached to the site of avulsion, usually the triquetrum.
- Two techniques for reattachment of the ligament exist: the use of drill holes or suture anchors. Multiple horizontal drill holes or suture anchors are placed in the dorsal, nonarticular, surface of the triquetrum (TECH FIG 6A).
- Numerous strands of nonabsorbable suture (size 2-0) are used to repair the avulsed ligament (TECH FIG 6B).
- Before tensioning and tying the sutures, the diastasis of the lunotriquetral joint must be reduced and the articular congruity at the midcarpal joint reduced. The reduction is secured by two 0.045-inch smooth Kirschner wires (TECH FIG 6C–E).
- The sutures are then tensioned and tied, but not cut short.
- Dorsal capsulodesis is then performed to augment the lunotriquetral ligament. A portion of the radiotriquetral ligament can be used to augment the lunotriquetral ligament repair by placing additional suture anchors into the lunate and triquetrum and sewing the radiotriquetral ligament to the lunotriquetral ligament.
- The ligament-splitting capsulotomy is repaired with nonabsorbable sutures (TECH FIG 6F).
- The extensor retinaculum is repaired with the extensor pollicis longus dorsally transposed.
- The skin is closed.
- A long-arm, bulky splint is applied.
Harvesting the Graft
- To avoid disrupting the extensor carpi ulnaris (ECU) sub-sheath, a 2-cm transverse incision is made through the skin and the ECU sheath 6 cm proximal to the ulnar styloid. The ECU tendon is identified (TECH FIG 7A).
- A small right-angle clamp or 90-degree retractor is used to isolate and elevate the ECU tendon (TECH FIG 7B).
- A 4-mm incision is made on the radial side of the ECU tendon to create a strip of tendon graft. A piece of 28-gauge wire is tied to the free end of the tendon graft (TECH FIG 7C).
- The ECU sheath is opened at the level of the carpometacarpal joint. The wire is looped and passed from proximal to distal through the sheath into the distal incision. The wire and tendon are gently pulled distally, creating a distally based tendon graft (TECH FIG 7D).
- The graft is passed deep to the extensor retinaculum.
- The 28-gauge wire is left tied to the end of the graft and a moist sponge is wrapped around the graft while the bone tunnels are prepared.

Bone Tunnel Creation and Graft Passage
- 0.045-inch Kirschner wires are advanced through the lunate and the triquetrum.
- The correct starting points for these Kirschner wires are the dorsal ulnar aspect of the triquetrum and the dorsal radial edge of the lunate.
- The holes should converge at the volar margin of the lunotriquetral joint and must not be intra-articular (TECH FIG 8A).
- If a reducible VISI deformity exists, it is important to place the Kirschner wires while the deformity is held reduced. Joysticks in the scaphoid and triquetrum are useful to maintain the reduction while the lunate and triquetral wires are placed (TECH FIG 8B).
- The position of the wires is checked with fluoroscopy to confirm the ability to safely enlarge the drill holes without fracture.
- The tunnels are created using a series of sharp awls or drill bits, gradually increasing the diameter until a 4- to 5-mm tunnel is created in both the lunate and triquetrum (TECH FIG 8C).
- Alternatively, a cannulated drill system can be used.
The wire previously secured to the end of the graft is looped and passed through the triquetral tunnel toward the lunate (TECH FIG 9A–C).
- An arthroscopic hook or probe is useful to hook the wire loop and pull it through the lunate bone tunnel (TECH FIG 9D,E).
- The wire is used to pass the tendon graft through the tunnels (TECH FIG 10A).
- While maintaining tension on the tendon graft, the articular surfaces of the lunate and triquetrum are reduced and two 0.045-inch Kirschner wires are passed percutaneously across the lunotriquetral joint.
- Reduction, pin position, and length are checked with fluoroscopy.
- The tendon graft is then woven through itself on the dorsum of the lunate and triquetrum and firmly secured with nonabsorbable suture (TECH FIG 10B,C).
- Excess tendon is trimmed, and the wound is irrigated with normal saline solution.
- The wound is closed as previously described in the ligament repair section.

TECH FIG 8 • A. Kirschner wires showing position of drill holes through triquetrum and lunate. The tips converge on the palmar, nonarticular surface of the joint. B. D,E. Arthroscopic hook used to pass wire or heavy suture through bone tunnels. (Copyright © Mayo Clinic.)
COMBINED REPAIR

- Ligament reconstruction with an ECU tendon strip can be combined with direct ligament repair to provide additional strength for the repair (TECH FIG 11).

- This is especially useful when the volar region of the lunotriquetral ligament is disrupted and the dorsal aspect of the ligament is attenuated.

TECH FIG 10 • A. Passing extensor carpi ulnaris (ECU) tendon strip through bone tunnels. B. ECU tendon has been passed through bone tunnels, tensioned, and sutured into itself. Kirschner wires placed percutaneously to maintain lunotriquetral joint reduction. C. Dorsal view of ligament reconstruction with ECU tendon strip. Ready for capsular repair. (Copyright © Mayo Clinic.)

TECH FIG 11 • A. Dorsal exposure before capsulotomy (fingers are to the bottom and the thumb is to the left). B. Lunotriquetral joint diastasis with dorsal lunotriquetral ligament disruption. The ligament remains attached to the dorsal lunate. C,D. Positioning Kirschner wires for drill holes. (continued)
**TECH FIG 11** (continued) **E.** 28-gauge wire passes through bone tunnels. **F, G.** The tendon graft is first advanced through the triquetrum and then through the lunate. **H.** The tendon graft is tensioned. **I.** Reduction should be verified and maintained with lunotriquetral Kirschner wires before final ligament tensioning and suture placement. **J.** Direct repair of dorsal lunotriquetral ligament utilizing suture form anchors placed into the triquetrum. **K.** Tensioning direct lunotriquetral ligament repair. **L.** Final view of the reconstruction after capsulotomy repair. Heavy nonabsorbable sutures secure the capsular repair.

**PEARLS AND PITFALLS**

**Direct repair**
- Position the drill holes in the triquetrum so that a strong bridge of bone remains to support the sutures and knots. Holes placed too close to the edge of the bone will allow the suture to pull through when tensioned.
- Pass the sutures through sufficient substance of the lunotriquetral tendon so that the suture does not tear or pull out of the tendon.
- The use of heavy, nonabsorbable suture is important for an adequate capsular repair.
- It is important to visualize and ensure the adequacy of the reduction before placing the Kirschner wires across the lunotriquetral joint.
- The senior author prefers to cut the Kirschner wire below the level of the skin. Other authors advocate percutaneous placement for easy removal.

**Ligament reconstruction with distally based ECU strip**
- Positioning the ECU tendon strip through the drill holes can be difficult. Stainless-steel wire or heavy monofilament suture can be passed first and used to shuttle the strip of tendon in the correct position.
- Tensioning the tendon and suturing it into itself can be challenging. A surgical clamp such as a Köcher or Allis can be attached to the proximal free edge of the tendon strip and used as a handle to apply traction to the tendon strip as it is being secured.
- Tension the tendon strip while the lunotriquetral joint is reduced.
- It is important to visualize and ensure the adequacy of the reduction before placing the Kirschner wires across the lunotriquetral joint.
- Adequate duration of postoperative immobilization is important to ensure a successful outcome.
POSTOPERATIVE CARE

- Edema control and range-of-motion exercises of the digits are initiated immediately postoperatively.
- Seven to 10 days after the procedure, the surgical splint is removed, sutures are removed, and a long-arm cast is applied for 6 weeks. A short-arm cast is then applied for an additional 4 to 6 weeks for a total period of immobilization of 10 to 12 weeks.
- The Kirschner wires are removed at 10 to 12 weeks and wrist range-of-motion exercises are commenced.

OUTCOMES

- A high-quality tendon repair is vital for a successful outcome of the lunotriquetral tenodesis.
- Several studies have shown that direct lunotriquetral ligament repair results in a successful clinical result.\(^5,9,11,15\)
- Reagan et al.\(^{11}\) reported that six of seven cases of direct lunotriquetral ligament repairs were successful.
- Favero et al.\(^5\) reported patient satisfaction of 90% with only one failure in 21 cases.
- In high-demand patients such as laborers and athletes, rupture or attenuation can occur and lead to late failure. Reconstruction with a strip of ECU tendon should be considered in this patient subgroup.
- A review of clinical outcomes comparing lunotriquetral ligament repair, ligament reconstruction, and lunotriquetral joint arthrodesis at our institution showed that patients treated with ligament reconstruction have the lowest reoperation rate.\(^13\)
- Rerupture after trauma and late attenuation appear to be common modes of long-term failure of direct repair.
- Review of the clinical outcomes at our institution showed that reconstruction with a strip of ECU tendon as described can be an effective treatment.\(^3\)

REFERENCES

DEFINITION

- The carpus is a complex, intercalated system of dual rows that allow paired motion within the radial–ulnar and flexion–extension plane. A disruption of the intrinsic ligaments of the carpus or a combination of ligamentous and osseous structures leads to a spectrum of injuries ranging from “wrist sprains” to complex perilunate injuries including lesser and greater arc injuries.
- Lesser arc injuries are purely capsuloligamentous.
- Greater arc injuries include a range of associated carpal fractures.
- Disruptions of the normal kinematics and stability of the carpal row lead to acute failure with a predictable pattern of posttraumatic degenerative changes.

ANATOMY

- There are eight carpal bones without tendinous insertions, whose motion is passively transmitted and guided by precise ligamentous architecture and bony geometry.
- Volar extrinsic ligaments are the prime stabilizers of the carpus and are oriented in a double-V arrangement with a relative weakness between these V’s called the space of Poirer.
  - The volar extrinsic ligaments include the inner-V ligaments: long radiolunate (LRL), radioscapulonate (RSL), short radiolunate (SRL), and ulnolunate (UL). The outer V consists of the radioscapulocapitate (RSC) and the ulnotriquetrocapitate complex (UTCC) (FIG 1A).
  - The dorsal extrinsic ligaments provide less structural stability and include the radiotriquetral (RT) and dorsal intercarpal (DIC) ligaments (FIG 1B).
- The intrinsic ligaments are direct intercarpal connections that provide intra-row stability.
  - These include the lunotriquetral and the scapholunate ligaments.
  - Complex, three-dimensional motion occurs with wrist movement: radial deviation and wrist dorsiflexion are paired, as are ulnar deviation and wrist volarflexion.

PATHOGENESIS

- These may involve high-energy injuries in which an axial load is applied to a hyperextended and ulnarly deviated wrist, placing the volar structures under tension and the dorsal structures under compression and shear.
- The energy dissipates in a radial to ulnar direction.
- Lesser arc injuries are purely ligamentous and advance through four progressive stages as originally described by Mayfield et al (FIG 2A):
  - Stage I: the scapholunate ligament
  - Stage II: the space of Poirer
  - Stage III: the UTCC and UL ligament
  - Stage IV: lunate dislocation
- Greater arc injuries proceed in the same direction but involve fractures through the radial styloid, scaphoid, lunate, capitate, triquetrum, and ulna, either solely or in combination (FIG 2B).
- Perilunate dislocations most commonly occur as dorsal dislocations of the capitate and surrounding carpus with respect to the lunate, which remains in the lunate fossa of the distal radius.
- A lunate dislocation often involves volar displacement of the lunate into the carpal tunnel, with the capitate articulating in the lunate fossa of the radius. Median neuropathy is common. The lunate is ousted from the wrist joint through the space of Poirer, creating a rent in the volar capsule that extends medially and laterally along the interval between the V ligaments. The rent is semilunar or crescentic in appearance.

NATURAL HISTORY

- Nonoperative management yields predictably poor results, with loss of reduction and progression to wrist deformity and pain.1,2

FIG 1 • A. Volar extrinsic carpal ligaments. LRL, long radiolunate ligament; SRL, short radiolunate; RSC, radioscapulocapitate ligament; UL, ulnolunate ligament; UTCC, ulnotriquetrocapitate complex; *, space of Poirer. B. Dorsal extrinsic carpal ligaments. RTq, radiotriquetral ligament; DIC, dorsal intercarpal ligament; *, scaphoid.
Typical instability patterns (depending on extent of injury) include scapholunate advanced collapse, scaphoid nonunion advanced collapse, and volar or dorsal intercalated segmental instability.

Definitive treatment is operative intervention.

PATIENT HISTORY AND PHYSICAL FINDINGS

A typical history may range from a fall and twist on an extended hand to a high-energy event with extreme forces transferred to the wrist. Patients complain of pain and stiffness.

Physical examination findings depend on the level of injury and the elapsed time from injury to presentation.

Stiffness, tenderness, crepitus, swelling, and resistance to motion are common findings. Deformity is usually minimal.

Depending on the severity of injury, the findings can be subtle and easily missed. The examiner must maintain a high index of suspicion.

DIFFERENTIAL DIAGNOSIS

Given the severity of this injury pattern and the frequency with which it is missed, greater and lesser arc injuries must be ruled out in any situation in which the wrist is traumatized.

- Wrist sprain
- Triangular fibrocartilage complex (TFCC) injury
- Extrinsic or intrinsic ligament disruptions
- Carpal fractures
- Distal radius or ulna fracture
- Median neuropathy
- Kienböck disease
- Ulnar impaction syndrome
- DeQuervain tenosynovitis
- Basal joint arthritis

NONOPERATIVE MANAGEMENT

Closed reduction of perilunate dislocations may be achieved by in-line traction and gentle wrist manipulation as described by Tavernier.6

In-line traction is helpful for muscle relaxation before reduction and can be applied using finger traps and weights suspended from the arm with the elbow flexed 90 degrees for 10 minutes.

The surgeon extends the wrist and applies gentle manual traction. The surgeon’s thumb stabilizes the lunate volarly.
and rotates the lunate into extension. The capitate is then translated up and over the lunate while simultaneously flexing the wrist. A snapping sound may be heard when the capitate reduces over the lunate.

- Closed reductions of lunate dislocations are frequently unsuccessful. As traction is applied to the wrist, the volar rent narrows to prevent reduction of the lunate into the wrist joint.
- Acute carpal tunnel syndrome in this scenario is a surgical emergency.
- Long-term outcomes of closed reduction have been shown to be suboptimal, and surgical treatment is warranted.

SURGICAL MANAGEMENT

Preoperative Planning

- All radiographs are reviewed.
- The surgeon should determine what ligaments are damaged and whether biosuture anchors are needed to augment repair.
- The surgeon should assess osseous structures and determine whether fractures need to be stabilized with hardware such as Kirschner wires or dual-pitch screws.
- If median neuropathy is present or impending, a carpal tunnel release should be performed.

Positioning

- Supine positioning with a well-padded pneumatic tourniquet on the upper arm
- The use of a radiolucent hand table with fluoroscopic imaging aids in repair and reduction.

DORSAL APPROACH

Incision and Dissection

- A universal dorsal skin incision is made under tourniquet control. The extensor retinaculum is exposed, raising medial and lateral skin flaps. Access to the dorsal capsule is gained through the 3–4 extensor compartment interval (TECH FIG 1A).
- The extensor pollicis longus (EPL) tendon is dissected distal to the extensor retinaculum and the third compartment is incised. The EPL is transposed radially to prevent injury to the tendon during manipulation and stabilization of the carpus (TECH FIG 1B).
- The fourth extensor compartment is incised longitudinally and the tendons are retracted. The dorsal capsule is now visible.
- One centimeter of the posterior interosseous nerve is excised as part of the procedure (TECH FIG 1C).
- A transverse rent extending through the dorsal capsule and radiotriquetral ligament is often found. This rent...
should be extended in both the radial and ulnar directions to allow visualization of the capitolunate interval.
- A more extensile ligament-sparing incision can also be used to gain considerable access to the carpus.
- Incise the capsule in a radial direction along the dorsal distal radial lip, leaving a small cuff of tissue attached to the radius for later repair.
- Incise ulnarly, along the dorsal radiotriquetral ligament and dorsal intercarpal ligament. This generates a radially based capsular flap (TECH FIG 1D).
- If the dislocation was not reducible closed, the capitate is prominent and the absence of the lunate is evident.
- The articular injury can now be assessed.

**Reduction and Fixation**
- Before reduction of the dislocation–subluxation, 0.045- or 0.062-inch Kirschner wire transfixation pins are inserted into the triquetrum and scaphoid through the dorsal incision in an in-to-out fashion. These pins are later driven back into the lunate to stabilize the reduction.
- The starting point for these pins is through the centroid of the aspect of the proximal pole of the scaphoid and triquetrum that articulates with the lunate (TECH FIG 2).
- Transfixation pins are unnecessary in the scaphoid if it is fractured since a screw in the scaphoid will stabilize the radial side of the carpus.
- In combination with manual traction and volar pressure on the lunate, insert a Freer elevator into the capitolunate

**TECH FIG 1** • A. Universal dorsal skin incision for the dorsal approach. B. The third extensor compartment is incised and the extensor pollicis longus (EPL) is transposed radially. The extensor digitorum communis (EDC) tendons are visible. (Thumb is at top left and wrist is to the right.) C. The fourth extensor compartment is incised and the EDC tendons are retracted ulnarly. The sensory branch of the posterior interosseous nerve to the wrist (vessel loop) is sacrificed. D. A ligament-sparing capsular incision may be made to visualize the carpus. Sc, scaphoid.

**TECH FIG 2** • Transfixation pins are placed through the scaphoid and triquetrum before reduction of the lunate. This facilitates placement of these Kirschner wires and advancement into the lunate after reduction. The entry point is the centroid of the intercarpal joint on the scaphoid and triquetrum. The tips of the Kirschner wires are seen slightly protruding from the scaphoid and triquetrum. The lunate is displaced volarly and is not visible.
joint around the proximal pole of the capitate and shoehorn the lunate into place.

- Reduce and stabilize carpal fractures.
- Attention is first directed toward fixation of an associated scaphoid fracture using proximal to distal (ante-grade) fixation.
  - The scaphoid is usually fractured at its waist or proximal pole.
  - In a noncomminuted fracture, stabilization is accomplished with a cannulated headless compression screw.
  - If comminution exists, autologous cancellous bone graft is applied before final tightening of the screw.

Ligament Repair

- Intercarpal ligament injuries may now be repaired.
- In a transscaphoid perilunate dislocation, the proximal pole of the scaphoid remains attached to the lunate with an intact scapholunate ligament. However, in lesser arc injuries, the scapholunate and the lunotriquetral ligament are disrupted.
- Before ligamentous repair, anatomic carpal realignment is ensured.
  - 0.045-mm Kirschner wires are introduced into the scaphoid, lunate, and triquetrum and used as joysticks to align these bones.
  - The previously set Kirschner wires used as transfixation pins are then advanced from the scaphoid and triquetrum into the lunate.

- Transfixation pins are also percutaneously introduced to stabilize the scaphoid and triquetrum to the capitate (TECH FIG 3A).
- Intraoperative fluoroscopy aids alignment and placement of Kirschner wires.
  - The scapholunate angle (40 to 60 degrees), capitolunate angle (less than 15 degrees), and radiolunate angle (less than 15 degrees) should be reduced and verified.
  - The C shape of the distal radius, lunate, and capitate should be concentric (TECH FIG 3B).
- Small (about 2 mm) suture anchors with nonabsorbable suture (2-0 to 3-0) are inserted for reattachment of the scapholunate and lunotriquetral ligaments, avoiding the Kirschner wires.
  - Most often the ligaments avulse from the scaphoid and the triquetrum; therefore, the anchors are placed in those locations.
  - When the intercarpal ligaments are beyond repair, suture anchors are unnecessary, and stability is established via extrinsic capsuloligamentous healing.
  - The dorsal capsular injury and extended capsulotomy is closed with nonabsorbable suture.
  - The EPL tendon is left transposed in a subcutaneous location (TECH FIG 3C).
  - The subcutaneous tissue and skin are closed in a standard fashion.

**TECH FIG 3** • Transfixation pins are in place protecting the ligament repairs and maintaining anatomic carpal alignment. Suture anchors were not required for repair in this case. The intercarpal ligament injuries were midsubstance.

- The PA radiograph shows the reduced trapezoidal shape of the lunate and restoration of the lines of Gilula. **A.**
- The lateral radiograph shows the reduced scapholunate, radiolunate, and capitolunate angles. The three concentric C’s are also visible. **B.**
- Repair of the extensor retinaculum and transposed extensor pollicis longus. **C.**
COMBINED DORSAL AND VOLAR APPROACH
(AUTHORS’ PREFERRED APPROACH)

Incision and Dissection
- A standard extended carpal tunnel approach is performed under tourniquet control (TECH FIG 4A).
- The median nerve is completely decompressed.
- The contents of the carpal canal are retracted and hematoma is evacuated.
- The volar capsuloligamentous injury, which is represented by an apex-distal, semilunar rent, is visualized (TECH FIG 4B).
- This rent courses between the RSC and LRL radially, and between the UTCC and ulnolunate ligaments ulnarly.
- In the case of a lunate dislocation, the lunate can be visualized within the carpal canal, having been extruded through the capsular tear.
- Next, the wrist is exposed dorsally as described above.
- The degree of injury is assessed.

Reduction, Fixation, and Repair
- Preset transfixation Kirschner wires as previously described.
- Reduce the carpus under direct visualization, with wrist extension and the aid of a Freer elevator to shoehorn the capitate into the lunate fossa.
- The volar approach facilitates the reduction by allowing direct access to the lunate.
- Surgical extension of the capsular tear between the RSC and LRL ligaments or between the UTCC and ulnolunate ligaments allows greater access to the wrist without further disruption of extrinsic ligaments.
- Through the dorsal incision, reduce, stabilize, and repair any associated carpal fractures and intercarpal ligament injuries in the manner described above.
- The volar capsuloligamentous rent is closed with nonabsorbable suture (TECH FIG 5).
- The flexor tendons may now be assessed. Often the tenosynovium surrounding the tendons within the carpal tunnel is thickened. A tenosynovectomy may be performed.
- The EPL should be left transposed dorsally.
- The subcutaneous tissue and skin are closed in a standard fashion.

TECH FIG 4 • A. Extended carpal tunnel incision used for the volar approach. B. A volar, semilunar, apex-distal, capsuloligamentous rent is visible at the space of Poirier. The lunate (Lu) is seen protruding from the rent.

TECH FIG 5 • The volar capsule is closed with nonabsorbable suture.
### POSTOPERATIVE CARE
- The immediate postoperative dressing includes a well-padded splint immobilizing the wrist and forearm in a neutral rotational position with about 20 degrees of wrist extension.
  - Edema control and prevention of skin maceration can be accomplished with the addition of sterile gauze dressings between the digits and a bulky dressing within the palm.
  - Active and passive digital range-of-motion exercises are encouraged immediately to prevent flexor tendon adhesions and digital stiffness.
  - Sutures are removed at 10 to 14 days and full-time cast or splint immobilization is continued for a total of 8 weeks postoperatively.
  - Pins may be removed at 8 weeks, and the patient may be converted to a removable splint to promote range of motion of the wrist.
  - At 12 weeks, strengthening is permitted with progressive resistance as tolerated.
  - Anticipated return to activities is 6 to 12 months.

### OUTCOMES
- Outcomes will vary with regard to stiffness and grip strength.
  - More accurate anatomic reduction will lead to improved results. Sotereanos et al\(^3\) used a dorsal–volar approach in 11 patients with perilunate dislocations and fracture-dislocations. Good to excellent results were achieved in 9 of 11 patients.
- Up to 50% loss of flexion–extension motion arc can be anticipated.\(^3\)
- Up to 60% diminished grip strength can be anticipated.\(^3\)

### COMPLICATIONS
- Missed diagnosis
- Postoperative pin-tract infections
- Median nerve injury
- Transient ischemia of lunate
- Chondral injury or chondrolysis
- Late carpal instability
- Nonunion or malunion of the scaphoid
- Posttraumatic arthritis

### REFERENCES
DEFINITION
- The triangular fibrocartilage complex (TFCC) is a complex anatomic structure located at the ulnar side of the wrist. It has several important biomechanical functions:
  - Extends the gliding surface of the radiocarpal joint
  - Cushions and stabilizes the ulnar carpus
  - Stabilizes the distal radioulnar joint (DRUJ)
- Disorders of the TFCC are responsible for the ulnar-sided wrist symptoms of pain, weakness, and instability that affect the patient’s function.
- The diagnosis and treatment of these injuries to the TFCC will restore stability, resulting in pain relief and a generally good prognosis for functional return.

ANATOMY
- The TFCC is a cartilaginous and ligamentous structure interposed between the ulnar carpus and the distal ulna (FIG 1A). It arises from the distal aspect of the sigmoid notch of the radius and inserts into the base of the ulnar styloid.17
- The TFCC attaches to the ulnar carpus via the ulnocarpal ligament complex (ulnolunate, ulnotriquetral, and ulnar collateral ligament) (FIG 1B).
- The radioulnar ligaments stabilize the DRUJ, limiting rotation as well as axial migration.7
- The dorsal and volar radioulnar ligaments are fibrous thickenings within the substance of the TFCC.
- As a result of this anatomic configuration, they function as a unit rather than as independent ligaments.
- The central, horizontal portion of the TFCC is the thinnest portion, composed of interwoven obliquely oriented sheets of collagen fibers for the resistance of multidirectional stress.
- The vascularity of the TFCC has been carefully studied.3 The TFCC receives its blood supply from the ulnar artery through its radiocarpal branches and the dorsal and palmar branches of the anterior interosseous artery. These vessels supply the TFCC in a radial fashion (see Bednar et al3 for a good image of TFCC vascularity).
- Histologic sections demonstrate that these vessels penetrate only the peripheral 10% to 40% of the TFCC. The central section and radial attachment are avascular.
- This vascular anatomy supports the concept that peripheral injuries can heal if injured and treated appropriately, whereas tears of the central portion do not heal if sutured and are usually debrided.

Biomechanics
- The TFCC has several important biomechanical functions: it transmits 20% of an axially applied load from the ulnar carpus to the distal ulna; it is the major stabilizer of the DRUJ; and it is a stabilizer of the ulna.1,6,18,19
  - The amount of the load transferred to the distal ulna varies with ulnar variance. A greater amount is transferred in positive ulnar variance than negative.
  - This results in a corresponding decreased thickness of the central portion of the TFCC in ulnar-positive wrists.
  - There is a variable load placed on the TFCC with forearm rotation. Supination causes a negative ulnar variance due to the proximal migration of the ulna. This is reversed with pronation as the ulna moves distally, causing it to become ulnar-positive.
  - The ulnar head also moves within the sigmoid notch in a dorsal direction with pronation and a volar direction with supination.
- The dorsal and volar radioulnar ligaments, which form the peripheral portion of the TFCC, serve as major stabilizers to translation at the DRUJ during forearm rotation.

PATHOGENESIS
- Traumatic injuries of the TFCC result from either the application of an extension, pronation force to the axially loaded wrist or a distraction force to the ulnar aspect of the wrist.

FIG 1 • A. Anatomic coronal section demonstrating the triangular fibrocartilage (TFC) and its relation to the lunate (L), triquetrum (T), distal ulna (U), and radius (R). B. Triangular fibrocartilage complex.
This will most commonly occur with a fall on the outstretched hand or a resisted torque force.

- The lesions are more common with ulnar-positive and neutral patients and are frequently found in patients with fractures of the distal radius.
- Several authors have examined the incidence of intracarpal soft tissue injuries associated with distal radial fractures.
- Geissler et al studied 60 patients, finding a TFCC injury in 26 (43%).
- In Lindau et al’s series of 51 patients, 43 had a TFCC injury (84%): 24 had a peripheral tear, 10 had a central perforation, and 9 had a combined central and peripheral tear.
- In a study of 180 wrist joints in 100 cadavers ranging in age from fetuses to 94 years, Mikic found that degeneration of the TFCC begins in the third decade of life.
- This degeneration increases in frequency and severity as people age.
- After the fifth decade of life, 100% of TFCCs appear abnormal.
- However, these age-related TFCC lesions are often asymptomatic.

**NATURAL HISTORY**

- The classification system described by Palmer is the most useful for describing TFCC injuries, dividing them into traumatic and degenerative.
- Traumatic lesions are classified according to the location of the tear within the TFCC. The traumatic class has been designated by Palmer as class 1, with subclasses of A, B, C, and D assigned to anatomic lesions within the TFCC (FIG 2A).
  - A class 1A lesion represents a tear in the horizontal or central portion of the TFCC. The tear is 2 to 3 mm medial to the radial attachment of the cartilage. It is usually oriented from dorsal to volar.
  - A class 1B lesion represents an avulsion of the peripheral aspect of the TFCC from its insertion onto the distal ulna. This can occur either with a fracture of the ulnar styloid or as a pure avulsion from its bony attachment. This type of injury disrupts the stabilizing effect of the TFCC on the DRUJ, resulting in clinical instability.
  - A class 1C lesion represents an avulsion of the TFCC attachment to the ulnar carpus by disruption of the ulnocarpal ligaments. These lesions result in ulnar carpal instability with volar translocation of the carpus.
  - A class 1D lesion represents an avulsion of the TFCC from its radial attachment. Isolated disc tears should be differentiated from disruption of the dorsal and volar radioulnar ligaments. Such global TFCC injury will result in DRUJ instability.
- Degenerative type 2 lesions are age-related, nontraumatic lesions to the TFCC, typically characterized by central perforations and positive ulnar variance. The natural history of such degenerative lesions, when and if they become symptomatic, is a progressive cascade of degenerative changes, as reflected in Palmer’s type 2 classification (FIG 2B).
  - The deterioration proceeds from TFC wear through central perforation (type 2C) to lunatotriquetral ligament tear and arthritic changes of the lunate, triquetrum, and distal ulna (type 2D or E).
  - Treatment is based on the stage of involvement.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Symptoms consist of ulnar-sided wrist pain, frequently with clicking, that typically occurs after a fall.
- The initial physical examination reveals swelling over the ulnar aspect of the wrist with inflammation of the tendon of the extensor carpi ulnaris.
- Point tenderness is present over the TFCC and distal ulna. The more isolated the point of maximal tenderness, the more specific the diagnosis.
  - A fovea sign (point tenderness directly over the ulnar TFC origin) indicates a type 1A or 1B TFCC injury or an ulnar extrinsic injury type [1C]).
  - Ulnar deviation and axial loading of the wrist (TFCC compression test) will elicit a painful response and a click with forearm rotation.
  - The DRUJ must be assessed for instability. Instability is best assessed with the forearm in neutral rotation, but it is also checked in full supination and full pronation.
  - The examiner stabilizes the distal radius with one hand and applies a force to the distal ulna, moving it dorsal and...
volar, looking for increased motion or subluxation of the distal ulna relative to the radius and comparing it with the opposite uninjured wrist.

- Significant instability can present as laxity of the distal ulna with a positive “piano key” sign and dorsal prominence of the distal ulna. This may be due to a significant tear or detachment of the dorsal or volar radioulnar ligaments.

- A click produced by ulnar deviation and supination over the extensor carpi ulnaris (ECU) sheath at the distal ulna indicates ECU instability with subluxation out of its sixth extensor compartment.

- A visual carpal supination deformity with ulnar prominence that can be passively corrected by a dorsally applied force to the pisiform indicates an ulnar extrinsic ligament tear.

- TFCC injuries do not occur in isolation; they are often a component of a spectrum of injury to the ulnar side of the wrist. The examiner must therefore evaluate all of the commonly injured structures on the ulnar side of the wrist.

- The lunatotriquetral joint must be assessed for instability due to a lunatotriquetral ligament tear. This would cause tenderness over the lunatotriquetral interval with a positive shock test (painful click as the lunate and triquetrum slide abnormally).

- Point tenderness over the triquetrum may signify a triquetral avulsion fracture.

- An audible clunk and visual subluxation of the carpus that occur with active ulnar deviation suggest that a midcarpal instability is present.

- Crepitus and pain over the pisotriquetral joint on the shear test may indicate pisotriquetral arthritis.

- The other soft tissue structures around the ulnar wrist should be examined, including the ulnar nerve, the dorsal ulnar sensory nerve branch, and the ulnar artery.

- Grip strength measurements using a Jamar dynamometer, while subjective, are helpful in quantitating patient effort and as a parameter to follow therapeutic progress.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- The diagnostic workup should include plain radiographs and a neutral rotation posteroanterior and lateral view.

- This will allow assessment for fracture, ligament instability resulting in carpal malalignment, and ulnar variance. It is important to determine ulnar variance because it will influence treatment options (FIG 3A).

- The DRUJ must also be examined radiographically to determine if subluxation, arthritis, or ulnar styloid abnormalities such as an acute or chronic nonunited fracture fragment are present.

- MRI is useful in the diagnosis of TFCC tears, especially the class 1A and D lesions.\textsuperscript{9,11} T2-weighted images in the coronal plane are of the greatest diagnostic value (FIG 3B).

- The TFCC has a homogenous low signal intensity. The synovial fluid of the joint appears as a bright image on T2 and will outline tears in the TFCC.

- A gadolinium arthrogram enhances the visualization of TFCC tears.

- The reported sensitivity and specificity of MRI in diagnosing injuries of the TFCC in the literature is variable.

- Golimbu et al\textsuperscript{9} reported a 95% accuracy of MRI in the detection of TFCC tears. MRI findings were verified arthroscopically.

- Schweitzer et al\textsuperscript{20} reported a sensitivity of 72%, a specificity of 95%, and an accuracy of 89%.

- Arthroscopic findings were correlated with the MRI and clinical examination in a series of patients with TFCC injuries reported by Bednar et al.\textsuperscript{2} The MRI sensitivity was 44% (the probability of a positive MRI when a TFCC lesion is present) and the specificity was 75% (the probability of a negative MRI when a TFCC lesion is absent). The clinical examination sensitivity was 95%. The MRI correlated with arthroscopic findings in 45% of the wrists studied.

- Joshy et al\textsuperscript{13} reported on a series of patients with a clinical suspicion of a TFCC tear studied by MR arthrography and then wrist arthroscopy. The MR arthrography sensitivity was 74% and its specificity was 80%. They caution that negative results of MR arthrography in patients with clinical suspicion of TFCC tear should be interpreted with caution.

- Wrist arthroscopy has recently become the criterion standard for both diagnosing and treating lesions of the TFCC.\textsuperscript{6}

- When compared to MRI and arthrography, arthroscopy most accurately determines the location of lesions and the size of tears and allows determination of whether a flap is unstable.

- Wrist arthroscopy can determine the coexistence of other lesions such as tears within the lunotriquetral interosseous ligament, ECU subsheath, or chondral lesions.

**DIFFERENTIAL DIAGNOSIS**

- ECU subluxation
- Ulnar extrinsic ligament tear
- DRUJ instability
- Triquetral avulsion fracture
- Lunatotriquetral ligament injury
- Pisotriquetral arthritis
- Ulnar artery thrombosis
- Ulnar neuropathy at the canal of Guyon
- Dorsal ulnar sensory neuritis
NONOPERATIVE MANAGEMENT

- The initial treatment of acute TFCC injuries includes immobilization of the wrist and DRUJ.
- The patient must be examined carefully to look for DRUJ instability or ECU subluxation.
- If the radiographs are negative and instability is not present, then immobilization for 4 to 6 weeks is recommended to allow healing of the TFCC disruption.
- A peripheral tear is expected to heal if the torn edges are held in close contact, due to the good vascularity of the periphery of the TFCC. Many central tears also become asymptomatic with immobilization even though there is no significant vascularity to the central portion.
- After immobilization, a therapy program involving range-of-motion exercises and gradual strengthening is initiated. Forceful grasp or torque is restricted for 8 weeks.
- If there is ongoing synovitis, a well-placed cortisone shot can further help to quiet this inflammation.
- Tears involving the ligamentous portion of the TFCC or those that heal with a flap of cartilage that impinges on the carpus or distal ulna will fail to respond to conservative treatment and will require operative intervention.
- It is reasonable to wait 3 to 4 months before proceeding to surgical treatment.
- Class 1B lesions without an ulnar styloid fracture and a stable DRUJ can be immobilized for 4 weeks in a cast. If an ulnar styloid fracture is present, closed reduction should be attempted. If adequate reduction is achieved, then cast immobilization is sufficient. If the styloid remains displaced, then open reduction and internal fixation is required.

SURGICAL MANAGEMENT

- Patients who remain symptomatic after adequate immobilization should undergo further workup, including MRI with or without gadolinium.
- The specific treatment for each traumatic class 1 lesion is determined by the type of tear found arthroscopically.
- Arthroscopic treatment has become increasingly the method of choice for many traumatic lesions.
- The treatment of traumatic radial detachment of the TFCC from the sigmoid notch of the distal radius is controversial. There appears to be no vascularity to this portion of the TFCC, so theoretically a reattached cartilage would not heal at this repair site. However, clinical experience with open repair of these tears has been positive.\(^5\,\,\,21\) This may be attributed to vascular ingrowth from the bony radial insertion site that occurs with abrasion of the attachment site, stimulating the formation of new vessels.
- If the radial tear includes disruption of one or both of the radioulnar ligaments, repair is required to prevent chronic DRUJ instability.
- The algorithm for the treatment of degenerative type 2 tears proceeds from arthroscopy to ulnar-shortening osteotomy (see Chaps. HA-94 and HA-95).
- Plain films should identify the ulnar variance, DRUJ alignment, abnormalities of the ulnar styloid, or the presence of arthritic changes. Positive ulnar variance has a strong association with degenerative tears.

Preoperative Planning

- All physical examination findings and radiographic study results must be reviewed.
- Examination under anesthesia is performed, including the tests discussed earlier, before positioning in the arthroscopy tower.

Positioning

- Wrist arthroscopy requires distraction, and the wrist is positioned in the traction tower (FIG 4).

WRIST ARTHROSCOPY

- Diagnostic wrist arthroscopy of the radiocarpal and midcarpal joints is completed and all pathology is identified.
- Recognize the appearance of a normal TFC (TECH FIG 1).
- The type of TFC injury is identified.
  - A trampoline test is positive when the surgeon’s probe sinks into the TFCC rather than bouncing off it like a drumstick on a snare drum. Such loss of disc compliance is often seen with a peripheral tear.\(^10\) However, laxity of the TFCC does not necessarily translate into DRUJ instability.
  - Loose bodies, if present, are removed.
  - Inflamed synovium is removed with a shaver or radiofrequency probe.
Peripheral TFC tears are well vascularized and amenable to repair using arthroscopic techniques. A two-needle method similar to that employed for the repair of a knee meniscus is described here (TECH FIG 2A).

Visualize the tear through the 3–4 portal.

Initial arthroscopic evaluation may not reveal a tear of the TFCC periphery, but often synovitis and a thin scar will be seen along the periphery of the TFCC at the location of the tear (TECH FIG 2B).

A probe placed through the 6R portal will demonstrate loss of the normal trampoline effect of the TFCC, indicating a peripheral tear and loss of mechanical function of the TFCC (TECH FIG 2C).

Débride the edges of the tear and undersurface scarring with a shaver to create mobile edges with fresh areas for healing.

Adhesions may be present between the undersurface of the TFCC and the distal ulna. These must be released and the TFC mobilized sufficiently to allow advancement to reattach it and to restore proper tension.

After débridement, a 1-cm longitudinal incision is made extending the 6R portal.

Avoid injury to branches of the dorsal ulnar sensory nerve.

Open the sixth extensor compartment radially for 1 cm and retract the extensor carpi ulnaris ulnarily, providing access to its subsheath.

The repair includes the subsheath of the ECU compartment as this is intimately associated with the peripheral TFC.

Two needles are passed across the tear under arthroscopic vision (TECH FIG 2D).

A wire loop is passed through one needle to retrieve a 2-0 PDS suture, which is passed through the other needle.

This allows the placement of a horizontal mattress suture across the tear (author’s preference) (TECH FIG 2E).

Alternatively, multiple simple vertical sutures placed at the periphery of the TFCC may approximate the torn edges and restore tension to the TFCC. The suture is tied either under the skin over the dorsal wrist capsule (preferred) or out of the skin over a bolster. Usually two or three sutures are placed.

Postoperatively, a short-arm splint is applied.

I have not found a significant difference between use of a short-arm splint and use of a long-arm or sugar-tong splint in regard to healing and outcome.

**TECH FIG 2**  
*A.* Meniscus repair needles with 2-0 PDS suture used for an out-to-in repair.  
*B,C.* Peripheral TFC tear with loss of compliance such that the probe sinks into the lax surface. Unlike a central tear, fibrous tissue and incomplete healing obscure the actual tear.  
*D.* Arthroscopic repair of a type 1B peripheral TFC complex tear. Two hollow needles are passed across the tear. A wire loop in one needle is used to pass 2-0 suture across the tear. The suture is tied over the capsule.  
*E.* The suture approximates the tear and restores tension to the TFCC.
OPEN REPAIR OF PERIPHERAL TFC TEARS WITHOUT ULNAR STYLOID FRACTURE

- If there is significant DRUJ instability and avulsion of the TFC from the ulna fovea, an open repair is preferred.
- Expose the fifth extensor compartment and retract the extensor digiti quinti minimi tendon.
- Create an L-shaped capsulotomy of the DRUJ and identify the foveal attachment site of the TFC (TECH FIG 3A).
- Reattach the TFC with a bone anchor or bone suture (TECH FIG 3B–D).
- Postoperative care mirrors that of arthroscopic TFC repair.10

TECH FIG 3 • Open repair of unstable TFCC avulsion. A. Dorsal exposure through the fifth extensor compartment. A DRUJ capsulotomy has been performed. B. Defining the foveal insertion site. C. Insertion of bone anchor at foveal attachment. D. Sutures in place.

OPEN REPAIR OF PERIPHERAL TFC TEARS WITH ULNAR STYLOID FRACTURE

- Expose the ulnar styloid using an incision just volar and parallel to the ECU tendon.
- Protect the dorsal ulnar sensory nerve and preserve the ECU sheath.
- Base the method of fixation (longitudinal Kirschner wire, screw, bone anchor, or tension band) on fragment size and surgeon comfort.
- If the ulnar styloid is comminuted and will not allow stable fixation, it can be excised and the TFCC attached to the ulna by a suture placed through drill holes in the ulna proximal to the fracture or using the suture anchor technique described earlier.
- The patient is immobilized in a short-arm splint or cast for 4 weeks before starting rotational motion.

Surgery for Radial-Sided TFC Avulsion Tears

- Assess the tear arthroscopically (TECH FIG 4A) and repair it in the manner detailed below if instability is present.
- Place a burr through the 6R portal to roughen the radial attachment of the TFCC (TECH FIG 4B).
- Drill two holes using a 0.062-inch Kirschner wire in a retrograde manner, starting at the TFC insertion site. These holes will allow placement of the repair suture.
- The wires must exit the radius on its radial border, just volar to the first extensor compartment.
- An incision is made over the exiting Kirschner wire to retract and protect the radial sensory nerve and the tendons of the first extensor compartment.
- A cannula is placed in the 6R portal, through which a meniscal repair suture (2-0 PDS suture with a long straight needle at each end) is passed through the torn radial aspect of the TFCC in a horizontal mattress fashion, with each needle passing through the predrilled holes in the radius. (TECH FIG 4C).
- The placement of the needles into the predrilled holes can be challenging since the holes are not visible by the scope in the 3-4 portal. Two 18-gauge spinal needles can be placed from the radial side of the radius through the bone until they can be seen in the joint at the attachment site for the TFCC. The needles provide a visible target for the meniscal repair suture needles.
- If the meniscal repair suture with long straight needles is not available, pass 18-gauge needles through the bone tunnels, then directly through the torn radial TFC. A 2-0 PDS suture is passed from one 18-gauge needle to the other using a wire retrieval loop.
- The suture is tied over the radius (TECH FIG 4D).
- A short-arm splint is applied.

WRIST INSTABILITIES

TRAUMATIC RADIAL TFC TEAR
A. Traumatic radial TFC tear. Such an isolated tear can be débrided or repaired based on the degree of instability. B. Radial TFC tear repair. Burring of the attachment site along the sigmoid notch of the radius to bleeding bone is necessary to introduce additional vascularity and promote wound healing. C,D. Radial tears are repaired with suture on meniscal needles, tied over a bone bridge on the radial aspect of the distal radius.

PEARLS AND PITFALLS

Indications
- Traumatic and degenerative TFC lesions with sufficient symptoms
- If the DRUJ is stable, allow 3 to 4 months of nonoperative treatment.

Preoperative evaluation
- Assess ulna variance.
- Physical examination under anesthesia
- Complete diagnostic wrist arthroscopy of both radiocarpal and midcarpal joints
- A complete history and physical examination of ulnar wrist pain causes

Treatment options relate to type of TFC lesion
- 1A: arthroscopic débridement
- 1B without fracture: arthroscopic or open repair (DRUJ instability)
- 1B with ulna styloid fracture and instability: reattach ulna styloid
- 1C: Rare 1B repair plus ulnar extrinsic ligament repair
- 1D: If isolated, débrane; if unstable, repair
- Degenerative lesions: arthroscopic wafer or ulna-shortening osteotomy

Pitfalls
- Excise only unstable central TFC portion.
- Protect dorsal sensory nerves and extensor tendons.

POSTOPERATIVE CARE
- After open or arthroscopic TFC repair, a short-arm splint or cast is applied for 4 to 6 weeks.
- Range-of-motion exercises are then progressed, using a removable splint for protection initially.
- Forceful wrist use is restricted for 3 months.

OUTCOMES
- Arthroscopic limited débridement of the central portion of the tear will provide excellent relief of symptoms, with 80% to 85% of patients having a good to excellent result.15
- The biomechanical effect of excision of the central portion of the TFCC has been examined.1,6 The excision of the central two thirds of the TFCC with maintenance of the dorsal and volar radioulnar ligaments as well as the ulnocarpal ligaments had no statistical significant effect on forearm axial load transmission. The removal of greater than two thirds will unload the ulnar column, shifting load to the distal radius and destabilizing the DRUJ. Adams1 further emphasized that the peripheral 2 mm of the TFCC must be maintained during central débridement in order not to have a biomechanical effect on load transfer.
- The results of arthroscopic repair of 1B TFCC lesions are equivalent to those reported for open repair. Gratifying outcomes are reached 85% to 90% of the time.5,6,22
- The treatment of radial detachment of the TFCC from the sigmoid notch of the distal radius remains controversial.
- Débridement of an isolated radial tear not associated with joint instability, similar to that for 1A lesions, yields excellent results.15
- Clinical experience with open repair of radial TFC avulsion tears has also been good.5,21 Short21 reported 79% excellent and good results in his series, with return of grip strength to 90%, after arthroscopic repair of radial TFC tears.

COMPLICATIONS
- Failure to make a complete diagnosis (eg, associated ECU subluxation)
Chapter 49 ARTHROSCOPIC AND OPEN TRIANGULAR FIBROCARTILAGE COMPLEX REPAIR

- Failure to appreciate DRUJ instability
- Loss of wrist motion
- Injury to dorsal sensory nerves
- Nonunion of the ulnar styloid or ulnar osteotomy

REFERENCES

DEFINITION
 Distal radioulnar joint (DRUJ) instability may be classified as acute or chronic, unidirectional (volar or dorsal) or bidirectional, and isolated or in association with other injuries. There is no consensus regarding the definition of clinically significant instability, though various radiographic criteria have been used. In general, the key physical finding is the presence of increased anteroposterior translation of the DRUJ with passive manipulation when compared with the normal side. Although the radius actually rotates around the stable ulna, by convention DRUJ dislocation or instability is described by the position of the ulnar head relative to the distal radius.

ANATOMY
 The DRUJ consists of the articulation between the ulnar head and the sigmoid notch of the distal radius and the associated supporting soft tissues. The DRUJ is not a congruent joint. The shallow sigmoid notch has a radius of curvature that is on average 50% greater than the ulnar head. Joint surface contact area is maximized at neutral rotation. Though the sigmoid notch is relatively flat, the dorsal and volar rims, which are typically augmented by fibrocartilaginous extensions, do provide an important contribution to joint stability. The soft tissue structures that contribute to DRUJ stability are the pronator quadratus, extensor carpi ulnaris (ECU) and its sheath, interosseous membrane, DRUJ capsule, and several components of the triangular fibrocartilage complex (TFCC). Multiple structures must be injured to result in joint instability.

The palmar and dorsal radioulnar ligaments are the prime components of the TFCC that stabilize the DRUJ. They are thickenings at the combined junctures of the triangular fibrocartilage articular disc, DRUJ capsule, and ulnocarpal capsule. As each radioulnar ligament passes ulnarly, it divides in the coronal plane into two limbs. The deep or proximal limbs of the radioulnar ligaments attach at the fovea and the superficial or distal limbs attach to the base and midportion of the ulnar styloid (FIG 1B). The total pronation–supination arc in a normal individual varies between 150 and 180 degrees. Normal pronation and supination involves a combination of rotation and dorsal-palmar translation of the distal radius on the stable ulna.

PATHOGENESIS
 The most common cause of DRUJ disruption is a fracture of the distal radius. Distal radius angulation greater than 20 or 30 degrees creates DRUJ incongruity, distorts the TFCC, and alters joint kinematics. More than 5 to 7 mm of radial shortening results in rupture of at least one of the radioulnar ligaments. Fractures of the tip of the ulnar styloid are not typically associated with DRUJ instability. Fractures of the base of the ulnar styloid can result in disruption of the radioulnar ligaments, causing DRUJ instability. Most isolated DRUJ dislocations (not associated with a fracture) are dorsal and caused by forceful hyperpronation and wrist extension, such as with a fall on an outstretched hand or the sudden torque of a rotating power tool.

![Image](image1.png)

**FIG 1** • A. Distal radioulnar joint (DRUJ) cross-section. The radius of curvature of the sigmoid notch is much greater than the radius of curvature of the ulnar head. B. DRUJ ligaments. (The disk component of the triangular fibrocartilage complex has been removed to show the deep limbs of the radioulnar ligaments.) The volar and dorsal radiopalmar ligaments, the major soft tissue stabilizers of the DRUJ, insert at the fovea and onto the base of the ulnar styloid.
Isolated volar DRUJ dislocations occur with an injury to the supinated forearm or a direct blow to the ulnar aspect of the forearm.

**Natural History**
- Delayed diagnosis and treatment of DRUJ injuries associated with distal radius fractures results in worse outcomes.\(^7\)
- Chronic instability rarely improves spontaneously.
- Although there is no proven association between DRUJ instability and the development of symptomatic arthritis, some degeneration should be expected in recurrent dislocators.

**Patient History and Physical Findings**
- Patients may report falling on an outstretched hand or a forced rotation of the hand followed by ulnar-sided wrist pain and swelling.
- Patients with chronic instability may report a clunk at the wrist with forearm rotation.
- Pain and weakness is exacerbated by activities requiring forceful rotation while gripping, such as turning a screwdriver.
- Increased passive volar-dorsal translation of the ulna relative to the radius is evidence of DRUJ instability.
- When treating an acute distal radius fracture with evidence of DRUJ disruption, the fracture should be reduced and stabilized first, followed by assessment of the DRUJ, as the fracture management alone usually provides adequate treatment for the DRUJ.
- In the absence of DRUJ arthritis, patients with DRUJ instability typically have full or nearly full wrist range of motion, including flexion, extension, pronation, and supination.
- A thorough patient examination should include the following tests:
  - Passive translation (“piano key” sign). Perform the test and compare results to the unaffected side. A positive test result indicates DRUJ instability, which is seen in 14 of 14 patients treated by ligament reconstruction.\(^2\)
  - Modified press test. Increased depression of ulnar head on affected side (“dimple” sign) indicates instability.\(^2\) Pain without increased depression may indicate a TFCC tear.\(^6\)
  - Passive forearm rotation. A painful clunk indicates gross DRUJ instability. This should not be confused with more subtle ECU subluxation.

**Imaging and Other Diagnostic Studies**
- A zero-rotation posteroanterior view is obtained by abducting the humerus 90 degrees, flexing the elbow 90 degrees, and placing the forearm on a flat surface. Signs of DRUJ instability on this view include:
  - Displaced fracture at the base of the ulnar styloid
  - Fleck fracture from the fovea of the ulnar head
  - Widening of the DRUJ
  - Greater than 5 mm of acquired ulnar or positive variance compared to the opposite wrist
- A true lateral radiograph is performed with the arm at the patient’s side and the elbow flexed 90 degrees. Obtaining a true lateral radiograph is important to avoid inaccurate assessment of DRUJ alignment. Mino et al\(^9\) showed that only 10 degrees of rotation from neutral resulted in an inability to correctly diagnose DRUJ dislocation on the lateral radiograph.

On a true lateral wrist radiograph, the lunate, proximal pole of the scaphoid, and triquetrum should overlap completely and there should be no space between the triquetrum and pisiform.

**CT** must be performed on both wrists, with each image obtained with the forearm in identical rotation to allow comparison between the normal and symptomatic joints (Fig 2).

The addition of applied stress to the joint during imaging may aid in detection of subtle instability.\(^10\)

MRI (with or without intra-articular dye) may be used to detect TFCC tears, although the reported sensitivity and specificity for such injuries is variable. MRI can also be used instead of CT to assess the shape of the sigmoid notch and joint stability.

**Differential Diagnosis**
- ECU tendinitis or subluxation
- Ulnar impaction syndrome
- DRUJ arthritis
- Pisotriquetral arthritis
- Lunotriquetral ligament injuries
- TFCC disc tears

**Nonoperative Management**
- Patients with mild chronic instability may benefit from a course of nonsteroidal anti-inflammatories, a splint that limits forearm rotation, and a forearm strengthening program.
- Patients with generalized ligamentous laxity and bilateral DRUJ instability have less predictable results with operative reconstruction. In such patients, all attempts at conservative management should be exhausted before considering surgery.

**Fig 2** • CT of distal radioulnar joint (DRUJ). A. Well-reduced asymptomatic DRUJ. B. Subluxated DRUJ on the symptomatic side. (A, B: dorsal is left and volar is right.)
SURGICAL MANAGEMENT

- Distal radioulnar ligament reconstruction is indicated in cases of chronic DRUJ instability where tissues are inadequate for primary repair of the TFCC.
- The goal of ligament reconstruction is to restore DRUJ stability and provide a full, painless arc of forearm motion.
- The technique described creates stability by near-anatomic reconstruction of the dorsal and volar radioulnar ligaments.
- If present, osseous malalignment must be addressed at the time of ligament reconstruction to obtain a good result.

Preoperative Planning

- The surgeon should review imaging studies for evidence of osseous deformity or degeneration of the DRUJ articular surfaces. Soft tissue reconstruction in the presence of substantial residual bony deformity or arthritis will yield poor results.

Intra-articular radioulnar ligament reconstruction requires a competent sigmoid notch for success. A notch that is developmentally flat or that has posttraumatic deficiency of either rim should be treated with a sigmoid notch osteoplasty at the time of ligament reconstruction.
- The surgeon should determine the presence of suitable tendon graft. The palmaris longus (PL) tendon is typically used. Alternative graft sources include plantaris, extensor digitorum longus, or most commonly a strip of the flexor carpi ulnaris tendon.
- The PL tendon can be identified by having the patient flex the wrist while holding the tips of the thumb and small finger together.

Positioning

- The patient is positioned supine with the affected limb resting on a hand table. Additional positioning may be necessary to allow access to graft harvest sites.
- A well-padded tourniquet is placed on the upper arm.

PALMARIS TENDON GRAFT HARVEST

- The PL tendon is identified by palpation. It is one of the most superficial structures at the distal wrist crease and lies just ulnar to the flexor carpi radialis tendon (TECH FIG 1A).
- A single 1-cm transverse incision is made at the proximal volar wrist crease overlying the PL tendon (TECH FIG 1B).
- A shepherd's hook is used to pull tension on the tendon and absolutely confirm its identity.
- The tendon is clamped with a hemostat and transected just distal to the hemostat.
- A small tendon stripper is passed distal to proximal along the PL tendon in the forearm to complete the harvest.
- Alternatively, a strip of the flexor carpi ulnaris tendon can be harvested using a tendon stripper through the same volar incision for graft passage.

DORSAL APPROACH

- A 5-cm skin incision is made between the fifth and sixth extensor compartments overlying the DRUJ (TECH FIG 2A).
- The fifth compartment is opened and the extensor digiti minimi is retracted.
- An L-shaped capsulotomy is made in the DRUJ capsule with one limb in line with the sigmoid notch and the other just proximal and parallel to the TFCC (TECH FIG 2B). The ECU tendon sheath marks the ulnar limit of the capsulotomy.
- The ECU tendon sheath is not disrupted during this approach.

TECH FIG 1 • Graft harvest. A. The palmaris tendon can be brought into relief by having the patient touch the thumb and small fingers while flexing the wrist slightly. B. A small transverse incision is made at the proximal wrist crease.
BONE TUNNEL PLACEMENT

- Careful subperiosteal dissection is used to elevate the soft tissue from the dorsal edge of the sigmoid notch for several millimeters.
- A guidewire for a 3.5-mm cannulated drill bit is driven from dorsal to volar through the radius.
  - The tunnel should begin several millimeters proximal to the lunate fossa and about 5 mm radial to the articular surface of the sigmoid notch (TECH FIG 3A).
  - The tunnel should be parallel to the articular surfaces of both the sigmoid notch and lunate fossa.
- Fluoroscopy is used to confirm guidewire placement, and the tunnel is made with a 3.5-mm cannulated drill bit (TECH FIG 3B).
- If a corrective osteotomy of the radius is planned, it is easier to make the bone tunnels before performing an osteotomy, but the tendon graft should not be placed or tensioned until the osteotomy is completed.
- The ulnar flap of the DRUJ capsulotomy is elevated to expose the ulnar head and neck, being careful not to interrupt the ECU tendon sheath.
- The ulnar bone hole travels from the ulnar fovea to exit on the lateral ulnar neck just volar to the ECU tendon (see Tech Fig 3A). Flex the wrist pronate the forearm, and retract the TFCC remnant to reveal the ulnar fovea. Pass a guidewire retrograde from the ulnar fovea to exit on the lateral ulnar neck just volar to the ECU tendon. Confirm the guidewire position with fluoroscopy. If flexing the wrist does not provide adequate exposure, the tunnel may be created antegrade from ulnar neck to fovea, while carefully protecting any TFCC remnant and the ulnar carpus (TECH FIG 3C).
- Standard drill bits may be used to enlarge the bone tunnels to accommodate the previously harvested graft. The ulnar bone tunnel must accommodate both limbs of the tendon graft.
GRAFT PASSAGE

- A second exposure is made to visualize the volar aspect of the radius bone tunnel.
- A 3-cm longitudinal incision is made extending proximally from the proximal wrist crease (TECH FIG 4A).
- Dissection is carried down between the ulnar neurovascular bundle and finger flexor tendons to reach the volar surface of the radius.
- A suture passer is passed through the radius bone tunnel from dorsal to volar and used to pull one end of the tendon graft back through the distal radius (TECH FIG 4B).
- A straight hemostat is passed over the ulnar head, dorsal to volar, to bluntly pierce the volar DRUJ capsule just distal to the ulnar head. The other end of the graft is grasped and pulled back through the capsule.
- At this point, both tendon ends should be visible through the dorsal wound. The suture retriever is used to pass both tendon ends through the ulna bone tunnel from the fovea to exit at the ulnar neck (TECH FIG 4C).
- A curved hemostat is used to guide the tendon ends around a portion of the ulnar neck in opposite directions, with one limb of the graft passing deep to the ECU sheath and the other around the volar neck (TECH FIG 4D).
- Avoid entrapping any nearby neurovascular structures.

TECH FIG 4 • Graft passage. A. A small volar approach is necessary to allow graft passage. B. A suture passer travels through the radial bone tunnel (dorsal to volar) to retrieve one limb of the graft (indicated by a red vessel loop). C. In this dorsal view, the graft is brought through the volar capsule into the ulnocarpal joint then the two ends are fed into the ulna tunnel. D. In this axial drawing the course of the free graft is visualized. The graft provides a near-anatomic reconstruction of the volar and dorsal radioulnar ligaments. E. The graft (red vessel loop) exits the radial bone hole (short arrow) into the dorsal wound and then enters the ulnar bone hole through the fovea (long arrow). The ends of the graft are then wrapped around the ulna neck.
**Chapter 50 INTRA-ARTICULAR RADIOULNAR LIGAMENT RECONSTRUCTION**

**POSTOPERATIVE CARE**
- The patient is placed in a long-arm splint with the forearm in neutral to slight pronation or supination, depending on the most stable DRUJ position. At the first postoperative visit, the patient is transitioned to a long-arm cast for 3 weeks.
- At 4 weeks postoperatively, the patient is placed in a well-molded short-arm cast for an additional 2 weeks.
- At 6 weeks after surgery, the cast is changed to a removable splint, which is worn for an additional 4 weeks.
- The patient should be able to return to most activities by 4 months after surgery, but heavy lifting and impact loading are avoided until 6 months postoperatively.

**OUTCOMES**
- Patients with a deficient sigmoid notch are more likely to experience recurrent instability if the deficits are not corrected.
- Most patients experience decreased pain and improved strength and stability while maintaining near-normal range of motion. However, full recovery may require 6 to 9 months.
- The described technique effectively restored stability in 12 of 14 patients while providing about 85% of the strength and range of motion of the contralateral unaffected side. The two failures resulted from deficiencies of the sigmoid notch that were not recognized preoperatively.

**PEARLS AND PITFALLS**

**COMPLICATIONS**
- Joint stiffness
- Recurrent instability
- Persistent pain
- Weakness of grasp
- Infection
- Complex regional pain syndrome

**REFERENCES**

**GRAFT TENSIONING AND FIXATION**
- The forearm is held in neutral rotation and the DRUJ is manually compressed.
- The two graft limbs are pulled taut and a half-hitch knot is made against the dorsal aspect of the ulnar neck.
- While maintaining firm tension in the graft, the half-hitch is secured with 3-0 nonabsorbable sutures (TECH FIG 5).

**TECH FIG 5 • Graft tensioning. Tension is held on the graft while the knot is secured with a suture.**

- Teoh and Yam reported similar results, with restoration of stability in seven of nine patients using a similar reconstructive method.

DEFINITION

- The diagnostic and therapeutic challenge presented by instability of the ulnocarpal joint reflects the inherent biomechanical and anatomic incongruity of the articulation.
- The triangular fibrocartilage complex (TFCC) provides the majority of anatomic and functional stability of the distal radioulnar and ulnocarpal joints.\(^1,16\)
- As expected, the consequences of TFCC lesions reflect a disruption of its normal function. The Hui-Linscheid procedure and the modified Herbert reconstruction are two approaches to achieve surgical stabilization of the distal radioulnar joint (DRUJ). The Hui-Linscheid reconstruction stabilizes the DRUJ by augmenting function of the ulnocarpal ligament,\(^6\) while the modified Herbert reconstruction restores the radioulnar and ulnocarpal functions of the TFCC by ligamentotaxic constraint of the ulnar carpus.\(^3\)

ANATOMY

- The ulnar carpus does not directly articulate with the distal ulna; instead, the ulnar carpus is suspended from the ulnar head by the TFCC.
- The TFCC is a collection of soft tissue structures that stabilizes the radial-ulnar-carpal unit (FIG 1). It consists of fibers originating from the subsheath of the extensor carpi ulnaris, the ulnocarpal ligaments, the dorsal and palmar radioulnar ligaments, and the triangular fibrocartilage proper.
- The TFCC provides a continuous gliding surface that spans the distal surfaces of the radius and ulna, allowing carpal movements and acting as a dynamic stabilizer of the forearm during pronation and supination.\(^12,18\) In addition to its radioulnar function, the TFCC stabilizes the ulnar side of the carpus, aids in load transference from the ulnar carpus to the ulna, and cushions ulnocarpal forces.\(^16\)
- The dorsal and volar distal radioulnar ligaments, which are often referred to as the marginal ligaments, help to stabilize the radioulnar joint through its extremes of motion.
- While controversy exists concerning the exact role of each marginal ligament, several authors have agreed that the ligaments act in concert to stabilize the DRUJ during pronosupination.
- The extensor retinaculum is a thick fibrous band of tissue that holds the extensor tendons against the distal radius and ulna to prevent bowstringing and displacement of the tendons (FIG 2). It is continuous with the palmar carpal ligament and shares connecting fibers with the flexor retinaculum just proximal to the pisiform. The extensor retinaculum attaches to the pisiform and triquetrum medially and to the lateral margin of the radius laterally. It is positioned from a radial-proximal to ulnar-distal direction.\(^15,19\)

PATHOGENESIS

- Injuries to the TFCC can occur secondary to trauma, such as a fall on the outstretched hand, or from degenerative changes caused by repetitive loading, especially in patients with rheumatoid arthritis. Palmer has classified TFCC abnormalities by differentiating between traumatic and degenerative pathologies, with further specification within each group.\(^11\)
- Dorsal subluxation of the ulnar head, with or without supination deformity of the radiocarpal complex and ulnocarpal instability, can occur with attenuation or tears of the dorsal radioulnar ligaments.\(^16,18\) The Hui-Linscheid reconstruction repairs these defects through augmentation of ulnocarpal ligament

![FIG 1](image)

The soft tissue structures encompassing the triangular fibrocartilage complex of the wrist stabilizing the radial-ulnar-carpal unit. The triangular fibrocartilage proper originates from the radius medially and attaches to the base of the ulnar styloid. Fibers originating from the subsheath of the extensor carpi ulnaris dorsally cross paths with fibers originating from the ulnocarpal ligaments volarly and blend with the triangular fibrocartilage proper.
Ulnocarpal instability may also result from incompetence of the ulnocarpal ligaments, either secondary to acute trauma or from cumulative attrition. The modified Herbert reconstruction addresses ulnocarpal instability by using ligamentotaxis to stabilize both the ulnocarpal and radioulnar aspects of the DRUJ.

**Natural History**

Ulnocarpal instability is a relatively common finding in the general population. Approximately two thirds of asymptomatic volunteers were found to have some form of ulnocarpal instability on physical examination. Medical or surgical intervention is necessary if symptoms are present or are worsening.

The unstable ulnocarpal joint uses the radiocarpal joint as a pivot. The abnormal rotation in this pathologic state leads to increased pain, weakness, and loss of function during wrist supination. In addition, an ulnar-sided supination deformity may be present.

**Patient History and Physical Findings**

In both acute and chronic cases, the clinical presentation of the ulnocarpal instability consists of ulnar-sided wrist pain with or without clicking, especially with forearm pronation–supination activities, such as putting topspin on a tennis ball with a forehand shot.

> There may be demonstrable laxity during supination and weakness in passive or active pronation–supination movements. These symptoms may hinder range of motion and function of the wrist.
> On physical examination, patients often localize tenderness to the ulnar carpus on palpation.
> The examiner should palpate the ulnar styloid.
> The examiner should palpate between the ulnar styloid and triquetrum.
> Visual inspection of the ulnocarpal area is important, looking for swelling and alignment of the carpal area in relation to the ulna. Swelling may be the result of acute injury. Position of tissues indicates stability or instability.
> In the absence of concomitant pathology, provocative maneuvers such as Watson and shuck tests are negative.
> Watson test: Pain and movement of the scaphoid despite blocking its normal capacity to flex in radial deviation is an indication of scapholunate tear or laxity.
> The Shuck test is performed to evaluate lunotriquetral instabilities.
> A positive piano key test indicates a complete peripheral tear of the TFCC and/or dorsal radioulnar ligament tear.
> Midcarpal instability can be ruled out with a negative wrist pivot shift test, as first described by Lichtman et al.
> In patients with ulnocarpal instability, the wrist assumes an ulnar-sided supination deformity similar to that seen in rheumatoid arthritis.
> A key to diagnosing ulnocarpal instability is the supination test, which is a diagnostic maneuver developed by the first author. This examination is performed by stabilizing the affected DRUJ with a firm grasp while stressing the wrist in supination and volar translation.
> When the wrist is loaded axially and returned through neutral in ulnar deviation, the patient’s pain is reproduced. The wrist may also “clunk” back into reduction.
> The contralateral wrist is also tested for comparison.

**Imaging and Other Diagnostic Studies**

- Standard posteroanterior and lateral radiographs have poor diagnostic value for ulnocarpal joint instabilities but can be used to rule out scapholunate interosseous ligament (SLIL) and lunatotriquetral interosseous ligament (LTIL) tears. On a pure lateral view, if there is DRUJ instability, the ulna will be dorsally positioned relative to the radius instead of being seen superimposed on the radius.
- Computed tomography is useful for visualizing joint congruity and fractures as well as subluxation or dislocation of the DRUJ.
- Live fluoroscopy during the supination test allows the examiner to evaluate and visualize the presence and amount of ulnocarpal joint instability (FIG 3).
  - The changing appearance of the triquetrum, demonstrated by its decreased length while in a position of supination, indicates ulnocarpal instability.
  - The pisiform’s location in relation to the triquetrum may also indicate the type of ligamentous tear or laxity by either moving together with the triquetrum during the supination test or appearing to be stationary as the triquetrum is moving.
  - Triple-injection arthrography of the midcarpal row, radiocarpal joint, and DRUJ can be useful in showing SLIL or...
LTIL tears, TFCC tears, and ulnar-sided TFCC tears, respectively.
- The findings must correlate with symptoms for accurate diagnosis.\textsuperscript{8,17}
- Standard magnetic resonance (MR) imaging effectively demonstrates the normal anatomy of the TFCC as well as the intrinsic and extrinsic ligaments of the wrist.
- Abnormalities of these structures can be detected with experience, but the radiographic literature has reported shortcomings of standard MR in diagnosing peripheral TFCC tears.
- MR arthrography, with injection of contrast into the DRUJ, has been shown as an adequate way of diagnosing peripheral TFCC tears, with a sensitivity of 85\% and specificity of 76\% when compared to wrist arthroscopy.\textsuperscript{14}
- Wrist arthroscopy is widely considered the gold standard of diagnostic studies of the wrist. Arthroscopic visualization allows for the determination of the size, location, and extent of ligamentous injuries of the wrist.
- Comparison of arthroscopy to arthrography by Cooney\textsuperscript{2} revealed arthroscopy to be the superior method of diagnosing injuries of the TFCC and interosseous ligaments.

**DIFFERENTIAL DIAGNOSIS**
- Fracture
- DRUJ instability
- Extensor carpi ulnaris subluxation
- TFCC lesions
- Ulnar impaction syndrome
- Degenerative changes of DRUJ and ulnar carpus
- Carpal instability, scapholunate tear (dorsal intercalated segment instability [DISI]), lunotriquetral tear (volar intercalated segment instability [VISI])
- Tendinitis
- Chondromalacia
- Ligament injuries
- Ulnocarpal instability

**NONOPERATIVE MANAGEMENT**
- Conservative treatment includes the use of a removable soft leather splint that minimizes motion of the wrist, such as those originally designed for use by gymnasts.
- If the patient wishes to return to athletic activities, he or she should proceed with cautious limitation while wearing a sports splint.
- Although these splints allow for motion of the wrist and for the use of athletic tools, the patient must understand that he or she must reduce the intensity of activity to a level that the wrist will tolerate.
- When activity levels are limited or more support is needed, such as while sleeping, a static splint is advised.
- Physical or occupational therapy, including training to increase range of motion and to strengthen the muscles spanning the ulnocarpal and distal radioulnar joints, may be beneficial.
- Nonsteroidal anti-inflammatories are also recommended before deciding on surgery, with an initial trial of 4 to 6 weeks.

**SURGICAL MANAGEMENT**
- The main indication for surgery is a painful ulnocarpal joint with diminished grip or pronosupination strength (or both) that does not respond to conservative treatment.
- Individuals with high demand for strong wrist function in weight-bearing supination (eg, golfers, tennis players, certain skilled labor professions) may be considered for surgery even without first receiving conservative treatment.

**Preoperative Planning**
- The surgeon should review all imaging studies to identify any concomitant pathology of the wrist joint.
- Arthroscopic examination of the wrist is generally undertaken immediately before ulnocarpal reconstruction to address any concomitant lesions or synovitis within the wrist.
- Diagnostic physical examination maneuvers are repeated while the patient is under anesthesia. These maneuvers include the piano key test and ulnocarpal supination test, as described earlier.
Positioning
- Using an arm board, the patient is positioned with the forearm in pronation and the elbow flexed at 45 degrees. The dorsal aspect of the wrist joint is prepared in a sterile manner.

Approach
- Modified Herbert reconstruction
  - Exposure of the dorsal surface of the wrist joint is the only surgical approach needed for the Herbert sling repair.
  - The Herbert sling procedure consists of the development of an ulnar-based flap of the extensor retinaculum, advanced at a 30- to 40-degree angle from distal ulnar to proximal radial by securing into the distal radial retinacular attachments.
  - This reduces the radioulnar joint and the carpus to the ulna with a single advancement of the extensor retinaculum (FIG 4).
- Hui-Linscheid reconstruction
  - A standard incision on the dorsal surface of the wrist is used to access the ulnocarpal articulation, the ulnar head, and the flexor carpi ulnaris.
  - A tendon graft is harvested from the flexor carpi ulnaris and passed through the tunnel in the ulnar head and looped back to its proximal insertion on the pisiform.

MODIFIED HERBERT RECONSTRUCTION
- Create a longitudinal incision over the fifth extensor compartment at the level of the wrist (TECH FIG 1A).
- Incise the extensor retinaculum between the fourth and fifth compartments, taking care not to enter the fourth compartment (TECH FIG 1B).
- Raise an ulnarly based flap of the distal two thirds of the retinaculum, and prepare the extensor digiti quinti (EDQ) for transposition dorsal to the retinaculum flap (TECH FIG 1C).
INCISION AND DISSECTION
- Start the incision at the level of the fifth carpometacarpal joint. Curve the incision over the ulnocarpal joint to reach the far ulnar border and continue to the middorsal forearm for exposure of the dorsal carpal ligament (TECH FIG 2A).
- Locate and protect the dorsal sensory branch of the ulnar nerve (TECH FIG 2B, C).
- Incise the extensor retinaculum over the sixth extensor compartment, taking care to protect the underlying extensor carpi ulnaris tendon and subsheath.
- Retract the extensor retinaculum medially to expose the capsule over the ulnocarpal joint and the subluxated ulnar head, creating an ulnarily based flap of retinaculum (TECH FIG 2D).

HUI-LINSCHEID RECONSTRUCTION

Incision and Dissection
- Place the wrist in neutral and apply downward force on the distal ulna to reduce the DRUJ.
- Translate the retinacular flap proximally and suture it to the periosteum of the ulnar border of the distal radius using 2-0 PDS absorbable sutures (TECH FIG 1D).
- Carefully imbricate the extensor retinaculum in an oblique fashion (30 to 40 degrees) from distal-ulnar to radial-proximal (TECH FIG 1E).
- The EDQ is relocated dorsally of the imbricated extensor retinaculum flap.

TECH FIG 1 • (continued) C. Raise an ulnar-based flap. Prepare the extensor digiti quinti to be transposed dorsal to the extensor retinaculum. D. The retinacular flap is sutured to the periosteum of the ulnar border on the distal radius. E. Imbricate the extensor retinaculum obliquely in a distal-ulnar to radial-proximal direction. The extensor digiti quinti should remain dorsally of the imbricated extensor retinaculum flap.

TECH FIG 2 • Hui-Linscheid reconstruction. A. Make a slightly curving incision over the ulnocarpal joint to reach the lateral ulnar border and continue it to the middorsal forearm for exposure of the dorsal carpal ligament. (continued)
Part 6  HAND, WRIST, AND FOREARM • Section V  WRIST INSTABILITIES

TECH FIG 2 • (continued) B. Take care not to injure the dorsal branch of the ulnar sensory branch during the incision and throughout the procedure. C. The ulnar nerve is located volar to the incision. The extensor retinaculum is incised at the fifth dorsal compartment. Protect the underlying extensor carpi ulnaris tendon and subsheath. D. Retract the extensor retinaculum medially to expose the capsule over the ulnocarpal joint and the subluxated ulnar head, creating an ulnar-based flap. E. Incise the capsule to expose the distal radioulnar joint while preserving the dorsal radioulnar ligament and taking care not to injure the extensor carpi ulnaris. F. Drill a 0.625-inch Kirschner wire through the ulnar head in a distal-to-proximal direction. The guidewire should be inserted obliquely starting from the base of ulnar styloid and aiming toward the synovial reflection proximally.

- Make a longitudinal incision in the capsule to expose the DRUJ while preserving the dorsal radioulnar ligament (TECH FIG 2E).
- Drill a 0.0625-inch Kirschner wire obliquely through the ulnar head beginning near the base of ulnar styloid to the ulnar fovea proximally (TECH FIG 2F).
- Placement of the Kirschner wire is confirmed visually and sequential hand awls are used to create a 4- to 5-mm bone tunnel.

Tendon Graft Harvest

- Locate the flexor carpi ulnaris (FCU) in the incision distally and trace it to the musculotendinous junction. This will allow about 10 cm of tendon graft for harvest (TECH FIG 3A).
  - If needed, a separate longitudinal incision on the palmar area of the wrist can be used.
  - Alternatively, a free tendon graft from the palmaris longus or other donor area may be used if the FCU tendon is inadequate.
- Split the FCU tendon longitudinally and cut the graft proximally at the musculotendinous junction. Leave the distal portion still attached at its insertion onto the pisiform (TECH FIG 3B).
- Perforate the pisotriquetral capsule in a dorsal to volar direction (TECH FIG 3C).

TECH FIG 3 • Hui-Linscheid tendon harvest. A. The flexor carpi ulnaris (FCU) is located distally and traced into the muscle belly to obtain about 10 cm of tendon graft. (continued)
The FCU tendon is passed intracapsularly using a tendon passer or by placing a Kessler suture into the tendon edge and using the suture to pull the tendon through the capsular perforation.

- Ensure that the graft does not place any tension on the ulnar artery or nerve (TECH FIG 3D,E).
- The FCU tendon graft is passed through the TFCC if it is perforated or through an enlargement of the prestyloid recess of the TFCC and through the drill hole in the distal end of the ulna.

**Completion of the Reconstruction**

- The carpal supination and the ulnar head dorsal subluxation is reduced by pulling the FCU tendon graft taut from its pisiform insertion.
- Hold this reduction by placing the forearm in supination and transfix the distal ulna to the distal radius with two parallel 0.062-inch Kirschner wires.
- Close the DRUJ capsule incision using a 3-0 nonabsorbable suture.
- The FCU tendon graft is pulled taut through the drill hole and then secured to the periosteum adjacent to the ulna bone tunnel using a 2-0 nonabsorbable suture.
- The FCU graft is doubled back superficially to the radioulnar capsule (TECH FIG 4A) and sewn to its pisotriquetral insertion (TECH FIG 4B).
- If the dorsal radioulnar ligament is found to be attenuated, imbrication of the ligament is performed.
- The extensor retinaculum is imbricated using a nonabsorbable 3-0 suture.

**PEARLS AND PITFALLS**

**Modified Herbert Reconstruction**

| Orientation of the capsulorrhaphy | Imbricate the extensor retinaculum in an oblique fashion (distal-ulnar to proximal-radial) to maximize the ulnocarpal ligamentotaxis effect of the repair. This will minimize the risk of postoperative supination deformity. If imbrication occurs at 90 degrees perpendicular to the DRUJ, only the DRUJ will be stabilized, not the ulnocarpal instability. |
| Placement of sutures in extensor retinaculum | Avoid injury to surrounding tissues or nerve structures (the dorsal branch of the ulnar nerve and the posterior interosseous nerve, terminal branch) when placing sutures in the extensor retinaculum (FIG 5). This will minimize the risk of postoperative wrist pain and dysesthesia. |
| EDQ tendinitis | The tendinitis usually resolves within 6 months. |
| Postoperative therapy | Advise the patient to avoid aggressive strengthening too soon after surgery, which may lead to loosening of the extensor retinaculum imbrication and failure of the Herbert sling repair. |

**Hui-Linscheid Reconstruction**

| Preservation of the nerve | The risk of damaging the dorsal branch of the ulnar nerve can be minimized by being aware of the dorsal ulnar nerve’s location during surgical incision, manipulation, and drilling. |
| Postoperative ulnar fracture | In the postoperative period, the FCU tendon graft may migrate within the ulnar tunnel, which may predispose the distal ulna to fracture. This risk can be minimized by sewing the FCU tendon graft to the ulnar periosteum and local soft tissues around the drill hole, decreasing the chance of the tendon gliding within the tunnel. |
| Nerve adherence | The ulnar nerve may adhere to surrounding scar tissue at the closing site of soft tissue. |

**POSTOPERATIVE CARE**

**Modified Herbert Reconstruction**

- Six weeks in a thumb spica Muenster cast with the forearm and wrist both positioned in neutral, followed by 6 weeks in a removable thumb spica splint

**Hui-Linscheid Reconstruction**

- Long-arm plaster cast for 6 weeks with the forearm and wrist both positioned in neutral. The cast and Kirschner wire are removed after 6 weeks.
- After 6 weeks, an ulnar gutter splint with “boost” padding is applied to the ulnar head dorsally and pisiform palmarly to support the wrist between mobilization exercises (FIG 6).
General Suggestions

- Gentle active rotatory motion during temporary splint removal is introduced at 6 weeks postoperatively at the patient’s discretion. Passive motion with a physical or occupational therapist is not necessary at this point.
- No heavy lifting or aggressive motion is permitted until 3 months postoperatively.
- Vigorous strengthening exercises to regain pronation are begun 3 months after the operation with a physical or occupational therapist at a pace with which the patient is comfortable, with exercise intensity increased gradually.
- A warm, moist wrap can be used around the wrist to provide additional stretching of the wrist before activities. Ice and nonsteroidal anti-inflammatory agents can be used to provide relief after each session.
- Examples of exercises:
  - Pronation and supination: Stretching can be achieved by holding a hammer or frying pan as a weight during the motions.
  - Wrist flexion and extension: Stretching can be achieved using bucket exercises. The patient places his or her arm on a table with the wrist hanging off the edge while holding an empty bucket. The bucket is filled with water until the point of discomfort. The patient holds the bucket for 2 to 3 minutes and repeats the exercise twice daily in flexion and extension.
  - If the patient’s preoperative activities included sports such as golf and tennis, these activities should be gradually incorporated into the strengthening program.
  - A Silastic sheet can be applied to aid scar remodeling. Scar massage may be started after the first 6 weeks.

OUTCOMES

- Modified Herbert reconstruction
  - A recent long-term follow-up study, ranging from 1 month to 13 years, of 39 wrists showed that 85% of the wrists remained stable at the ulnocarpal joint (in preparation for publication).
- Hui-Linscheid reconstruction
  - Successful short-term clinical outcomes have been reported in a small patient series by Hui and Linscheid, with patients reporting satisfactory and excellent outcomes.6
  - Mild limitations in pronation may be expected.

COMPLICATIONS

- The sling repair can loosen if aggressive strengthening occurs too quickly.
- If imbrication of the extensor retinaculum is not performed in an oblique direction, the ulnocarpal effect of the sling is lost, and a supination deformity of the wrist may occur or recur.
- Pain and dysesthesias at dorsal branch of ulnar nerve: Care must be taken when placing sutures for imbrication of the extensor retinaculum to avoid injury to surrounding tissues or nerve structures.
- EDQ tendinitis usually resolves 6 months after the operation.
- Damage to the ulnar nerve during the surgical procedure is concerning because of its anatomic location. The nerve is immediately exposed after the opening incision and is vulnerable during drilling of the ulnar tunnel. Dorsal ulnar nerve damage ranging from irritation to neurona may occur.
- Additionally, the nerve will be passing directly over an area of soft tissue closure and may be affected by the surrounding scar tissue.
- A protective covering (such as those used for recurrent nerve entrapments) to protect the dorsal ulnar nerve may minimize damage to the nerve.
- Other potential complications may occur as a result of the Kirschner wire, such as migration, infection, and nerve injury.

REFERENCES

DEFINITION
- Tears of the dorsal radiocarpal ligament (DRCL) are more common than previously suspected. They are best seen through a volar radial portal and are amenable to arthroscopic repair.
- Tears of the DRCL have been implicated in both volar and dorsal intercalated segmental instabilities, and they also have a role in midcarpal instability.3,5
- DRCL tears appear to be part of a spectrum of radial- and ulnar-sided carpal instability, as evidenced by the frequent association with scapholunate and lunotriquetral ligament injuries as well as triangular fibrocartilage (TFC) tears.
- Isolated DRCL tears can be solely responsible for wrist pain. The presence of an associated DRCL tear when seen in combination with a scapholunate, lunotriquetral, or TFC tear connotes a greater degree or duration of carpal instability and portends a poorer prognosis after treatment.12
- Good results are obtained after arthroscopic repair of isolated DRCL tears. Results of DRCL repairs are less predictable when seen in combination with other types of carpal pathology.11
- Recognition of this condition and further research into treatment methods is needed.

ANATOMY
- The DRCL is an extracapsular ligament on the dorsum of the wrist. It originates on the tubercle of Lister and moves obliquely in a distal and ulnar direction to attach to the tubercle of the triquetrum. Its radial fibers attach to the lunate and lunotriquetral interosseous ligament.4
- The dorsal intercarpal (DIC) ligament originates from the triquetrum and extends radially to attach onto the lunate, the dorsal groove of the scaphoid, and then the trapezium.
- The lateral V configuration of the DRCL and the DIC functions as a dorsal radioscapohoid ligament.
- It can vary its length by changing the angle between the two arms while maintaining its stabilizing effect on the scapholunate joint during wrist flexion and extension.
- This would require changes in length far greater than any single fixed ligament could accomplish.14
- When viewed from a volar radial portal, the DRCL is seen immediately ulnar to the 3-4 portal, just underneath the lunate (FIG 1A).
- The actual fibers of the DRCL may not be seen unless there is a tear present, since it is normally covered by an epiligamentous sheath (FIG 1B).

PATHOGENESIS
- It is instructive to consider the wrist as having a number of primary and secondary stabilizers.
- The scapholunate interosseous ligament (SLIL), the lunotriquetral interosseous ligament (LTIL), and the triangular fibrocartilaginous complex (TFCC) are the primary stabilizers.
- The capsular ligaments, including the radioscapohoid, radiolunotriquetral, ulnolunate, ulnotriquetral, dorsal radiocarpal, and dorsal intercarpal ligaments, can be thought of as secondary stabilizers.6
- A chronic tear of a primary stabilizer may culminate in the attenuation or tearing of the secondary stabilizer.
- This is seen in patients with a triquetrolunate dissociation of more than 6 months’ duration, in whom arthroscopy often reveals fraying of the ulnolunate ligaments and ulnotriquetral ligaments.17
- DRCL tears appear to be part of a spectrum of radial- and ulnar-sided carpal instability, as evidenced by the frequent association with SLIL, LTIL, or TFC tears. They have also been associated with midcarpal instability.10
- The DRCL tear may occur after or precede these injuries.
- In a recent study, 35 of 64 patients who underwent arthroscopy for the diagnosis and treatment of refractory wrist pain were noted to have associated DRCL tears, for an overall incidence of 55%.9
- Five patients had an isolated DRCL tear.
- 13 patients in this series had SLIL instability, tear, or both; 7 of 13 (54%) also had a DRCL tear. Of this subgroup four
patients had Geissler stage 1 or 2 instability and three had a Geissler stage 3 or 4 tear.
- Seven patients had LTIL instability, tear, or both; 2 of 7 (28%) also had a DRCL tear. Of this subgroup one patient had Geissler stage 2 instability and one had a Geissler stage 3 or 4 tear.
- Two patients had a capitohamate ligament tear; one of these patients also had a DRCL tear.
- Seven patients had a solitary TFCC tear; 6 of 7 (86%) were in association with a DRCL tear. One patient had a chronic ulnar styloid nonunion and a DRCL tear. There was TFCC fraying but no tear or detachment.
- Two or more lesions were present in 23 patients; DRCL tears were present in 12 patients (52%). Sixty-two percent of the combined lesions that were associated with a DRCL tear also included a TFCC tear.

dressing of dorsal wrist pain.
- Each successive stage denotes a longer standing or more severe condition, and this has a negative impact on the prognosis.
- An isolated DRCL tear does not necessarily lead to other intracarpal ligament or TFCC tears.

### PATIENT HISTORY AND PHYSICAL FINDINGS
- A typical patient with an isolated DRCL tear presents with complaints of intermittent dorsal midline wrist pain that may be sporadic but last 2 or 3 days; the pain is precipitated by repetitive loading or torquing movements of the wrist.
- When there is an underlying SLIL or LTIL tear or instability or TFCC tear, the pain may be more persistent and localized to the radial or ulnar side of the wrist.
- There are no physical findings that are pathognomonic of a DRCL tear. When there is no other associated wrist pathology, the diagnosis can be made only at the time of arthroscopy.
- Patients with isolated DRCL tears tend not to have localizing carpal tenderness and typically have a normal wrist examination, although some are mildly tender over the tubercle of Lister.
- Positive physical findings are usually related to any associated wrist pathology. In patients who have scapholunate instability, scaphoid tenderness and a positive scaphoid shift test are usually present.
- When there is an associated TFC tear, the patient will often have tenderness over the ulnar capsule and may have crepitus and pain with ulnar loading of the pronated wrist.
- If midcarpal instability is present, the patient may have a positive midcarpal shift test.

### IMAGING AND OTHER DIAGNOSTIC STUDIES
- Imaging studies are of mostly of value for ruling out associated carpal pathology since they are ineffective at making the diagnosis of an isolated DRCL tear.
- Plain radiographs and arthrograms are normal.
- The MRI is typically normal, although in one patient in the author’s series an MRI was wrongly interpreted as showing a dorsal ganglion due to a high fluid signal intensity over the dorsal capsule (FIG 2).

DRCL, dorsal radiocarpal ligament; LTIL, lunotriquetral interosseous ligament; SLIL, scapholunate interosseous ligament; TFCC, triangular fibrocartilage complex.

DIFFERENTIAL DIAGNOSIS
- Dynamic scapholunate instability
- Scapholunate ligament tear
- Dorsal wrist syndrome

NONOPERATIVE MANAGEMENT
- Patients should be treated with at least 1 month of wrist splinting, nonsteroidal anti-inflammatories, and activity modification with avoidance of repetitive gripping and lifting.
- Failure to respond is an indication for a radiocarpal corticosteroid injection followed by 1 additional month of splinting.
- Patients who continue to have wrist pain should then undergo imaging studies to rule out associated intra-articular pathology.

SURGICAL MANAGEMENT
- An arthroscopic repair is especially indicated for stage 1 (ie, isolated) DRCL tears, since the results are quite favorable.
- Repairs may also be considered in stage 2 and 3A DRCL tears, where the associated interosseous ligament tear or TFCC tear is treated arthroscopically.
- Stage 3B and stage 4 tears will likely be unresponsive to a DRCL repair since the outcomes are quite variable in the face of combined pathologies (Table 2).

Preoperative Planning
- Preoperative investigations should include plain radiographs to rule out a static carpal instability pattern.
- A double-row wrist arthrogram or an MR arthrogram is performed to assess the intracarpal ligaments and TFC.

Positioning
- The patient is positioned supine on the operating table with the arm abducted.
- Some method of overhead traction is useful. This may include traction from the overhead lights or a shoulder holder along with 5- to 10-lb sand bags attached to an arm sling. A traction tower such as the Linvatec tower (Conmed, Linvatec Corp, Largo, FL) or the ARC wrist traction tower designed by Dr. William Geissler (Arc Surgical LLC, Hillsboro, OR) greatly facilitates instrumentation.
- A 2.7-mm 30-degree angled arthroscope with a camera attachment is necessary.
- A fiberoptic light source, video monitor, and printer are also standard equipment.

DRCL, dorsal radiocarpal ligament; LTIL, lunotriquetral interosseous ligament; SLIL, scapholunate interosseous ligament; TFCC, triangular fibrocartilage complex; STT, scaphotrapeziotrapezoidal.

VR PORTAL
- A 2-cm longitudinal incision is made in the proximal wrist crease, exposing the flexor carpi radialis (FCR) tendon sheath (TECH FIG 1A).
- The sheath is divided and the FCR tendon retracted ulnarily.
- The radiocarpal joint space is identified with a 22-gauge needle and the joint inflated with saline (TECH FIG 1B).

A blunt trocar and a cannula are introduced through the floor of the FCR sheath, which overlies the interligamentous sulcus between the radioscaphocapitate ligament and the long radiolunate ligament.
- A 2.7-mm 30-degree angled arthroscope is inserted through the cannula (TECH FIG 1C).
The repair is performed by inserting a curved 21-gauge spinal needle through the 4-5 portal while viewing through the arthroscope, which is inserted in the VR portal (TECH FIG 2A–C).

A 2-0 absorbable suture is threaded through the spinal needle and retrieved with a grasper or suture snare inserted through the 3-4 portal (TECH FIG 2D, E).

A curved hemostat is used to pull either end of the suture underneath the extensor tendons, and the knot is tied either at the 3-4 or 4-5 portal (TECH FIG 2F).

With dorsal traction, the encircling suture pulls the torn DRCL up against the dorsal capsule, preventing it from impinging into the joint.

The repair may be augmented with thermal shrinkage if the torn edge of the DRCL is voluminous (TECH FIG 2G).
**Pearls and Pitfalls**

Procedural tips
- Use the hook probe in the 3-4 portal to palpate the DRCL. Tears may not be evident until the free edge is pulled into the joint.
- Be sure to assess the scapholunate and lunotriquetral intervals from the midcarpal joint to assess any dynamic instability. Consideration may be given to thermal shrinkage of the palmar aspect of the scapholunate ligament when there is an associated dynamic scapholunate instability.
- To ensure that the extensor tendons are not entrapped, use a hemostat to thread either end of the suture underneath the extensor compartment. Tie the suture under the skin only after the wrist traction is backed off.
- When performing capsular shrinkage, use copious irrigation to prevent thermal chondral damage. Monitor the temperature of the outflow fluid.

**Postoperative Care**
- After an isolated DRCL repair the patient is placed in a below-elbow splint with the wrist in neutral rotation.
- Finger motion and edema control are instituted immediately. At the first postoperative visit the sutures are removed and the patient is placed in a below-elbow cast for a total immobilization time of 6 weeks.
- Wrist motion with use of a removable splint for comfort is instituted after cast removal.
- Gradual strengthening exercises are added after 8 weeks.
- Dynamic wrist splinting is instituted at 10 weeks if needed.

**Outcomes**
- The five patients who underwent an isolated DRCL repair graded their pain as none or mild.9
- No patient required pain medication and all had returned to their previous occupation without restriction.
- The pre- and postoperative wrist motion was unchanged in four of these patients, with less than 15% loss of motion in the fourth patient.
- Grip strengths were 90% to 130% of the opposite side.
- A dorsal capsulodesis was performed in the seven patients with scapholunate instability.
Three of these patients graded their pain level as none or mild, with both returning to full duty.

Four graded their pain as moderate or severe, with all four changing their occupation.

Four patients underwent DRCL repair or shrinkage and LTIL pinning.

Two patients had no pain, and two had chronic, moderate pain.

Seven patients underwent DRCL repair and TFCC repair or debridement, wafer resection, or both.

Two had no pain (with wafer resection), two had occasional mild pain, and three had chronic moderate pain.

Of the patients with combined injuries who underwent a DRCL repair and treatment for associated tears of the SLIL, LTIL, or TFCC, seven of nine had chronic moderate pain.

COMPLICATIONS

There were no complications related to the DRCL repair as described.

Potential complications from use of a volar radial portal would include injury to the radial artery or the palmar cutaneous branch of the median nerve.

Use of capsular shrinkage is still unproven and cannot as yet be considered a standard of care of the treatment of intercarpal ligament injuries.

REFERENCES

DEFINITION

- Disruption of distal biceps tendon at its insertion

ANATOMY

- Distal tendon inserts into the biceps tuberosity on the proximal radius.
- A relatively avascular zone exists just proximal to the tendon’s insertion site.  

PATHOGENESIS

- Injury typically results from an eccentric muscle contraction. The forearm is forced into extension from a flexed position as the biceps muscle fires
- Avascular changes in the distal tendon and possible impingement in the interosseous space between the tuberosity and the proximal ulna may contribute to rupture.  

NATURAL HISTORY

Complete ruptures

- Distal biceps tendon ruptures usually occur in middle-aged men, similar to pectoralis major tendon ruptures and Achilles tendon ruptures.
- The initial pain subsides quickly but there is usually a noticeable deformity in the anterior brachium as the biceps muscle contracts and retracts. The degree of the retraction can be mitigated by the lacertus fibrosus, which may remain intact.
- The patient usually reports loss of flexion and supination strength. This is especially noted in patients who require repetitive supination, such as mechanics and plumbers. Pain is usually not a predominant complaint, although some patients will experience fatigue-type pain and cramping in the retracted muscle belly.
- Studies have revealed a 25% reduction in flexion strength and a 40% loss of supination strength.  

Partial ruptures

- Partial distal biceps tendon injuries are usually more painful than complete tears. Patients usually present with pain in the antecubital fossa, especially with resisted flexion and supination. There is an absence of clinical deformity.
- Partial tears can progress to complete tears.

PATIENT HISTORY AND PHYSICAL FINDINGS

- History of a rapid eccentric load on the involved extremity
- In acute cases of a complete distal biceps tendon rupture, there is usually a significant amount of ecchymosis in the antecubital fossa, distal arm, and proximal forearm.
- The distal biceps tendon is not palpable in the antecubital fossa. Comparison to the uninvolved side is helpful.
- Local edema can make the diagnosis a little more difficult, but the “hook test” has been found to be a very reliable diagnostic tool. To perform the test, the patient actively supinates the forearm while the examiner attempts to “hook” the distal biceps tendon from the lateral side.  
- The degree of proximal retraction of the tendon can be mitigated by the lacertus fibrosus.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- MRI is usually not necessary to make the diagnosis. The only caveat is that if the examiner feels that the distal biceps tendon is intact, the injury might be more proximal at the myotendinous junction or only a partial tear at its insertion.
- It is important to make the distinction between the common complete avulsion from the radial tuberosity and an injury at the myotendinous junction, as the more proximal injuries are best treated nonoperatively.  
- Partial tears occur at the radial tuberosity, are usually not associated with ecchymosis, and demonstrate no proximal retraction. They present late with pain with resisted flexion and supination. The distal biceps tendon is palpable and frequently tender.
- MRI can aid in the diagnosis of partial tendon ruptures.

NONOPERATIVE MANAGEMENT

- Nonoperative management of complete distal biceps tendon ruptures entails the use of modalities to reduce pain and swelling and simply allowing the patient to use the extremity as tolerated. Strengthening should focus on elbow flexion and supination.
- The surgeon should discuss with the patient that complete distal biceps tendon ruptures are not usually associated with residual pain but rather loss of flexion (30%) and supination (40%) strength.  
  If that is compatible with the patient’s job and lifestyle, nonoperative management is acceptable.
- Partial biceps tendon ruptures and ruptures at the myotendinous junction are treated in a similar manner. The patient should proceed to strengthening when full painless range of motion is obtained.
- Operative intervention is considered when nonoperative management fails for partial ruptures. Usually a minimum 3 to 4 months of observation is appropriate. Patients should be counseled that pain is more of a predominant complaint with these partial injuries.

SURGICAL MANAGEMENT

Complete and Partial Ruptures

- The EndoButton (Smith & Nephew, Andover, MA) method of fixation has been shown to have the highest ultimate tensile load.  
  Clinical studies with the EndoButton have also demonstrated good results with few complications.  
- Other methods are suture anchor and interference screw fixation.
Chapter 53  DISTAL BICEPS TENDON DISRUPTIONS: ACUTE AND DELAYED RECONSTRUCTION

Chronic Disruptions

- The definition of “chronic” is vague. Some authors have stated that greater than 8 weeks is chronic and that a graft is needed in these situations. However, we have been able to primarily repair distal biceps tendon ruptures out to 3 months. In these situations the elbow might not extend beyond 60 degrees on the table, but within 3 months after the repair the patient’s range of motion is full. The biceps brachii, like the pectoralis major, has a significant ability to stretch back out over time.

- The surgeon should discuss with the patient that a more chronic rupture might require graft and should discuss the type of graft to be used. Semitendinosus (either autograft or allograft),16 Achilles tendon allograft13 (with the bone plug inserted into the radial tuberosity or just soft tissue repair), flexor carpi radialis autograft,9 and fascia lata6 have been described.

Positioning

- The patient is placed in the supine position on an armboard with a sterile tourniquet on the upper arm.

Approach

- The approach depends on the surgeon’s preferred method of fixation.

Classic two-incision techniques had complications such as heterotopic ossification and posterior interosseous nerve palsy. Therefore, single-incision anterior approaches were developed with various methods of fixation, including suture anchors, interference screws, and the EndoButton.

ENDOBUTTON

- A longitudinal 4- to 5-cm anterior incision starting at the antecubital fossa and extending distally along the ulnar border of the brachioradialis is used. The lateral antebrachial cutaneous nerve and superficial radial nerve are identified and protected.

- The distal biceps tendon is retrieved into the wound. This can be accomplished by flexing the elbow and using a retractor to lift the skin of the distal arm for exposure.

- The tendon can be adherent to the adjacent tissues or the lacertus fibrosus. This may require a limited tenolysis to mobilize the tendon stump. Protect and isolate the lateral antebrachial cutaneous nerve and the brachial artery.

- On occasion, the biceps tendon cannot be retrieved through the anterior incision. In that case, an incision can be made medially along the distal aspect of the arm. The tendon is isolated and prepared and then passed into the distal wound.

- Once the tendon is isolated, a no. 2 nonabsorbable suture is woven into the distal biceps tendon using a locking Krackow technique or other locking suture technique. The locking sutures should extend 4 to 5 cm above the stump. The goal is to create a locking stitch proximally and allow about 1 cm of the distal biceps tendon to be unlocked.

- The two sutures extending from the tendon stump are then passed through the two central holes of the EndoButton.

- The sutures are tied, leaving no space between the end of the tendon and the EndoButton (TECH FIG 1A).

- Alternatively, one suture from the tendon can be passed through one of the central holes of the EndoButton and then back through the other central hole and the knot is then tied, thus placing the knot between the EndoButton and the tendon stump.

- Passing sutures (kite strings) are placed in the other two holes of the EndoButton.

- The radial tuberosity is exposed, and a burr is used to create an oval cortical window roughly the same dimension as the distal tendon stump. This is performed while an assistant holds the forearm in full supination. Two small Bennett retractors can be placed on either side of the radial tuberosity. Then, the EndoButton drill is used to create a hole in the far cortex to pass the button.
Keith needles or a Beath needle are used to pass the passing sutures (kite strings) through the bicortical hole and are retrieved as they pass through the skin on the dorsal side of the forearm (TECH FIG 1B).

One of the passing sutures is independently pulled, drawing the tendon into the radial tuberosity. Continued tension on this kite string draws the EndoButton in its vertical orientation through the hole in the far cortex of the radius (TECH FIG 1C).

Once the EndoButton is on the far side of the radius, the other suture is pulled to flip it and lock it in its horizontal orientation on the far side of the radius (TECH FIG 1D).

We use fluoroscopy to confirm placement of the button. The passing sutures are then pulled completely out after anatomic tendon placement is visually confirmed.

TECH FIG 1 • (continued) C. The tendon is pulled into the proximal radial hole as the EndoButton is advanced through the distal hole. D. The EndoButton is flipped to secure it on the other side of the radial cortex.

SUTURE ANCHOR OR INTERFERENCE SCREW FIXATION

- The same anterior approach is used, and the tendon is retrieved in a similar manner with both suture anchor and interference screw fixation. However, the radial tuberosity is prepared differently.
- In the case of interference screw fixation, a hole is drilled in the radial tuberosity. The diameter of the hole depends on the system (and the size of the screw) being used.
- In the case of suture anchor fixation, the radial tuberosity is lightly decorticated and suture anchors of choice are placed. Some authors use two suture anchors, and most use some kind of a sliding knot to advance the tendon onto the bone.

TWO-INCISION TECHNIQUE

- The anterior incision is made transverse in the antecubital flexion crease and used to locate the distal tendon stump. A second longitudinal incision is made 1 cm radial to the subcutaneous border of the radius in the proximal forearm at the level of the biceps tuberosity.
- Dissection is initially made in the extensor carpi ulnaris muscle and then through the supinator muscle. Take great care to avoid subperiosteal dissection on the ulna to decrease the risk of synostosis.
- The forearm is placed in maximal pronation and an oval cavity is created in the biceps tuberosity with a burr. Drill holes are then placed into this cavity with the forearm in supination.
- A no. 2 Fiberwire suture is then placed in the distal tendon in a Krackow technique.
- The sutures are then passed from anterior to the posterior incision with a long hemostat and retrieved. It is critical to pass the sutures in the interosseous space.
- The sutures are then passed through the drill holes and tied over bone with the forearm in supination.

CHRONIC DISTAL BICEPS TENDON RECONSTRUCTIONS

- More exposure of the biceps tendon and the myoten- denous junction is required for the chronic reconstructions. This can be accomplished by creating a second incision at the medial aspect of the distal arm.
- One could connect the two anterior incisions, but this risks creating additional scarring.
- A more meticulous dissection is required to protect the lateral antebrachial cutaneous and musculocutaneous nerves. Invariably there will be considerable scarring and adhesions, especially between the biceps tendon and lacertus fibrosus. Some of the lacertus can be used in the reconstruction.
- We have used semitendinosus autograft, which is harvested in a fashion similar to that used with anterior cruciate ligament reconstructions.
The tendon is doubled up and the two free ends are woven into the remaining distal biceps tendon and the myotendinous junction (TECH FIG 2A).

A Bunnell tendon passer is very effective at passing the tendon ends.

The length of the graft is chosen so that the reconstruction is tight at 60 degrees of elbow flexion. This can be accomplished by fixing it distally first and then performing the weave, or vice versa.

A nonabsorbable suture is passed through the graft–tendon construct, and this is secured to the radial tuberosity (TECH FIG 2B).

### Pearls and Pitfalls

### Postoperative Care

- Radiographs are obtained at the time of surgery and at the first postoperative visit to ensure that the fixation (EndoButton or anchors) is in good position.
- For the EndoButton repair we remove the splint at 2 weeks and allow active and passive range of motion but no lifting greater than a cup of coffee for 6 weeks. Strengthening is then started, but rarely is formal physical therapy necessary.
- Other authors have reported good results with early range-of-motion therapy.\(^1\)
- Others use a more conservative approach and limit full extension until 6 to 8 weeks after surgery.

### Outcomes

- Patient-weighted outcome measures such as the DASH and the MEPS have been used in many studies and have demonstrated excellent results with primary repair.\(^1,5\)
- Objective data including strength testing have also demonstrated good results with anatomic repair, especially with regard to restoring supination strength.\(^5\)
- Chronic repairs or reconstructions have also performed well.\(^17\)

### Complications

- Certain fixation methods have been associated with a higher occurrence of certain complications.
- Classic two-incision technique: Heterotopic ossification, radioulnar synostosis, and posterior interosseous nerve palsies. Heterotopic ossification and radioulnar synostosis rates have been decreased by avoiding the ulnar periostheum.\(^3,7\)
- Single-incision technique: Lateral antebrachial cutaneous and superficial radial nerve palsies
- Loss of motion

### References

DEFINITION
- Flexor tendon injuries can occur in any of the five described zones within the finger, hand, wrist, or forearm. All such injuries require surgical repair to restore active finger flexion.
- The most challenging injuries to manage are those in zone II, where two flexor tendons occupy a narrow fibro-osseous sheath. Successful repair requires meticulous technique and a careful postoperative therapy regimen balancing the risks of adhesion formation versus rupture.

ANATOMY
- The flexor tendons form two layers in the forearm (zone V; FIG 1A), with the thumb’s flexor pollicis longus (FPL) and the fingers’ flexor digitorum profundus (FDP) muscles deep to the flexor digitorum superficialis (FDS) muscle. At the wrist the FPL and FDP tendons remain deep, with the index and small FDS tendons above, and the middle and ring FDS tendons most superficial.
- The median nerve runs down the forearm beneath the fascia of the FDS on its undersurface, becoming superficial within the carpal tunnel just proximal to the volar wrist crease (zone IV), with the flexor tendons closely packed together.
- Exiting the carpal tunnel, the flexor tendons cross the palm (zone III) toward the individual digits.
- The two tendons of each non-thumb digit (the thumb has just the FPL) enter the fibro-osseous sheath (zone II) at the level of the metacarpophalangeal (MP) joint. The FDS then divides into two slips to form the decussation termed the chiasm of Camper, through which the FDP passes from deep to superficial (FIG 1B).
- The two slips of the FDS insert along the proximal aspect of the volar surface of the middle phalanx, and the FDP proceeds distally to insert along the volar surface of the base of the distal phalanx.
- The flexor sheath extends from the level of the MP joint to the distal interphalangeal (DIP) joint. Multiple condensations of discrete fibers are found along its course and are named as either annular or cruciate pulleys, reflecting the orientation of the fibers forming the pulley (FIG 1C).
- The thicker, annular (A1 through A5, from proximal to distal) pulleys hold the tendons close to bone while the more slender cruciate (C1 through C3) pulleys collapse with digit flexion, allowing the sheath to shorten without buckling. Zone II is that part of the sheath where both FDS and FDP tendons are present, and zone I is distal to the FDS insertion.
- Tendon nutrition within the sheath is provided indirectly via synovial fluid and directly via vascular inflow through mesenteric folds called vinculae, with one vinculum longus and one vinculum brevis to each flexor tendon.

PATHOGENESIS
- Most acute flexor tendon injuries are the result of open trauma, with sharp transection of the tendon. In such cases, other structures are often injured as well. In particular, examination should include assessment of sensibility and capillary
refill to identify injury to the digital nerves and vessels that would affect preoperative planning.

- A less common injury mechanism is closed avulsion of the FDP from its distal attachment to bone. The term “jersey finger” is sometimes used for this injury, as it is often the result of an athlete’s fingers forcibly flexing to grab an opponent’s jersey, followed by sudden and forceful extension of the DIP joint against resistance as the opponent pulls away. This avulsion injury is addressed elsewhere.

### NATURAL HISTORY

- Flexor tendon injuries require surgical repair to restore active digit flexion. Early repair is crucial, with several studies pointing to better results when repairs are performed within the first 7 days after injury.3,7

- Outcomes aside, as a practical matter it is easiest to repair the tendon before proximal tendon retraction occurs, requiring additional incisions. Late repair with tendon retraction and muscle shortening can also result in tension at the repair site, leading to gapping of the repair (which increases the failure rate) or influencing the surgeon to splint the wrist or digits in excessive flexion, leading to joint contractures.

### PATIENT HISTORY AND PHYSICAL FINDINGS

- Methods for examining the hand or upper extremity with an acute flexor tendon injury
  - Isolate FDP: While maintaining the injured digit’s proximal interphalangeal joint extended, the examiner asks the patient to actively flex the DIP joint (FIG 2A).
  - Isolate FDS: While maintaining all uninjured digits in full extension, the examiner asks the patient to actively flex the injured digit’s proximal interphalangeal joint (FIG 2B).
  - Uncooperative or unresponsive patient
  - Tenodesis effect: The examiner extends the wrist; flexion is observed at the interphalangeal joints if the flexor tendons are intact.
  - Forearm compression: Pressure applied to flexor tendon muscle bellies results in interphalangeal joint flexion if flexor tendons are intact.
  - The examiner inspects for normal flexion cascade (FIG 2C).
  - Examination of the digit to rule out associated digital nerve injury is required.

### PHYSICAL FINDINGS

- Laceration
- Affected digit held in unopposed extension
- Inability to actively flex interphalangeal joints (if both tendons are cut), isolated DIP joint (if FDP only is cut) or isolated PIP joint (if FDS only is cut)

### IMAGING AND OTHER DIAGNOSTIC STUDIES

- The sudden loss of active flexion after a laceration overlying the flexor sheath almost always represents a tendon injury. Radiographs should be obtained to rule out associated fractures that would require treatment at the time of tendon repair. Lacerations due to glass, metal fragments, and so forth should be imaged to localize any residual foreign bodies for removal.
- In the setting of a closed injury with the sudden loss of active flexion, one must consider the possibility of a tendon avulsion from its insertion. Radiographs may demonstrate an avulsed fleck of bone. In the more common cases of an FDP avulsion, this bone fragment may remain in the region of the distal phalanx or may be pulled proximally into the flexor sheath. If no bony fragment is seen on a plain radiograph and the diagnosis is still in doubt, ultrasound may help.

### DIFFERENTIAL DIAGNOSIS

- Pain after injury may cause a patient (especially a child) to hold a digit or hand immobile, mimicking tendon injury.
- Testing for the tenodesis effect (digits passively flex with wrist extension) or compressing the flexor musculature in the forearm should help with diagnosis in these situations.

### NONOPERATIVE MANAGEMENT

- There is no nonoperative means of restoring active flexion to a digit whose flexors have been cut, as the tendon ends retract and do not heal to one another.
- If a flexor tendon laceration is encountered within the first 4 weeks after injury, it is probably worthwhile attempting primary repair. After that time, discussion should be held with the patient regarding other options.
- For late presentation of an isolated FDP laceration in zone I, it may be practical to do nothing, as full proximal interphalangeal motion should still be present. If the DIP joint is or

---

**FIG 2** • **A.** Isolation of distal interphalangeal flexion to test flexor digitorum profundus integrity. **B.** Isolation of proximal interphalangeal flexion to test flexor digitorum superficialis integrity. **C.** Loss of normal flexion cascade after tendon laceration in palm.
becomes unstable, a DIP joint fusion or tenodesis of the distal FDP stump can be performed. One large series reported successful primary tendon grafting for isolated FDP lacerations even in zone II, but this is not widely performed.

- For late presentation of zone II injuries involving both tendons, staged tendon reconstruction (see Chap. HA-55) may be an option.

### SURGICAL MANAGEMENT

- The goal of flexor tendon surgery is a repair that will allow early motion, will not fail due to gap formation or suture pullout, and will not develop adhesions limiting final range of motion.
- Several variables under control of the surgeon contribute to repair strength:
  - Number of strands (most important determinant; a four-strand repair with an epitenon suture added has been shown in laboratory studies to withstand limited early active motion)\(^6\),\(^{11}\)
  - Suture size (3-0 or 4-0 is sufficient; larger suture increases resistance to gliding)
  - Configuration of repair (cruciate repair requires only one knot, buries the knot within the repair site, and allows for equal distribution of force across all four strands)\(^5\)
  - Use of locking stitches (adds resistance to suture pullout)
  - Addition of an epitenon suture (increases repair strength and decreases gap formation and gliding resistance)\(^6\)
  - Presence of a gap (greater than 3 mm at any point will likely result in rupture)
  - Bunching of repair (due to taking too large a “bite” of tendon end; increases gliding resistance and therefore risk of rupture)
  - Integrity of pulleys (at least half of both A2 and A4 should be preserved to maintain tendon excursion and allow tip-to-palm contact)
  - Repair of one versus both tendons (if repair of both FDS slips impedes gliding, one slip should be resected, or the FDS not repaired at all)
  - It is well accepted that core suture strength is directly related to the number of suture strands crossing the repair site between proximal and distal tendon ends; all else being equal, using more strands means a stronger repair.\(^{11}\)
  - This concept must be balanced against other factors: too many sutures crossing the repair site limits the available surface area for exposed tendon ends to heal; more sutures and knots increase the gliding resistance of the tendon; and the more sutures placed, the longer the surgical time, which is associated with risks such as infection and anesthesia-related issues.

- Strickland\(^6\) showed that a four-strand zone II repair with an epitenon suture is strong enough to tolerate an immediate light active range-of-motion protocol, which allows for early gliding of the repair and decreases the risk of adhesion formation.
- Suture size contributes to repair strength, but one study showed 3-0 and 4-0 suture to resist repair rupture equally well and 2-0 suture to increase gliding resistance significantly.\(^1\)
- Adding at least one locking stitch (making an additional pass to capture more tendon fibers) has been shown to increase repair strength and minimize gap formation.
- Multiple studies suggest that when both tendons are cut in zone II, repair of the FDP and only one slip of FDS rather than both slips results in decreased gliding resistance and improved range of motion.\(^9\),\(^10\),\(^13\)

### Preoperative Planning

- As noted previously, it is usually preferable to perform tendon repair early (if other circumstances allow).\(^3\),\(^7\) The upper limit of time past which proximal stump contracture is likely to cause technical difficulty is variable. Although 3 to 4 weeks is a commonly cited limit for primary tendon repair, in rare cases the vinculae may prevent retraction and allow repair even later.
- Patients presenting late should be fully counseled regarding other options, including the potential for intraoperative changes in plan.

### Positioning

- Flexor tendon surgery, like most hand surgery, is generally performed with the affected extremity on a hand table, with the shoulder abducted 90 degrees and the elbow extended. The forearm is supinated, exposing the volar surface of the digits.
- A positioning device such as a lead hand can be helpful in stabilizing digits for surgery (once tendon ends have been delivered into the wound) and keeping other digits out of the way.

### Approach

- Incisions should be planned so as to incorporate the laceration into the exposure.
  - Zigzag (Bruner) or midlateral approaches both work well; they can be combined if needed.
  - Midlateral incisions extending proximally on one side of the digit and distally on the other can give large flaps and excellent exposure.
  - The chief concern is not to cross a flexion crease at a right angle since the resultant scar will tend to contract and limit extension.

### PRIMARY REPAIR IN ZONE II

#### Retrieval of Tendon Ends

- A zigzag or Bruner incision is made, sometimes in combination with mid-lateral incisions (TECH FIG 1A).
- Often some manipulation is needed to bring the tendon ends into the wound; for the proximal tendon end, wrist flexion and “milking” of the forearm may succeed. The distal stump is best exposed by extending the incision so that the repair can be performed without holding the digit flexed.

- Initial exposure should include both digital neurovascular bundles, whether or not they were injured along with the tendon or tendons.
- If digital nerve or artery repair is needed, this should be done after the tendon repair so that the more delicate microsuture used is not disrupted with manipulation of the digit. Exposure of these bundles even when uninjured allows much more freedom for manipulating the cut tendon ends.
Once the neurovascular bundles are exposed and protected, the sheath should be cleared of overlying soft tissues and inspected. The sheath laceration can be extended with a sidecut to form an L-shaped flap, always preserving as much as possible of the A2 and A4 pulleys. Creating such flaps can facilitate retrieving the tendon ends.

Because most flexor tendon injuries occur with the digit in flexion, the skin laceration is generally more proximal than the tendon laceration. This means that exposure of the distal stump often requires considerable distal extension of the incision, often to the level of the DIP joint and obliquely across the pulp of the distal phalanx.

The proximal tendon end may be held in place near the laceration by its vinculae, but it will often have retracted well proximally.

It is reasonable to make several attempts to retrieve the proximal tendon end through the sheath with an appropriately small instrument (curved tendon passer, small hemostat, etc.), keeping in mind that the less damage to the tendon end, the easier the repair and the less scarring that will result. Flexing the wrist and “milking” the forearm will sometimes encourage a proximally migrated tendon to protrude into the wound.

If these measures fail, a short transverse incision along the distal palmar crease can be made, as if exposing the A1 pulley for a trigger finger release, and the tendon exposed at this level.

A pediatric feeding tube can be threaded from one wound to the other and sutured to the tendon in the proximal wound (TECH FIG 1B).

The tube and flexor tendon can then be retrieved into the distal wound and the tube and suture cut free.

Once the proximal end is in the planned repair site, the tendon can be pinned with a 25-gauge needle to prevent retraction back into the sheath (TECH FIG 1C).

Often the distal location of the distal stump requires that the proximal tendon end be threaded past the original laceration site to a more distal “window” made in the sheath for tendon repair. This, coupled with flexion of the DIP joint, should allow for apposition of the tendon ends and repair under minimal tension.

**Tendon Repair**

- Four-strand cruciate repair is effected using 3-0 nonabsorbable suture, with a 6-0 Prolene running locking epitendon suture, and repair of one slip of FDS (TECH FIG 2).

**Epitenon-First Repair**

- For very oblique lacerations it may be easier to perform an epitenon-first repair, coapting the cut tendon ends smoothly, and then performing the core stitch beginning through a slit on the outside of the tendon, burying the knot in this same slit (TECH FIG 3).

- The repair is otherwise the same as a four-strand cruciate repair.
TECH FIG 3 • A–D. The hand is to the right and the fingertips to the left. 
A. Oblique laceration of flexor tendons in zone II; tendon ends retrieved and 
pinned in place for repair. B. Epitenon repair performed first. C. Core suture 
begun via small incision in tendon proximal to repair; otherwise similar to stan-
dard cruciate repair. D. Core stitch completed and knot buried in small incision 
used for starting point.

PEARLS AND PITFALLS
- Early repair is easiest and gives best results.
- Midlateral incisions give wide exposure.
- Hold tendon ends in place with 25-gauge needles to allow tension-free repair.
- A four-strand locking cruciate repair using 3-0 nonabsorbable suture combined with a 6-0 absorbable running epitenon stitch will 
  allow protected early active motion and has been shown to maximize the outcome.
- Limiting repair of FDS to one slip minimizes overcrowding in zone II and allows better tendon gliding.
- For partial lacerations, no repair is necessary unless greater than 60% of the cross-sectional area of the tendon has been divided.
- Any flap of tendon should be trimmed to prevent later triggering.24,12

POSTOPERATIVE CARE
- If a primary repair has been performed as described above, 
an immediate light active “place and hold” therapy regimen 
can usually begin safely as long as the patient is reliable.

OUTCOMES
- A recent meta-analysis of multiple studies over the past 15 
  years found a rupture rate of 4% to 10% and good to excellent 
  results in about three quarters of patients.5 Present-day tech-
  niques should allow for continued improvement in these results.
- Injury mechanism is a predictor of outcome and is beyond 
  the surgeon’s control. An uncomplicated, isolated sharp flexor 
  tendon laceration that is treated acutely represents the best 
  possible scenario for a highly functional digit. Additional in-
  jury to bone, tendon, or nerve negatively affects outcome.

COMPLICATIONS
- Two extremes of bad outcomes are tendon rupture and ten-
  don adhesions. Ruptures are rare, but adhesions, and resultant 
  limited motion, are common.
- If ruptures are noticed immediately, a repeat repair should 
  be performed, although the patient and surgeon should be pre-
  pared for the need to proceed intraoperatively with other 
  reconstructive options.
The management of tendon adhesions is discussed in Chapter HA-55.

REFERENCES
DEFINITION

- Flexor tendon trauma and repair are commonly complicated by adhesions, limiting the gliding capacity of the tendons.
- These injuries have long been highly challenging.
- The extracellular matrix, which is composed of collagen, is often covered by mesothelium, and no further improvement with therapy is seen, surgical treatment should be considered.
- The spectrum of treatment of flexor tendon adhesions ranges from nonoperative treatment to different surgical modalities, from tenolysis to a two-stage tendon reconstruction.
- The operative decision is based on different factors, such as the quality of the tendon involved and the integrity of the surrounding sheath. Some of these factors can be evaluated only during the operation.
- All treatment options should be discussed preoperatively and the surgeon should be prepared to make the final decision based on operative findings.
- Tenolysis consists of surgical release of tendon adhesions to restore tendon gliding and digital motion. This can be a very satisfying procedure in selected cases, particularly when adhesions are localized to just a portion of the sheath.
- Proper patient selection is crucial and several questions must be asked: Will the patient cooperate with extensive hand therapy? Is the functional improvement after this complex and time-intensive process likely to be better and more rapid than with fusion of an interphalangeal (IP) joint or even with amputation of the digit?

ANATOMY

- Refer to Chapter HA-54.

PATHOGENESIS

- Injury (or repair) of the tendon and its synovial sheath is the basis for the development of adhesions.
- The initial mode of inflammatory reaction is similar to that after any tissue injury. Initiation of adhesion formation begins with deposition of a fibrin matrix that typically occurs during the coagulation process.
- This matrix is gradually replaced by vascular granulation tissue containing macrophages, fibroblasts, and giant cells.
- The clots are slow to achieve complete organization. In this process, they consist of erythrocytes separated by masses of fibrin that are covered with layers of flattened cells and contain a patchy infiltrate of mononuclear cells.
- The adhesion matures into a fibrous band, often containing small nodules of calcification.
- Mature adhesions are often covered by mesothelium, are vascularized, and contain other connective tissue fibers, such as elastin. The extracellular matrix, which is composed of collagen, proteoglycans, fibronectin, and elastin, plays a central role in the management of tendon healing as well as the development of adhesions. Degradation products in the matrix are chemotactic for fibroblasts, leukocytes, and endothelial cells.
- During the first few days after trauma, T cells and macrophages accumulate in the location of injury and stimulate the synovial cells to produce fibronectin. Collagen types 1 and 3 accumulate between tenocytes and around the tendon by 1 week after trauma. Adhesions between the tendon and its sheath can be seen by this time as a thickening of the epitenon to five to seven cell layers. Fibronectin is present as well and serves as scaffolding for the developing scar.
- The process described occurs to a lesser extent in the proximal zones of the flexor tendons. Zone II tendon injuries occur in the milieu of two tendons gliding in a constrictive fibro-osseous tunnel. In other zones, this potential for development of adhesions exists to a much lesser extent.
- Three types of adhesions have been described:
  - Loose adhesions arising from subcutaneous tissue and allowing some glide of the tendons
  - Moderately dense adhesions from the synovial sheath or pulleys that are remarkably restrictive of tendon motion
  - Dense adhesions arising from the bony floor or volar plate, penetrating the dorsal aspect of the tendon
  - Both dense and moderately dense adhesions prevent tendon motion and jeopardize healing.
  - The role of different cytokines has been evaluated in the pathogenesis of adhesions in general and tendon adhesions in specific.
  - Transforming growth factor-beta (TGF-β) has been shown to be a prominent regulator of tendon healing, although its precise role is still unclear and under extensive research. In the laboratory, these factors have been shown to be regulated by physical factors such as shear stress as well as by specific neutralizing antibodies or chemical modulators such as 5-fluorouracil.

NATURAL HISTORY

- Symptomatic adhesions result in substantial morbidity such as decreased range of motion, joint contracture, decreased strength, and substantial decrease in hand and upper extremity function. Adhesions occur with every tendon injury and depend on the extent of injury, the mobilization of digits after the injury, and the treatment applied. They are especially severe and symptomatic in injuries in zone II. Before the widespread use of early and intensive mobilization protocols after injury and repair, limited success was achieved and tenolysis was frequently required.
- Strickland and Glogovac reported in 1980 on the advantage of early mobilization of zone II flexor tendon injuries.
In their report, by 160 days after repair, 10 of 25 patients achieved less than 70% of the expected range of motion of the proximal and distal IP joints. Although there are limited reports regarding the natural history of these injuries when untreated, this report gives us a sense of the typical outcome of flexor tendon repair in the era before early motion protocols.

- Tenolysis is by far the most common secondary procedure performed after digit replantation, according to a recent meta-analysis. Although stiffness of a replanted finger is a result of multiple causes, the adhesion of tendons is a leading cause of this problem.
- Tang estimates that 10% of repaired flexor tendons will need surgical treatment of adhesions. Moderately dense adhesions of the synovial sheath or pulley and dense adhesions of the bone to tendon are difficult to alter once they have formed. These adhesions should be treated surgically.
- Proximal to zone II, the limitation in range of motion and need for flexor tenolysis are less common, even in the setting of a severe injury.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Evaluate both passive and active range of motion.
- Note the skin integrity and the location and condition of scars and previous surgical incisions.
- Look for other deforming conditions, such as maligned fractures.
- The examiner should search for other factors limiting range of motion, such as intra-articular pathology, scar contracture of the skin, extensor tendon contracture or adhesions, interosseous muscle contractures, or capsular and collateral ligament contractures.
- The neurovascular status of the digit is documented.
- The continuity of both flexor tendons in all digits is evaluated:
  - Continuity of the flexor digitorum superficialis (FDS) tendon
  - Active flexion of the proximal interphalangeal (PIP) joint is evaluated for each digit separately. The adjacent digits are held in full extension by the examiner at the metacarpophalangeal (MP), PIP, and distal interphalangeal (DIP) joints to assess for intact fibers of the FDS inserting into the middle phalanx. This does not exclude a partial tear of the tendon.
  - Continuity of the flexor digitorum profundus (FDP) tendon
  - Active flexion of the DIP joint with the examiner grasps the mid-dle phalanx to assess for intact fibers of the FDP inserting into the distal phalanx. This does not exclude a partial tear of the tendon.
- Range of motion (ROM): If passive ROM exceeds active, the pathology is at least partly musculotendinous (tendon adherent, incompetent, or both).
  - The “seesaw effect”: The examiner should passively extend and flex the DIP, PIP, and MP joints. Extend one joint followed by the other to assess for the seesaw effect. Nonarticular contracture is revealed when one joint is flexed, the other can be extended, and vice versa.
  - The Bunnell intrinsic tightness test is performed to evaluate flexion of the PIP joint with the MP joint extended and then flexed. With intrinsic tightness, there is less passive flexion of the PIP joint when the MP joint is held extended than when the MP joint is flexed (therefore, the surgeon may need to release the intrinsics as part of treatment).
  - Evaluate for lumbrical contracture: An intrinsic tightness test is performed with the fingers radially or ulnarly deviated. With lumbrical contracture, there is less passive flexion of the PIP joint with the finger deviated or with the DIP joint flexed in comparison to intrinsic testing. If present, this suggests lumbrical muscle contracture as part of the pathology.
  - Alternatively, the test is performed with the DIP joint flexed as well as the PIP joint.
  - Evaluate for extensor contractures: The examiner flexes the wrist and MP joints and examines flexion of the PIP and DIP joints. With extensor contractures there will be limited flexion of the digit IP joints with flexed wrist and MP joints.
  - Evaluate for flexor contractures: The examiner extends the wrist and MP joints and examines extension of the IP joints. With flexor contracture, there will be limited extension of the digit IP joints with extension of the wrist and MP joints.
  - The Landsmeer test is performed for evaluation of contracture of the oblique retinacular ligament (extending from the volar aspect of the PIP joint to the dorsal aspect of the DIP joint). In a positive test, passive extension of the PIP joint will result in extension of the DIP joint as well. Continued shortening of the ligament will result in a boutonniere deformity.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs of the hand are taken to evaluate for bony and articular pathology as well as the presence and location of implants. Skeletal deformity secondary to avulsion injuries may be seen.
- CT scans may be helpful in selected cases for bony and articular pathology.
- Magnetic resonance imaging (MRI) or ultrasound may be useful in identifying tendon or capsular injury as well as aiding in the differential diagnosis of severe tendon adhesions versus rupture.

**DIFFERENTIAL DIAGNOSIS**

- Intrinsic muscle contracture
- Capsular or collateral ligament contractures
- Malalignment of fracture
- Extensor tendon adhesions
- Rheumatoid arthritis
- Dupuytren’s disease
- Neurologic causes
- Burns
- Congenital anomalies
- Complex regional pain syndrome

**NONOPERATIVE MANAGEMENT**

- ROM exercises as well as pain management play a role in several clinical situations:
  - During the period after repair of the injury
  - When the functional results are satisfactory to the patient and meet his or her needs
  - Delayed healing of soft tissue or bony injury
  - Limited passive range of motion
  - When the patient is uncooperative with perioperative care and therapy
  - The therapy should include full active as well as resistive exercises designed at maximizing the active ROM achieved, before surgical treatment.
Surgical Management

- Tenolysis of the flexor tendon requires intact tendons and pulleys in order to succeed. Patients for whom tenolysis is appropriate have reached a plateau in function despite appropriate therapy, and have significantly greater passive than active range of motion.
- Prerequisites for tenolysis also include healing of all fractures and wounds with soft, pliable skin and minimal inflammatory reaction around scars.
- The timing of tenolysis is the subject of debate. Recommendations range from 3 to 9 months after the tendon repair or grafting. Strickland recommends waiting at least 3 months after repair, with 4 to 8 weeks without measurable improvement in active motion with intensive therapy.
- Concomitant procedures should be considered carefully and limited to those procedures that will not affect postoperative therapy.
  - Capsulotomies of the PIP or DIP are often necessary in these cases and may be performed, although some authors warn of inferior results with this addition.
  - Pulley reconstruction with tenolysis should be avoided if possible, although successful combined procedures have been described.
  - Procedures requiring immobilization should not be performed concomitantly with the tenolysis. Examples include tendon lengthening or shortening, free skin grafts, or osteotomies.
  - Local anesthetic supplemented by intravenous analgesia and tranquilizing drugs was popularized by Schneider. This allows the surgeon to evaluate the extent of adhesiolysis achieved by having the patient actively flexing the digit during surgery. The patient can also see the results, motivating him or her to achieve a similar range of motion postoperatively.
  - Anesthetic options include local infiltration into the palm and a wrist block.
  - The use of local anesthesia is limited by the use of a tourniquet, which causes paralysis of the muscles after 30 minutes and may be difficult for the patient to tolerate past that time. To deal with these problems, a sterile forearm tourniquet may be elevated 30 minutes into the procedure, releasing the arm tourniquet.
  - Regional and general anesthesia are additional techniques suitable for a tenolysis procedure. General anesthesia is necessary in cases of questionable patient cooperation, tolerance to pain or other contraindication to local or regional anesthesia, or where time to completion of tenolysis (and any associated procedures) is expected to exceed the likely duration of a local or regional block.
  - Foucher et al report that they have abandoned local anesthesia or “selective sensory blocks” except in late tenolysis where they have doubts about the performance of the muscle. Instead, they use a separate incision in the palm or forearm to test flexion at the end of the procedure.

Preoperative Planning

- Surgical supplies including implants necessary to perform a staged tendon reconstruction should be available.

Positioning

- The patient is positioned supine with the upper extremity on a hand table. A lead hand splint is recommended.

Approach

- Wide exposure of the flexor tendon is necessary. This may be accomplished either by a zigzag (Brunner-type) incision or by a midlateral incision (Fig. 1). The Brunner zigzag incision provides the best exposure of the tendon and pulley system.
- A midlateral exposure will protect the neurovascular structures dorsally and will cause less scar directly over the tendon. It may also cause less wound tension during early therapy.

Flexor Tenolysis

- Expose the flexor tendons starting from the unaffected region and proceeding to the involved areas (Tech Fig 1A).
- Define the borders of the tendons (Tech Fig 1B).
- Raise both flexor tendons as one, carefully lysing the adhesions around them.
  - This may be performed using a scalpel, tenotomy scissors, or a Freer elevator (Tech Fig 1C).
- Retraction and manipulation of the elevated tendons should be accomplished in as atraumatic a fashion as possible using a Penrose drain or blunt instrument.
- If possible, separate FDS from FDP tendons.
- The FDS tendon may need to be sacrificed if the scarring is extremely severe in order to achieve adhesiolysis under the pulleys and smooth gliding of the tendon.
- Resection of a slip of FDS has been shown to improve FDP gliding after repair in zone II injuries.
- In some cases it may be preferable not to separate severely adhered tendons, allowing them to act as one, where a single combined tendon is mobilized to its insertion.
Adhesiolysis may be facilitated using these instruments and techniques:

- A modified 69 Beaver blade (McDonough and Stern 45-degree Beaver blade) with an angle of 45 degrees (TECH FIG 2A).
- Schreiber knee arthroscopy blades.
- Braided suture (0 Mersilene, 2-0 Prolene) or dental wire may be inserted between the tendon and phalanx and used as a Gigli saw to separate the tendon from bone by pulling on the suture ends back and forth along the tendon (TECH FIG 2B).
- Alternatives to collect and pass the suture include use of a blunt elevator with a hole at its distal tip, which may be inserted under the pulley from a proximal to distal direction, and a wire loop or a needle inserted backward in the gutter between the phalanx, the tendon, and the sheath.
- Meals developed a set of instruments specifically designed for tenolysis (George Tiemann & Co, Hauppauge, NY).

- Débride the tendons free of previous suture material or frayed edges.

The necks of these tenolysis knives follow the natural curvature of the finger and have semisharp blades that conform to the circumference of the tendon sheath with either a convex or a concave edge (TECH FIG 2C).
### ADDRESSING THE PULLEY SYSTEM

- Preserve as much of the pulley system as possible. It is crucial to preserve the A2 and A4 pulleys to prevent bow-stringing and loss of tip-to-palm contact in full flexion. This may be performed by creating transverse windows along the course of the tendon. Some resection of the pulleys is possible (TECH FIG 3).

- In case sacrifice of part of these pulleys is crucial to achieve better tendon excursion or to facilitate the release of adhesions, about half of a pulley can be incised.\(^\text{17}\)

- Widening of the pulleys may be performed with small pediatric urethral dilators or cardiac coronary artery dilators.

### EVALUATION OF ADEQUACY OF RELEASE

- Adequacy of release must be evaluated and may be assessed using several techniques.

- If the patient is awake, he or she can actively flex the digit. Otherwise a traction flexion check should be performed for each of the flexor tendons separately.

- Through the palmar extension of the exposure, pull on the tendon with a blunt tendon hook or retractor (TECH FIG 4A).

- If the expected excursion cannot be tested through the palmar incision, proximal exposure of the tendon may be necessary through a separate incision proximal to the wrist (TECH FIG 4B).

- An Allis clamp may be placed around the tendon and pulled gently to examine the tendon’s excursion.
POSTOPERATIVE CARE

- Hand therapy is initiated the day of surgery in the postanesthesia care unit if an isolated tenolysis is performed without pulley reconstruction.
- A detailed referral note or discussion with the therapist is necessary to plan the rehabilitation program for each patient. Patient history, type of injury, surgical intervention and intraoperative findings, motivation, and pain tolerance should be discussed. The condition of the tendon and pulley system and the vascularity of the digit may alter the course of therapy and should be reported.
- It is crucial that the patient be motivated and understand the therapy protocol, the need for frequent meetings with the therapist, and the daily exercises to be performed independently.
- Adequate pain control is ensured.
- Local blocks may be used in selected cases to allow early mobilization.15
- Transcutaneous nerve stimulators are recommended by some for postoperative pain reduction in combination with oral medication.
- Wound care education should be part of the first therapy meetings.
- Edema control is frequently necessary. The patient should be instructed to elevate the hand during the first days after surgery as well as to perform hourly fist pumps with the hand elevated. Gentle compression with a glove, Coban wrap, or elastic bandages should be considered.
- Early mobilization of the tendon is crucial to the success of the procedure, although the quality of the tendon should be taken into account. A weak tendon should limit the therapy to
A limited exercise protocol, although this may be an indication in itself for staged reconstruction or grafting rather than simple tenolysis.

- Various protocols have been described that balance the maintenance of active flexion ROM achieved in the operating room, maintaining the mobility of the joints as well as the full ROM of active extension. The common protocols achieve a small differential gliding of the FDS versus the FDP tendon.
- Blocking and strengthening exercises should be added at a later date. This may depend on the quality of the lysed tendon, although usually after 4 to 6 weeks these exercises are considered not to endanger the tendons' continuity.
- Trumble and Sailer begin light resistive exercises at 6 weeks and add progressively more resistance after 8 weeks.
- Continuous passive motion (CPM) is under investigation. There have been reports of increased risk of tendon rupture and force required for passive ROM. CPM should not be used in place of active ROM exercises. However, it may be of value if passive ROM is limited or the patient is apprehensive about moving actively. It may also minimize edema and scar formation.
- A protective resting wrist-based splint may be necessary in cases with a thin or damaged tendon. A closely supervised therapy program is important in these cases. Static–progressive or dynamic splints may be needed to treat patients with joint stiffness or contractures.
- A fabricated pulley ring may be used during active motion exercises if the pulleys are tenuous.
- In patients with a weak tendon, therapy should begin with “place and hold” exercises. In these exercises, the digit is passively flexed and then actively held in place by the patient.
- This minimizes the tensile forces on the weak tendon while passing it through its maximal excursion. Further protection may be added when the exercises are performed with the wrist or MP joints flexed. This program should be carried out for 4 to 6 weeks. Active ROM exercises may be added later on.
- Hourly exercises by the patient should be part of any protocol.

OUTCOMES

- Good outcomes after flexor tenolysis have been reported, but outcome measures have varied across reports (Table 1).
- Significant complications have been reported in all series, including a significant number of patients with either no improvement or with postoperative worsening. Less information is available but poorer results have been reported after tenolysis in children (under 11) and for the thumb.
- Strickland reported that 64% of tenolysed digits after zone II injury had at least 50% improvement in active ROM. Twenty percent of the patients had no improvement and 8% had rupture of the tendon.
- Jupiter et al. used the Strickland formula (Table 1) for the evaluation of 37 replanted digits and 4 replanted thumbs treated with flexor tenolysis. They reported good to excellent results with 24 of the 37 digits. Only poor or fair results were found after thumb flexor tenolysis.
- Several factors negatively influenced the final results: classification of injury, inferior results of tenolysis with avulsion or crush injuries, number of amputated digits, capsulotomy, level of injury (inferior results with zone II injuries), digit injured (inferior results with thumb procedures), and multiple tenolysed digits.
- The authors recommend tenolysis of digit flexors when indicated, but not of the thumb flexor.
- Foucher et al. reported their results after the treatment of 78 digits, 9 of which were thumbs, and excluding replanted digits. They implemented both their technique of pulley reconstruction and of therapy. The therapy included the use of percutaneous catheters for additional pain control for 3 weeks and passive extension exercises beginning 2 days following the tenolysis surgery. A splint providing some flexion (of MP and IP joints) was removed hourly for exercise. The result after a mean period of 21.5 months was graded both by total active motion (TAM) measurement and the Swanson method for functional evaluation (Table 1). Of the 78 digits, 3% were unimproved and 13% were made worse by the tenolysis. For the remainder of the cases, the TAM improved from 135 degrees to 203 degrees. Using Swanson’s assessment the functional deficit improved from 41% to 20%. The thumbs achieved less success, with two cases unimproved, while the rest resulted in an improvement of 65 degrees to 115 degrees, or a decrease in deficit from 12% to 2% according to Swanson. The authors did not separate the results according to the zone of injury and did not report the results for the entire group of patients.
Eggi et al.6 evaluated the change in ROM of each joint of the digit in 8 digits treated with flexor tenolysis out of a group of 32 digits with varying zone II injuries requiring tenolysis. They found a decrease of 5 degrees of MP active ROM and an increase of 25 and 35 degrees of PIP and DIP active ROM, respectively. TAM improved by 55 degrees. They found an additional improvement in TAM when the tenolysis was combined with PIP capsulolysis. The authors compared the results of flexor tenolysis with patients treated with flexor and extensor tenolysis in the same digit and found better total active motion (63-degree improvement) and better extension with the second group. The five patients with palmar injury alone achieved 80% good to excellent results according to the Buck-Gramcko scoring system, while only 55% good to excellent results were seen in digits tenolysed after replantation.

Reports of tenolysis in children are rare. Birnie and Idler4 compared treatment of children under and over the age of 11 after repair of zone II and III flexor tendon injuries. They concluded, by using Strickland’s method (Table 1) that under age 11, tenolysis was of no significant benefit. Of the 21 digits of children between the ages of 11 and 16, 13 had good to excellent results, 5 were graded poor, and 2 suffered rupture of the tendon. Of the eight digits of children ages 10 and under, two had fair results and six had poor results. They explained that under the age of 11, the cooperation of the patient necessary for the success of the procedure cannot be expected. Early therapy was more difficult in this group, resulting in inferior results. Within a group of 12 children after flexor tendon repair, Kato et al.13 described one successful tenolysis after zone II injury in a child age 3 years 10 months. They reported that the tenolysis was performed 9 months after the initial injury and repair and that the result of the tenolysis was excellent.

**COMPPLICATIONS**

- Rupture of the flexor tendon may be the result of poor-quality tendon or aggressive therapy as well as patient non-compliance. It may be prevented by limiting tenolysis only to tendons of good quality. Eggi et al.6 reported rupture in 3 of 16 flexor tendons tenolysed that were treated successfully with two-stage reconstruction. Jupiter et al.13 reported 2 ruptured tendons of 37 replanted digits, both in zone II injuries. Others have claimed this to be a rare yet disastrous complication.1

- Rupture of a pulley, more significantly A2 or A4 pulleys, may result from narrowing or fraying of the pulleys as part of the trauma or further compromise with surgical intervention.

- Multiple surgical treatments of the digits involved in various trauma mechanisms may result in significant scarring, decreased vascularity, delayed wound healing, and infection, further compromising the functional results. Adherence to careful surgical technique, including atraumatic handling of tissue, is crucial to minimize these complications.1,19

- Foucher et al.18 reported eight complications in 72 patients (78 digits): two with delayed healing, two with flexor tendon exposure, two with rupture, and two diagnosed using bone scan to have a localized form of reflex sympathetic dystrophy.

**Prevention of Recurrence**

- Bathing the tendon in a steroid solution to prevent recurrence of adhesions has been suggested but has only anecdotal evidence of efficacy. Others have reported that corticosteroids...
REFERENCES

DEFINITION
- Staged flexor tendon reconstruction is required in the settings of delayed diagnosis of a flexor digitorum profundus (FDP) and flexor digitorum superficialis (FDS) disruption or failed previous attempt at primary repair within zone II of the digital tendon sheath.
- During the first stage of the reconstruction process, a silicone rod is placed within the flexor tendon sheath. The role of this implant is to help re-establish a frictionless inner lining of the sheath that will accommodate the placement of a tendon graft in the second stage.

ANATOMY
- Flexor tendons can be divided into five zones (FIG 1A).
- Bunnell originally described the region between the A1 pulley and the FDS insertion, zone II, as “no man’s land” because the initial results after attempted primary tendon repair were so poor he felt that no one should attempt this procedure.
- In the limited confines of zone II the two flexor tendons function together and rely on the digital sheath and its frictionless synovial interface for gliding and proper function.
- Another complicating anatomic characteristic of zone II is the chiasm of Camper. Here FDP passes through the slips of FDS, creating another potential region for adhesions (FIG 1B).

PATHOGENESIS
- Zone II has the highest probability of developing adhesions and the poorest prognosis after repair.
- Violation of the sheath, the lining, or the blood supply to the tendons by trauma or infection may lead to dense scar and adhesion formation and can compromise the results after either a primary repair or an attempt at single-stage reconstruction with a tendon graft.

NATURAL HISTORY
- Flexor tendon injuries that are not reconstructed can progress to a stiff and sometimes painful digit.
- If both tendons are not functional, no active proximal (PIP) or distal (DIP) interphalangeal motion will be possible, but if only the FDP tendon is disrupted, active PIP flexion will be present.
- If a digit with incompetent flexor tendons is subjected to repeated extension stress, as in pinch, the volar supporting structures will become lax over time, leading to hyperextension and an unstable joint.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The examiner should elicit information about the initial injury, such as when it occurred and if there were...
The flexor tendon sheath is incised, taking care to preserve the A2 and A4 pulleys. An L-shaped flap can be made within the flexor sheath to aid in access to the flexor tendons and protect the A2 and A4 pulleys (TECH FIG 1A).

The scarred tendon is excised, leaving a portion of the distal stump of the FDP intact at its insertion. This is useful in securing the tendon rod in stage 1 and the tendon graft in stage 2.

Isolated chronic disruption of the FDP tendon with an intact FDS tendon is best treated nonoperatively. Attempts at reconstruction of the FDP tendon risk function of the FDS tendon.

Buddy taping or trapping of the injured finger by an adjacent figure during finger flexion may allow concealment of the functional deficit between stage 1 and stage 2 or in the patient who is not a candidate for staged-tendon reconstruction.

Indications for two-stage flexor tendon reconstruction include:

- Loss of FDP and FDS
- Protective sensation
- Nearly full passive range of motion
- Good quality skin in the region of zone II
- A cooperative patient willing to participate fully in rehabilitation

The patient will need to have access to a good hand therapist before and after each of the stages of this complex reconstructive process.

For the second stage of the procedure a tendon must be harvested to use for the reconstruction. Often, a palmaris longus graft is used. If the patient does not have a palmaris longus, then a long toe extensor or plantaris tendon can be used. In this situation, the lower extremity must also be prepared out into the surgical field.

For both stages of the procedure the patient is placed supine on the operating table with the arm abducted on a hand table. A nonsterile tourniquet is placed around the upper arm for hemostasis.

Stage 1: A volar Brunner incision is made over the flexor tendon sheath and extended proximally into the palm. A second incision is made in the distal forearm to ensure placement of the rod within the carpal tunnel.

Stage 2: A limited Brunner incision is made at the level of the distal junction of the repair. A separate incision is made at the level of the proximal junction of the repair. This can be the same incision in the distal forearm as in stage 1 if the tendon graft is long enough. Alternatively, the proximal junction will be in the palm with shorter tendon grafts. A third incision or set of incisions will be made for the tendon harvest.

If a digital nerve laceration is identified, it should be repaired at this stage.

Release any adhesions within the sheath.

Release any flexion contractures of the joints by releasing the volar plate and accessory collateral ligaments.

Be sure to preserve the proper collateral ligaments.

If the A2 or A4 pulleys are absent or have been excised with the scar release, they need to be reconstructed. A tendon graft can be used to reconstruct the pulleys (TECH FIG 1B).
The tendon should be passed between the proximal phalanx and the extensor tendon for A2 reconstruction. For A4 reconstruction, the tendon can be passed dorsal to the extensor tendon. A silicone Hunter rod is inserted into the sheath. Distally, it is secured to the remnant of the FDP tendon with non-absorbing suture. If there is not enough of the tendon remnant, it can be secured to surrounding tissue at the base of the distal phalanx. Some Hunter rods can be secured using a screw placed in the distal phalanx. Proximally, the silicone rod is passed through the carpal tunnel and allowed to glide free with the flexor tendons in the distal forearm (TECH FIG 1C). All skin incisions are closed with 4-0 nylon after ensuring hemostasis. The patient is then placed into a dorsal blocking splint holding the fingers into an intrinsic plus posture. Rehabilitation is started early after surgery, often within 1 week, to ensure that the patient regains full passive range of motion. The scar tissue must be soft and supple before the patient is scheduled for the second stage of tendon reconstruction. On average this takes 3 months.

TECH FIG 1 • A. Creating a L-shaped flap can aid in accessing the underlying flexor sheath contents while preserving the important A2 and A4 pulleys. B. Tendon weaves for reconstruction of A2 and A4 pulleys. C. A “passive” silicone implant running under A2 and A4 pulleys is secured distally to the flexor digitorum profundus stump and extends proximally to the distal forearm.

STAGE 2

Incisions and Graft Harvest

A limited Brunner incision is made distally at the level of the DIP joint so that the distal FDP stump can be located within the sheath. The sutures securing the silicone rod to the profundus stump are released. Do not extend the incision or dissection into zone II, as this will compromise the re-established tendon sheath that has been created by the body’s reaction to the silicone rod. A second incision is made in the distal forearm so that the proximal portion of the silicone rod can be localized. A third set of incisions is then made for tendon graft harvest. This is typically from the palmaris longus, long toe extensor, or plantaris tendon (TECH FIG 2). Plantaris often makes the best donor if a long segment of tendon is needed.

Graft Placement

The tendon graft is then sutured to the proximal end of the silicone rod. The silicone rod is then retrieved from the distal wound, pulling the tendon graft into the tendon sheath (TECH FIG 3A). The distal end of the tendon graft is secured to the distal phalanx with bone anchors. The anchors should be inserted in the footprint of the FDP stump and angled slightly proximally. The proximal angle will ensure that the anchor stays within the bone rather than penetrating the dorsal cortex. It is important to ensure that the anchor does not penetrate the DIP. Alternatively, the tendon graft can be secured to the distal phalanx with a pullout suture tied over the nail, as in a zone I flexor tendon repair. This has been associated with deformities to the nail after suture removal and has no proven biomechanical advantage over suture anchors. Additional fixation can be provided by using the remaining FDP stump and securing this to the tendon graft with a nonabsorbable suture in figure 8 fashion. The distal incision is closed at this point. It will become difficult to gain access to this incision after graft tension is set.
Chapter 56  STAGED DIGITAL FLEXOR TENDON RECONSTRUCTION 2573

TECH FIG 3 • A. Technique for using the silicone rod to draw the tendon graft into the flexor tendon sheath and out through the distal incision. B. Re-creation of the normal finger cascade. C. A Pulvertaft weave is used for the proximal junction between the tendon graft and the flexor digitorum profundus or superficialis in the forearm.
Tendon graft tension is set from the proximal wound. The correct amount of tension is determined with the wrist in a neutral posture and is set by evaluating digital flexion cascade (TECH FIG 3B).

- It may be wise to exaggerate the cascade slightly so that as the graft relaxes and lengthens, the normal flexion cascade is created.
- If the cascade is significantly exaggerated, however, a quadriga effect will result.
- The proximal end of the tendon graft is then woven into the proximal recipient tendon stump with a Pulvertaft weave (TECH FIG 3C).

- The recipient stump proximally can be either the FDS or the FDP to the injured finger. If the initial injury is more than a few months old, the muscle belly of the injured FDP or FDS may be atrophic or scarred proximally in the forearm, which would limit postoperative results. In this setting, the recipient tendon can be a side-to-side anastomosis to the neighboring FDP, which will provide the appropriate excursion.
- All skin incisions are closed after ensuring hemostasis. The patient is then placed into a dorsal blocking splint with the wrist slightly flexed and the MP and IP joints flexed.
- Rehabilitation is started within a few days (see Postoperative Care).

PEARLS AND PITFALLS

**Pulley preservation**

Both the A2 and A4 pulleys must be maintained or reconstructed at stage 1 to prevent bowstringing and maximize the amount of active flexion (FIG 2; see Tech Fig 1B).

**TENOLYSIS**

- This is often necessary after stage 2 of tendon reconstruction. Tenolysis is indicated when passive range of motion is greater than active range of motion. This surgery should not be performed until 3 to 6 months after stage 2.
- The tendon must be exposed within zone II of the tendon sheath and tenolysis performed within the flexor sheath, taking care to preserve the A2 and A4 pulleys. If residual resistance is noted after tenolysis in the finger, an additional incision may be made at the level of the proximal junction to address any adhesions at that level.
- Immediate hand therapy must be initiated postoperatively and can be easier on the patient if a wrist block is performed with a long-acting local anesthetic to preserve motor function while producing an effective sensory block.

**ALTERNATIVE TO STAGE 1**

- The silicone rod that we use is considered “passive” and has no attachment to the proximal flexor motor.
- An "active" alternative exists in which the rod can be secured to the tendon proximally and function as a graft. This can eliminate the need for stage 2 (TECH FIG 4).
- These implants have been associated with a higher rate of complication in the limited number of studies that have examined them.

**TECH FIG 4** • In an active tendon rod, the motor tendon is looped through the ring in the proximal rod, woven through itself, and fixed with nonabsorbable suture so that active motion can be performed.

**FIG 2** • Sagittal MRI showing bowstringing of a flexor tendon (arrow) over the proximal phalanx due to an incompetent A2 pulley.
Chapter 56  STAGED DIGITAL FLEXOR TENDON RECONSTRUCTION

POSTOPERATIVE CARE

- The pre- and postoperative hand therapy is perhaps the most important component of this reconstruction procedure.
  - Patients must be motivated and compliant.
  - Therapists must be knowledgeable.
  - Before stage 1 and stage 2, the patient must have nearly full passive range of motion and a soft tissue envelope that will accommodate the subsequent stages of the process.
  - Stage 1 postoperative therapy is initiated within 48 hours and continues until the patient is ready for stage 2.
    - If pulley reconstruction was performed, the therapist can make ring splints for the patient to wear to protect the pulleys.
    - In general, the patient needs to be monitored for signs of infection. Edema should be controlled with elevation and compressive dressings as needed.
    - A custom splint is used when not exercising. This splint should hold the injured fingers in an intrinsic plus posture, with the MP joints in 70 degrees of flexion and the IP joints held in full extension. The wrist is held at neutral.
    - Passive range of motion of all involved digits is initiated, with emphasis on obtaining full composite flexion and full PIP extension.
    - Active range of motion exercises are also used to establish full active extension of all digits and full flexion of the uninvolved digits. Buddy-taping can be employed to facilitate motion of the operated digit.
    - The protocol for postoperative therapy after stage 2 is as follows:
      - 0 to 3 weeks postoperatively
        - Precautions: No active finger flexion, no passive finger extension
        - The patient is splinted with a dorsal extension block splint holding the involved digits in an intrinsic plus posture and the wrist at neutral. The splint should be worn at all times.
      - Therapist-directed exercises begin with passive flexion and active extension in the splint. The PIP and DIP joints are secured to the splint in extension between exercise sessions.
      - Wound care and edema control are also incorporated and the patient must be observed for signs of infection.
      - 3 to 6 weeks postoperatively
        - Precautions: Monitor closely for PIP flexion contractions, no passive finger extension, no splint removal
        - Active range of motion is initiated with “place and hold” exercises and progressed to full active range-of-motion exercises by 4 weeks after surgery while still in the splint.
        - Once the surgical wounds have healed, soft tissue massage should be incorporated to soften the volar tissues.
      - 6 to 9 weeks postoperatively
        - Precautions: No resisted active motion, light functional activities only
        - Reliable patients can be weaned from the dorsal blocking splint.
        - The active flexion and extension exercises should be continued. Blocking exercises are initiated for PIP and DIP flexion to facilitate tendon glide and pull-through. Combined finger extension exercises are slowly initiated with the wrist in slight flexion. If the patient is a heavy scar former, this begins at 6 weeks; if average, at 7 weeks; if light, at 8 weeks.
      - 9 to 12 weeks postoperatively
        - Precautions: No lifting or uncontrolled use
        - Splinting should be modified to correct any residual joint contractures and increase soft tissue excursion.
        - The patient can be allowed to begin progressive strengthening and should continue active range-of-motion and tendon gliding exercises as well as scar management as needed.
      - 12 to 14 weeks postoperatively
        - Precautions: No heavy lifting

Full passive range of motion should be achieved before stage 1 and again before stage 2. Less than maximum passive range of motion preoperatively will markedly worsen the functional result after stage 2.

Establishing the correct cascade with the appropriate amount of tension on the tendon graft in stage 2 is important. The graft will likely relax and lengthen as the patient goes through rehabilitation. A slight exaggeration of the cascade at the time of surgery may ultimately produce the normal cascade as the tendon graft lengthens. Gross exaggeration of the cascade, however, will produce a quadriga effect. The uninjured digits will be less than fully flexed when the injured digit has reached full flexion in the palm (FIG 3).

Hand therapy

A good therapist and a motivated patient are critical for a good outcome for this surgery.

FIG 3 • Clinical photograph of the quadriga effect. The long finger, in which the flexor digitorum profundus has been repaired with too much tension, is maximally flexed into the palm and the adjacent fingers cannot be actively flexed further.
Splinting is continued as needed to address contractures. Active range-of-motion and strengthening activities are continued. Resistance is gradually increased up to about 30 lbs by week 14.

14 to 16 weeks postoperatively
- The patient progresses to full resistive strengthening exercises and activities.
- A work-hardening program is initiated if needed to prepare for return to work.
- If the patient is less reliable, the above protocol is followed except that dorsal blocking splinting is continued for up to 9 weeks and active motion is delayed at least 4 weeks.

OUTCOMES
- Because there are few alternatives to this staged process of reconstruction, there are limited articles comparing this treatment to another. Most of the investigations in the literature are retrospective reviews documenting overall postoperative motion and outcome ratings based on objective and subjective rating systems.
- The larger studies have shown good and excellent results in the 70% to 80% range, depending on the grading system used.
- Final total active motion is about 70% of the contralateral uninjured digit.
- Typically a significant discrepancy exists between ultimate total passive motion and total active motion. A flexion contracture of about 20 degrees at the DIP joint is common.
- The most common reported complication, seen in 30% of patients, was the need for a tenolysis.
- Other common complications that resulted in the need for further surgery included infection, tendon rupture, pulley rupture with bowstringing, and incorrect tendon tensioning.

COMPLICATIONS
- The most common complication is the development of adhesions that limit active motion. This can be assessed by a discrepancy between the active and passive range of motion. If there are significant discrepancies after at least 3 months of therapy after stage 2, then a tenolysis is recommended. This is followed immediately by a rigorous course of therapy to regain active motion. By 3 months, the tendon graft and junction sites should be strong enough to allow for unrestricted active motion.
- Bowstringing is common if the A2 and A4 pulleys are compromised by initial trauma or released with the scar and adhesions during stage 1. In this setting, these pulleys should be reconstructed during stage 1. If they are found to be incompetent during the stage 2, then pulley reconstruction must be performed and the tendon graft must be delayed until the patient has healed from the pulley reconstruction and once again demonstrated nearly full passive range of motion.
- Infection should be monitored for closely, given the previous history of a penetrating wound that caused the tendon laceration in the first place and the implantation of a synthetic material during stage 1 of the procedure. Infections should be managed aggressively because the local inflammation can produce further contractures and adhesions.

REFERENCES
DEFINITION

- Traumatic disruptions of the extensor mechanism represent a broad spectrum of injuries, frequently seen because of the tendons’ superficial location, and frequently associated with concomitant injury to bone, skin, and joint.\textsuperscript{15}
- Repair can be technically demanding. The extensor tendons are thin, have limited excursion, and are intolerant of shortening, especially in the digits.
- Reconstruction of subacute and chronic extensor tendon injuries are more challenging and less effective than early repair, underscoring the importance of appropriate treatment of an acute injury.

ANATOMY

- Extensor tendon zones of injury (Verdan) (FIG 1A)\textsuperscript{13}
  - The extensor mechanism is divided into eight zones in the fingers and five in the thumb, numbered from distal to proximal.
- Even-numbered zones are over bones and odd-numbered ones are over joints.
- Extrinsic extensors (FIG 1B and Table 1)
  - Digital and wrist extensor muscles originate from the lateral epicondyle and condyle, with musculotendinous junctions 3 to 4 cm proximal to the wrist joint. The extensor indicis proprius (EIP), extensor pollicis longus (EPL), abductor pollicis longus (APL), and extensor pollicis brevis (EPB) all originate more distally from the ulna, the radius, or both and have more distal extension of muscle fibers.
  - The four extensor digitorum communis (EDC) tendons originate from a common muscle belly and have progressively limited independence moving from the index to small fingers.
  - The fascia over the extensor tendons thickens at the wrist to form the extensor retinaculum, with vertical septa separating the six extensor compartments (FIG 1B).
  - Juncturae tendinum provide interconnections between the EDC tendons just proximal to the metacarpophalangeal (MCP) joints.

FIG 1 • A. Extensor tendon zones of injury. B,C. The digits are to the left and the wrist is to the right. B. The top of the figure is radial and the bottom is ulnar. Wrist and hand extensor tendon anatomy, with numbers to identify the extensor tendon compartments. R is the reflected extensor retinaculum and J is a junctura tendonum. Note the combined extensor digitorum communis (EDC) tendon to the ring and small finger. In the fourth compartment, the extensor indicis proprius (EIP) tendon is deep to the EDC tendons and has more distal muscle fibers. In the hand, it is just deep and ulnar to the index EDC tendon. See Table 1 for more details. C. The digital extensor mechanism. 1. Terminal tendon. 2. Triangular ligament. 3. Proximal interphalangeal (PIP) joint. 4. Central slip tendon. 5. Sagittal band. 6. Lateral band, which will become the terminal tendon distally. 7. Conjoined lateral band, with fibers to base of middle phalanx and to the lateral band. This patient has an unusual proprius tendon to the long finger (*), passing ulnar to the EDC tendon and beneath the junctura.
The EIP and extensor digiti minimi are ulnar and deep to the EDC in the hand and at the MCP joint. The EIP passes beneath the junctura tendinum.

There can be considerable variability of the extensor tendons on the dorsum of the hand, with less than 50% of people having a separate EDC tendon to the small finger. Duplicated, interconnected tendons are common.

The sagittal band holds the extensor tendon over the metacarpal head at the MCP joint, and, through its connection to the volar plate, extends the joint.

Intrinsic extensors (FIG 1C)

Intrinsic extensors originate in the hand and include the four dorsal interossei, three palmar interossei, and four lumbricals. The thenar and hypothenar muscles also contribute to interphalangeal extension.

The intrinsic tendons join to form the conjoined lateral bands volar to the axis of the MCP joint, and continue dorsal to the axis of the proximal (PIP) and distal (DIP) interphalangeal joints. This allows them to simultaneously flex the MCP joint and extend the PIP and DIP joints, in addition to providing digital adduction and abduction.

PATHOGENESIS

Zone I

Disruption of the extensor tendon over the DIP joint will result in a terminal extensor lag after an open or closed injury (FIG 2).

Sudden forced flexion of the extended DIP joint can lead to an avulsion of the tendon from its insertion on the distal phalanx (mallet finger), possibly with an associated distal phalanx fracture.

The long, ring, and small fingers are most frequently involved, although closed mallet injuries can also be seen in the index finger and thumb.

Zone II

Laceration over the middle phalanx can give the clinical appearance of a zone I injury.

Injury to the periosteum and middle phalanx can lead to increased swelling, extensor tendon adherence, and DIP stiffness.

Zone III

Disruption of the central slip at the PIP joint may occur as a closed rupture (with or without an associated bone injury) or be associated with traumatic arthrotomy.

Central slip avulsion is seen with volar PIP joint dislocations.

Early closed injuries may present with swelling, pain, and little extension loss but can progress to a boutonnière deformity as the lateral bands migrate palmarly and become flexors of the PIP joint in the weeks after injury. Close follow-up is warranted for suspicious injuries.

Zone IV

Injuries occur over the proximal phalanx and typically involve only a portion of the extensor mechanism.

Lacerations are usually partial as the extensor “hood” covers almost 75% of the circumference of the digit. With a complete central slip laceration, PIP extension may be maintained (through the lateral bands) initially, although a boutonnière deformity may develop later.

Differentiation between complete and incomplete injury can be difficult, but pain or weakness with resisted PIP extension (especially from an initially flexed position) can be suggestive. As above, close follow-up is warranted for suspicious injuries.

Zone V

Tendon injury occurs over the MCP joint.

There may be an open laceration or a closed injury to the sagittal band with extensor tendon subluxation.

Most frequently, the radial sagittal band is disrupted in closed injuries allowing ulnar subluxation of the extensor tendon.

The surgeon should assume there is an open MCP joint injury with any tendon laceration around the joint.

Zone VI

Disruption of extensor tendon is over the dorsum of the hand.

Single tendon and partial tendon lacerations may be difficult to identify due to maintenance of some digital extension though an intact junctura tendinum and EDC tendon from an adjacent digit (FIG 3).
Zone VII
- Lacerations occur over the wrist and through the extensor retinaculum.

Zone VIII
- Pathology is located in the forearm at the musculotendinous junction or muscle belly.
- It may be difficult to detect concurrent posterior interosseous nerve injury in the presence of proximal extensor muscle lacerations.

Thumb
- The terminal extensor tendon is thicker than in other digits—mallet injury is rare.
- Tendon lacerations at, and distal to, the MCP joint are not associated with retraction of tendon ends, and primary repair is straightforward. Lacerations proximal to the MCP joint are associated with EPL retraction (often of the wrist).

### NATURAL HISTORY

- Untreated complete tendon lacerations at and distal to zone V will lead to persistent (and sometimes progressively worsening) digital deformity, often with continued pain and development of a flexion contracture.
- Untreated terminal tendon injuries may lead to a swan-neck deformity due to proximal migration of the digital extensor mechanism and increased extension force at the PIP joint.
- Delayed treatment of central slip injuries may lead to boutonnière deformity and PIP flexion contracture as the lateral bands migrate palmarly.
- Untreated tendon lacerations proximal to zone V will heal in lengthened fashion with pseudotendon formation. There may be a persistent extensor lag, weakness, or pain. Gradual loss of muscle length and elasticity (sometimes within as little as a week or two) can make delayed primary repair more difficult.
- EPL tendon lacerations proximal to the MCP joint may be difficult to primarily repair as little as 2 weeks after the injury, requiring tendon grafting or EIP transfer.
- Partial tendon lacerations involving less than 50% of the tendon width, longitudinal lacerations, and single lateral band lacerations will generally function well without repair.

### PATIENT HISTORY AND PHYSICAL FINDINGS

- Assessment and documentation of skin and soft tissue injury is important to aid in planning for débridement and extension of the skin incision for exposure and determining the need for soft tissue coverage.
- A complete neurologic and tendon examination is critical to rule out concurrent or remote injury that will alter treatment or outcome.
  - The EIP is examined. It is deep to other extensor tendons, with the most distal musculotendinous junction.
  - The extrinsic extensor tendons are examined with the wrist in neutral, testing MCP extension against resistance. (Isolated PIP extension can be performed by the intrinsic muscles even in the presence of complete extrinsic extensor tendon lacerations.)
  - Examination of the digits may identify extensor lag, weakness, or pain with resistance to extension at the PIP or DIP joints.
- Active and passive range of motion and strength are assessed. Active motion loss helps determine tendon deficits, while loss of passive motion may be pain-related or represent remote injury or arthritis. Lacerations proximal to the juncture of the DIP joint may have nearly full motion, but with weakness on strength testing (FIG 3).

### IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs are necessary to evaluate for any fractures, foreign bodies, preexisting injury, or arthritis that may alter treatment or affect the final result.
- Ultrasound or MRI are occasionally useful for suspected radiolucent foreign bodies. While both studies can be used to more fully evaluate tendon injuries, treatment decisions are usually based on history and physical examination.

### DIFFERENTIAL DIAGNOSIS

- Radial nerve or posterior interosseous nerve injury
- Extensor tendon subluxation at the MCP joint
- Chronic PIP flexion contracture and “pseudo-boutonnière” deformity
- Physiologic swan-neck deformity or DIP joint osteoarthritis with apparent mallet deformity
- Underlying joint deformity and arthrosis

### NONOPERATIVE MANAGEMENT

- Disruption of the terminal extensor tendon (mallet finger)
  - Treatment consists of full-time static DIP splinting for 6 to 8 weeks, followed by an additional 6 weeks of protective splinting at night and with high-risk activities.
  - Patients must be counseled as to the importance of maintaining full DIP extension, even during splint changes.
  - A dorsal splint (FIG 4A) can allow the patient nearly full use and sensibility of the digit, although palmar or thermoplastic splints can be used in some cases (provided that full DIP extension can be ensured). A good fit without excessive DIP hyperextension which can cause skin injury is critical.
  - The PIP is generally left free and motion encouraged. For patients with moderate PIP hyperextension, the PIP may be flexed 30 degrees and incorporated in the splint for the first 3 weeks of treatment.
  - Treatment can be initiated as late as 4 months after the original injury and still lead to a good result, although a couple more weeks of full-time splinting may be necessary.
Final results: About 80% of patients should regain full flexion with less than a 10-degree extensor lag. Patients with a greater extension lag after 6 weeks may benefit from 2 or 3 more weeks of full-time splinting. Swelling around the DIP joint can persist for months.

Central slip avulsion
- This is treated with full-time static PIP splinting in extension, with active and passive DIP flexion encouraged for 6 weeks, followed by 6 weeks of night splinting.
- Intermittent use of dynamic extension splint is warranted for PIP flexion contracture.

Closed sagittal band rupture
- The patient is placed in a below-elbow cast with the MCP joints supported in full extension (to allow no more than 10 degrees of flexion) for 6 weeks.
- Compliant patients can be switched to a hand-based splint after 3 weeks of casting with the MCP joint supported in 30 degrees of flexion (FIG 4B).
- Surgical treatment is indicated for closed ruptures presenting more than 2 weeks after injury or those that do not respond to conservative treatment.

Partial extensor tendon lacerations
- Conservative treatment is indicated if the laceration is known to involve less than 50% of the tendon width and in longitudinal tendon lacerations.
- If the degree of injury is unknown, conservative treatment should be considered in patients with full active extension, minimal or no pain with resisted extension, and good extension strength. Surgical exploration and repair is indicated if there is an extensor lag, weakness, or pain with resisted extension.
- Partial digital extensor tendon lacerations are treated in the manner described earlier, with splinting for 2 to 3 weeks, followed by a monitored gradual exercise program to ensure that an extensor lag does not develop.
- Partial hand and forearm extensor tendon injuries are treated similarly. A splint or cast is used for 3 weeks with mild wrist extension and 30 degrees of MCP flexion. The PIP joints are left free.

SURGICAL MANAGEMENT

Preoperative Planning
- A careful examination is performed to determine the structures that are injured or will need repair (eg, open joint injuries, fractures, flexor tendon or nerve injuries) and to inform the patient of the extent of the procedure, anticipated rehabilitation, need for occupational and non-occupational restrictions, and expected outcome.
- If the wound is infected at the time of presentation, irrigation and débridement should be followed by a course of antibiotics. Delayed primary tendon repair can be carried out 7 to 14 days later (sooner for EPL lacerations proximal to the MCP joint and EDC lacerations proximal to the juctura).
- The surgeon should anticipate the need for tendon graft or transfer for subacute injuries or those with tendon loss.
- Local anesthesia and a digital tourniquet can be used for injuries distal to the PIP joint. The need for an upper arm tourniquet for more proximal injuries may necessitate a general or regional anesthetic, unless the anticipated surgical time is less than 30 minutes. Regional anesthesia can offer extended postoperative pain relief and muscle relaxation during the initial recovery period.

Positioning
- Standard positioning is used with the hand on a hand table and the surgeon at the head.
- Preparation and draping is done above the elbow to allow dressing and splint application before removal of drapes.
- A carefully padded tourniquet is applied, set to 100 mm Hg above systolic blood pressure (sometimes more for obese patients, and less for children or those with small arms).

Approach
- Wound exploration and débridement are performed in a bloodless field, with appropriate light and magnification. Injuries over a joint usually require joint exploration and irrigation.
- The skin laceration can be extended to improve exposure, allow retrieval of retracted tendons, provide access to place sutures, and to decrease skin tension during retraction. Long, narrow skin flaps are avoided. Longitudinal incisions on the dorsum of the hand and fingers can cross over joints (unlike on the digital flexor surface).
- Bipolar electrocautery is used as needed, with care taken not to injure dorsal cutaneous nerves. If there is any doubt regarding hemostasis, the tourniquet is deflated before closure. Drains are seldom needed.
- Only the skin in the fingers, hand, and distal forearm is closed, with limited subcutaneous sutures more proximally if needed.
SUTURE TECHNIQUES

- Suture technique is determined by the thickness and shape of the tendon and the nature and character of the laceration (TECH FIG 1).
  - Thin tendons (e.g., in digits) can be repaired with a horizontal cross-stitch suture (Silfverskiöld), simple running, figure 8, or horizontal mattress suture using 4-0 or 5-0 braided or monofilament nonabsorbable material.
  - Thicker tendons can support a two- or four-strand grasping repair with a 2-0, 3-0, or 4-0 nonabsorbable braided suture (e.g., Ethibond, Ticron, or Fiberwire), optionally reinforced with a 5-0 or 6-0 monofilament epitendinous suture placed in a simple running or cross-stitch fashion.
- In general, repair strength is related to number of suture strands crossing the repair site, the thickness of the suture, and the locking style of the stitch.

TECHNIQUES
SUTURE TECHNIQUES

The strongest repairs are the Silfverskiöld cross-stitch for flat tendons, and the four-strand cruciate suture for tendons able to accept a core suture. A. Running suture. B. Horizontal mattress. C. Silfverskiöld cross-stitch (which can also be used as a circumferential epitendinous tidying suture over a core suture). D. Modified Kessler. E. Modified Bunnell. F. Krackow. G. Four-strand cruciate suture.

REPAIR IN THE FINGERS

Zone I (DIP Joint)

Soft Tissue Mallet Treatment

- In patients with closed tendon disruptions who cannot tolerate a splint for occupational reasons, pinning across the DIP joint with a 0.045-inch Kirschner wire exposed at the tip or buried under the skin may be indicated. Pin removal is performed 6 weeks later, followed by motion exercises and 6 weeks of splinting at night and during vigorous activity.
- Lacerations in zone I are treated with primary surgical repair.
  - A figure 8 or running cross-stitch with a 5-0 nonabsorbable suture can be placed in the tendon, taking care to avoid shortening the tendon. This is supported with a 0.045-inch Kirschner wire across the DIP joint for 6 weeks. The DIP should be in neutral extension, without hyperextension.
  - An easier and often better alternative is use of a "tenodermodesis" stitch of 4-0 nylon through both the tendon and skin (TECH FIG 2). This can be especially useful in cases treated in the emergency room, or in children, where the small tendon is difficult to accurately repair.
    - Full-time extension splinting (as in a closed mallet finger) or a 0.045-inch Kirschner wire across the extended DIP joint is required.
    - The suture can be removed in 2 to 3 weeks, but the splinting should continue for a total of 6 weeks full time and another 6 weeks at night.

Bony Mallet Treatment

- It remains controversial whether mallet fractures with greater than 50% of the distal phalanx involved or with DIP joint subluxation should be treated surgically or by splinting alone. Surgery is more likely warranted in younger patients and those with greater amounts of subluxation. If conservative management is being considered, be sure to obtain a good lateral radiograph with the digit in the DIP splint, as DIP extension to neutral may demonstrate subluxation that was not apparent when the joint was flexed.
  - A large bone fragment is present, with subluxation of the DIP joint (TECH FIG 3A-B).
  - Place a 0.045-inch Kirschner wire down the shaft of the distal phalanx, almost to the DIP joint.
  - Maximally flex the DIP and place a 0.035-inch Kirschner wire at the anticipated location of the reduced dorsal fragment of the distal phalanx. The skin entry point is
Zone III (Over PIP Joint)
- Use a running 4-0 or 5-0 suture to repair the central slip in the manner detailed earlier (TECH FIG 4).
- Repair the lateral band or bands with single 4-0 or 5-0 monofilament suture in a figure 8 fashion.

Reconstruction in Cases with Tendon Loss
- Consider V-Y advancement of the central tendon or a “turndown” of the central slip proximal to the laceration to cover the defect.20
- Extend the skin incision proximally, almost to the MCP joint.
- Incise a V in the central slip, with the apex just distal to the MCP joint, and the distal end the width of the tendon, taking care not to damage the overlying epitenon (TECH FIG 5A, red line).
- Advance the tendon distally. Disrupt the loose alveolar tissue between the tendon and periosteum as little as possible.
- Close the V into a Y with a 4-0 or 5-0 suture, and repair the distal end of the advanced central slip as described earlier (TECH FIG 5B).
- An alternative method involves creating a rectangular flap of central slip proximally and turning it up to attach distally (TECH FIGS 5A–D).20
- Suture anchors or small holes drilled in the middle phalanx are occasionally needed to secure the tendon to the...
dorsal base of the middle phalanx, especially if the dorsal margin of the base of the phalanx is lost.

**Postoperative Management**

- Postoperative rehabilitation for children, less compliant adults, and cases with a tenuous repair involves static splinting or pinning of the PIP joint in full extension for 4 weeks, followed by a protected motion program.
- For compliant adults, an early motion protocol can be initiated.6
  
  - 0 to 30 degrees of active PIP flexion and extension is allowed starting a few days after surgery, using a palmar flexion block splint with a free wrist and MCP joint.
  - 10 to 20 repetitions are performed each hour, with a static PIP splint in full extension when not exercising.
- DIP flexion exercises are performed in the static PIP extension splint.
- If no extensor lag develops, PIP motion can be increased to 40 degrees after 2 weeks, 50 degrees after 3 weeks, and 70 degrees after 4 weeks. The splinting is discontinued at 6 weeks.
- Results are often less than perfect, especially in cases with tendon loss, where some loss of motion should be expected.

**Zone IV (Over Proximal Phalanx)**

- The tendon at this level may be thicker and support a grasping or locking core stitch with a 4-0 braided nonabsorbable suture, reinforced with a running 5-0 monofilament suture.
- If the tendon is too thin, repair as in zone III.
- Postoperative management is as in zone III.

**Zone V (Over the MCP Joint)**

- The tendon is much thicker at this level and can sometimes support a 3-0 or 4-0 braided nonabsorbable core suture with a running simple or cross-stitch suture over the repair, incorporating any laceration of the sagittal band.
- An abnormal resting cascade of the digits suggest a tendon laceration (TECH FIG 6A).
- Lacerations over the MCP joint often extend into the joint. The skin laceration is extended and débrided and the wound explored. Large capsular rents (arrow in TECH FIG 6B) can be repaired with a simple running 5-0 absorbable monofilament suture. Small capsular lacerations are left open.
- The tendon end is retrieved, and a 3-0 nonabsorbable core suture is placed. The first loops of the cruciate stitch are shown (TECH FIG 6C).
The distal locking stitch is placed on one side of the tendon but not pulled tight until the tendon ends are accurately approximated. The limbs of the X are individually tightened (TECH FIG 6D).

The core suture is completed and will not slide (TECH FIG 6E).

The repair is reinforced with a 5-0 nonabsorbable monofilament suture. This can be circumferential proximal to zone V, but only over the dorsal surface of the tendon distally (TECH FIG 6F).

The resting cascade of the digits shows the repaired finger to be slightly “tighter” than normal immediately after the repair (TECH FIG 6G).

A forearm-based splint is applied with 30 degrees of wrist extension, less than 30 degrees of MCP flexion, and fully extended PIP and DIP joints (TECH FIG 6H).

After 8 to 10 days, this splint is converted to a short-arm cast supporting the MCP joints in extension (including all fingers for index lacerations and the ulnar three for other lacerations) but leaving the PIP joints free for another 3 weeks before institution of a therapy program.

Alternatively, an early protected motion program can be initiated.3,9

**Repair of Distal “Compromised” Zone V Lacerations**

In this clinical situation a standard end-to-end repair may be tenuous or may not be possible secondary to contracted or lost tendon substance. A tendon interpositional graft may be required.

- Partially incise the distal tendon transversely 5 mm distal to the cut edge.
- Weave tendon graft in a volar to dorsal direction through this transverse incision in the distal stump.
- Sew the graft to the proximal stump to the distal tissue and back to itself using nonabsorbable material (TECH FIG 7).
- Sew the proximal stump to the tendon graft using a Polvartaft weave.
**TECH FIG 7** • Tendon graft is woven volar to dorsal through the transverse incision in the distal tendon stump. A Polvertaft weave is used to secure the graft to the proximal tendon stump.

**Zone VI (Metacarpal Level)**
- The tendon is thicker and repair is similar but technically easier than in zone V.
- Use a 3-0 or 4-0 braided nonabsorbable suture, reinforced with a circumferential running cross-stitch 5-0 or 6-0 monofilament suture.
- Rehabilitation is as for zone V.

**Zone VII (Wrist and Extensor Retinaculum)**
- Suture repair and postoperative management are as in zone VI.
- The extensor retinaculum is incised for repair and retrieval of the proximal tendon stump.
- Retinacular closure is performed with a 4-0 absorbable suture to prevent tendon bowstringing. A portion of the retinaculum may need to be excised to allow the repair site to glide smoothly.
- The EPL can be repaired outside of the retinaculum and left in the subcutaneous tissue.
- Postoperative management is the same as for Zone V injuries.

**Zone VIII**
- Make a generous incision to determine the resting orientation of the tendons before débridement and repair. It may be helpful to tag proximal tendon ends with labels to define them before further dissection changes their position.
- In the distal forearm, conventional repair with grasping sutures is possible. EDC tendons can be repaired as a group if necessary.
- Proximally, repair can be much more difficult. 3-0 interrupted absorbable sutures can be used in fibrous septa within muscle along with repair of epimysium.
- Postoperative management is as for zones V to VII.

**PEARLS AND PITFALLS**

**Tetanus prophylaxis**\(^{16}\)
- Tetanus toxoid “booster” should be given to patients with at least three previous doses, but last dose more than 5 years ago for tetanus-prone wounds (>1-cm laceration, crush, burn, high-energy injury, or with infection, devitalized tissue, or gross contamination) or more than 10 years ago for wounds not prone to tetanus.
- Tetanus immune globulin should be given for tetanus-prone wounds in patients with unknown or incomplete vaccination history. It is not clear, however, that “tetanus-prone wounds” are more likely to cause tetanus.
- The greatest protection against tetanus is a completed childhood vaccination series.
- A tetanus booster at the time of injury does not change the likelihood of developing tetanus.

**Lacerations proximal to juncturae tendinum**
- Extensor lag may be more subtle, sometimes noted only with lack of active MCP hyperextension, pain with resisted range of motion, or lack of palpable EDC tendon on dorsum of hand.
- Full PIP extension may be possible through the lateral bands even in the presence of a complete tendon laceration.

**Subacute lacerations**
- Be prepared for EIP transfer or free tendon graft for delayed treatment of EPL lacerations.
- Side-to-side repair to adjacent extensor tendons or use of a free tendon graft is occasionally needed for treatment of chronic injuries involving other tendons.

**Clenched-fist injuries**
- Extensor tendon injury may be well proximal to the skin injury.
- Associated MCP joint injuries are common.

**Shortened repair**
- Digital extensor mechanism is very sensitive to shortening, with resulting loss of flexion.

**Distal forearm extensor tendon lacerations**
- Before exploring proximal injury, locate and label individual tendon ends (based on location).
- Detailed exploration (for incision and drainage, foreign body removal, etc.) may distort tendon position, making it impossible to determine correct proximal motor to attach to each distal tendon end.

**Proximal forearm lacerations**
- Associated nerve injury (especially the posterior interosseous nerve) can make diagnosis and treatment difficult.
POSTOPERATIVE CARE

Postoperative care is detailed under the surgical technique for each individual location.

OUTCOMES

Good or excellent results can be anticipated in most patients, with worse outcomes seen in the digits and with concomitant soft tissue or bone injury. Loss of digital flexion is a greater problem than small losses of extension.\(^2\)\(^,\)\(^16\)

Stronger suture techniques and early dynamic postoperative protocols may result in better functional outcomes earlier,\(^17\) although few controlled studies show improvement in long-term results when compared to static splinting programs, which are easier, more predictable, and less expensive.\(^12\),\(^14\)

Early motion programs may be most beneficial in zones III and IV.

COMPLICATIONS

Infection
Rupture of repaired tendons
Stiffness
Primary joint stiffness after immobilization
Adherence of repaired tendon to surrounding skin, bone
Extensor lag

REFERENCES

DEFINITION

- Traumatic injury to the extensor tendons of the hand and forearm results in the disruption of tendon substance, causing a loss of active wrist or digital extension.
- Primary repair of the extensor tendon usually can be performed within 7 days after appropriate irrigation and débridement of wounds and stabilization of any fractures.\(^5\)
- Late reconstruction of extensor tendon injuries presents an operative challenge and often requires the use of tendon transfer and grafting techniques.

ANATOMY

- The extensor mechanism of the hand and wrist is a complex system involving balanced interplay between extrinsic and intrinsic components (FIG 1).
- The extrinsic extensor tendons are divided into superficial and deep groups in the forearm:
  - Superficial: extensor carpi radialis longus and brevis (ECRL and ECRB), extensor digitorum communis (EDC), extensor digiti minimi (EDM), extensor carpi ulnaris (ECU), and anconeus
  - Deep: abductor pollicis longus (APL), extensor pollicis brevis and longus (EPB and EPL), extensor indicis proprius (EIP), and supinator
- Wrist extension is provided by the ECRB, ECRL, and ECU.
- Finger and thumb extension is provided by the APL, EPB, EPL, EDC, EIP, and EDM.
- The radial nerve innervates all extensor muscles of the hand, except the intrinsics, which are innervated by the median and ulnar nerves. The radial nerve’s deep motor branch becomes the posterior interosseous nerve (PIN).

![Diagram of the extensor mechanism of the hand and wrist](image_url)
There are six fibro-osseous dorsal compartments at the level of the wrist covered by the extensor retinaculum. The contents of each compartment are as follows:
- I: APL, EPB
- II: ECRL, ECRB
- III: EPL
- IV: EDC, EIP
- V: EDM
- VI: ECU

The intrinsic system of the hand consists of the seven interosseous muscles (three palmar and four dorsal) and four lumbrical muscles.

The intrinsic muscles pass volar to the axis of the metacarpophalangeal (MP) joints and dorsal to the interphalangeal (IP) joints; thus, the intrinsic system will flex the MP joints and extend the IP joints.

On the dorsum on the hand, the fibrous bands of the juncturae tendinum connect the extensor digitorum tendons of the long, ring, and small fingers.
- This interconnection is what allows grouped extension of the fingers.
- The EIP and EDM are ulnar to their respective EDC tendons and function as independent extensors of the index and small fingers.

Over the MP joints, tendons are held in a central position by the sagittal bands, which envelop the MP joint and attach to the volar plate.

The dorsal extensor apparatus is formed distal to the MP joint from contributions of both extrinsic and intrinsic tendons.
- The central slip, the continuation of the extrinsic extensor tendon, inserts into the dorsal base of the middle phalanx.
- The lateral bands are formed from the intrinsic muscles on either side of the finger and send fibers to the middle phalanx as well as contributions to the central slip.
- The lateral bands combine dorsally over the middle phalanx to form the terminal extensor tendon, which inserts on the dorsal base of the distal phalanx.
- The transverse and oblique retinacular ligaments stabilize the tendons of the dorsal apparatus.

Traumatic injuries to the extensor tendons can be described in terms of nine anatomic zones (Table 1).³

Even-numbered zones overlie bones and odd-numbered zones overlie joints.

Vascular supply⁵
- Forearm: nutrition via small arterial branches from the surrounding fascia
- Wrist: derived from mesotenon; nutrition via diffusion
- Hand: derived from paratenon; nutrition via perfusion

PATHOGENESIS
- Extensor tendons are susceptible to traumatic injury because of their relatively superficial location and thin tendon substance.
- Acute repair within 7 days is recommended, but direct repair of acute injuries is occasionally impractical in cases with extensive soft tissue damage or segmental tendon loss.
- In these cases, skeletal stabilization is obtained first (Fig 2), followed by soft tissue coverage, and finally late reconstruction of the disrupted extensor mechanism.
- Also, late presentation of traumatic disruptions of an extensor tendon makes direct repair difficult because of tendon retraction and subsequent extrinsic tightness.
- Traumatic injury to the extensor tendons can also occur after upper extremity fractures.
- Acute rupture of the EPL tendon has been associated with displaced distal radius fractures.
- Delayed EPL rupture has been associated with minimally displaced distal radius fractures. These attritional ruptures are generally attributed to compromise of the tendon’s vascular supply by soft tissue damage and hemorrhage after fracture with an intact third extensor compartment.⁴
- Delayed extensor tendon ruptures of the EPL, EDC, and EIP have been reported as a complication after volar and dorsal plate fixation of distal radius fractures.²

FIG 2 • Preoperative picture of a patient with severe soft tissue loss, including extensor muscle, after a motorcycle accident, which required extensor tendon reconstruction.
NATURAL HISTORY

- Without treatment, complete extensor tendon disruptions will result in a persistent loss of active extension or incomplete extension of the wrist or digits (or loss of active abduction and extension of the thumb, depending on which tendon or tendons are involved).
- A late tendon imbalance resulting from pull of the flexor tendons against a disrupted or weakened extensor mechanism with or without fixed joint contracture may develop if reconstruction is not performed.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient most commonly has a history of penetrating or blunt trauma to the dorsal forearm or hand with resultant loss of active extension of the wrist, fingers, or thumb (FIG 3). Loss of soft tissue may be associated with the original injury.
- In cases of attritional rupture of the EPL tendon, the patient may have a recent or remote history of a distal radius fracture, usually only minimally displaced.
- Physical examination methods include the following:
  - MP extension. Incomplete MP extension indicates extensor tendon disruption in zones proximal to the MP. If the other fingers are not kept flexed, the patient may be able to fully extend the affected finger in the presence of a completely lacerated tendon.
  - EPL test. An EPL rupture manifests as a loss of extension of the thumb IP and MP joints.
  - Tenodesis test. A loss of extensor tendon continuity will result in loss of the tenodesis effect. Wrist flexion will have no effect on finger extension.
  - A complete evaluation of the elbow, forearm, wrist, or hand begins with a thorough inspection of all open wounds and an assessment of the extent of soft tissue compromise.
  - Local or regional anesthesia can assist with patient comfort during the examination.
  - A comprehensive neurovascular examination must be performed before using any anesthetic. Special attention is directed to the status of the radial nerve, specifically the PIN.
  - Compromise in PIN function may result from compression neuropathy, direct injury, or underlying elbow pathology.
  - If there is a suspicion of joint violation, then injection of sterile saline with or without methylene blue into the joint can verify whether the joint capsule has been disrupted.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- AP, lateral, and oblique plain radiographs of the affected area (elbow, forearm, wrist, or hand) are obtained to rule out the presence of a foreign body, underlying fracture, or bony deformity or pathology.
- In cases of late presentation of suspected extensor tendon rupture, MRI is occasionally useful to confirm the diagnosis and identify the location of the retracted tendon ends.

DIFFERENTIAL DIAGNOSIS

- Radial nerve or PIN palsy
- Flexor tendon injury
- Intrinsic tightness
- Tendon adhesions
- Tendon subluxation (MP joint level)
- Joint contracture, subluxation, or deformity
- Soft tissue contracture

NONOPERATIVE MANAGEMENT

- Conservative treatment of injuries proximal to the metacarpals usually is not possible because of tendon retraction and muscle contracture and will result in persistent loss of extension of the wrist or digits.4
- Chronic extensor mechanism disorders distal to the metacarpals without fixed deformity will respond to splinting and intensive therapy. Such conservative management may result in an acceptable functional outcome for select patients.

SURGICAL MANAGEMENT

- Most extensor tendon lacerations are amenable to direct primary repair if treated relatively early.
- Indications for reconstruction of extensor tendon injuries include loss of extension of the wrist, fingers, or thumb resulting in a functional deficit.
- When delay or loss of tendon substance precludes a direct repair, tendon grafting or transfer may restore function successfully.

Preoperative Planning

- The patient must be provided with a realistic assessment of the potential gains from surgery as well as details of the treatment plan.
- Any fixed joint contractures should be identified and treated with therapy and splinting before extensor tendon reconstruction to optimize outcomes.
- In cases of severe soft tissue loss, coverage must be obtained before proceeding with extensor system reconstruction.
  - This may include free or island muscle, fascial, or skin flaps in addition to full- or split-thickness skin grafts.

Positioning

- The patient is positioned supine with a hand table attached to the operative side.
- A tourniquet is usually used to operate in a bloodless field

Approach

- The approach depends on the tendon transfer or grafting technique required and is detailed in the Techniques section.
END AND SIDE WEAVE JUNCTURES

- Tendon transfer or graft junctures are often best secured using an end weave technique (TECH FIG 1).
- The Pulvertaft method is a common weave used.
  - A pointed tendon-grasping and -passing instrument is invaluable and allows one tendon to be brought through the substance of the other tendon with minimal trauma.
  - The tendon weave is performed at right angles. For example, the first entry is horizontal, the next vertical, and then the third horizontal. At least three weaves are needed.

**TECH FIG 1** • End weave technique. The smaller tendon is passed through and sutured.

EIP TO EPL TRANSFER

- The distal EIP tendon is identified through a 1-cm incision over the index finger MP joint. The EIP is ulnar to the EDC II.
- A second incision is made just distal to the extensor retinaculum at roughly the radiocarpal joint level, and the EIP tendon is identified in the radial aspect of the fourth extensor compartment.
  - The EIP is readily identified by its distal muscle belly.
  - The EIP tendon is separated from the EDC II and transected through the incision over the MP joint.
  - The tendon is then brought through to the proximal incision.
- A third incision is centered over the scaphotrapezial trapezoid joint and the distal stump of the disrupted EPL tendon is identified (TECH FIG 2A).

**TECH FIG 2** • Extensor indicis proprius (EIP) to extensor pollicis longus (EPL) transfer. **A.** After the EIP tendon is identified, it is brought through the proximal incision. The distal stump of the EPL tendon is identified as well. **B.** The EIP tendon is passed through and is woven into the EPL tendon. **C.** After proper tensioning, the thumb should extend as the wrist flexes.

- A subcutaneous tunnel is created to connect the incision at the wrist and the incision near the base of the thumb.
- The EIP tendon is passed through the tunnel and attached to the distal stump of EPL using an end weave technique (TECH FIG 2B).
- Tension should be set so that when the wrist is extended, the thumb IP joint flexes, allowing the tip of the thumb to touch the tip of the index finger. The thumb IP joint should fully extend when the wrist is flexed (TECH FIG 2C).
- The thumb is immobilized with the wrist extended about 20 degrees and the thumb IP joint at 0 degrees for 4 weeks.

END-TO-SIDE SUTURING FOR EDC DISRUPTIONS

- A longitudinal incision is made on the dorsum of the hand over the appropriate area.
- The disrupted tendon end is identified and isolated.
- An end-to-side repair is performed to the adjacent intact tendon.

- Tension must be set so that the fingers are in extension when the wrist is flexed and the MP joints are flexed 20 to 30 degrees when the wrist is extended about 20 degrees. The normal flexion cascade must be re-established.
**EIP TO EDC (FOURTH/FIFTH) TRANSFER**

- The EIP tendon is isolated and freed in a manner similar to that described for the EIP-to-EPL transfer.
- An incision is made dorsally on the hand, over the disrupted extensor tendons of the ring and small fingers.
- The EIP is mobilized and inserted into the distal stump of the disrupted tendon of the small finger.
  - If disrupted, the extensor digiti quinti (EDQ) is sewn side to side to the transfer.
- The distal stump of the ring finger is attached to the adjacent intact common extensor tendon of the long finger. If the EDC to the long finger is also ruptured, it is sewn to the intact EDC to the index while the EDC to the ring is sewn to the EIP transfer (TECH FIG 3).

**FLEXOR CARPI ULNARIS TO EDC TRANSFER**

- A longitudinal incision is made over the flexor carpi ulnaris (FCU) in the distal forearm.
- The FCU tendon is transected just proximal to the pisiform and is freed up proximally.
- A second oblique incision is made 5 cm below the medial epicondyle in the proximal forearm.
- The FCU fascial attachments are incised to free up the entire muscle belly.
- A third incision begins on the dorsal-ulnar mid-forearm and angles distally toward the tubercle of Lister to expose the disrupted EDC tendons.
- A tendon passer or Kelly clamp is passed subcutaneously around the ulnar border of the forearm to pull the FCU tendon into the dorsal wound.
- Muscle may be excised from the FCU to reduce bulk.
- The FCU tendon is woven through the EDC tendons at a 45-degree angle just proximal to the dorsal retinaculum.
- The FCU is secured under maximum tension, with the wrist and MP joints in neutral.

**FLEXOR CARPI RADIALIS TO EDC TRANSFER**

- A longitudinal incision is made over the flexor carpi radialis (FCR) in the distal forearm.
- The FCR tendon is identified and transected near its insertion.
- The tendon is freed up proximally to allow additional excursion.
- A second longitudinal incision is made on the dorsal forearm, extending from the mid-forearm to just distal to the dorsal retinaculum.
- The FCR is then passed subcutaneously around the radial border of forearm and delivered into the dorsal wound.
- The FCR tendon is then inserted into the EDC tendons and positioned superficial to the retinaculum.
- The transfer is secured with the FCR under maximum tension and wrist and MP joints in neutral (TECH FIG 4).
Pronator Teres to ECRB Transfer
- An incision is made over the volar-radial aspect of the mid-forearm.
- The pronator teres (PT) tendon is identified and followed to its insertion into the radius.
- A strip of perioesteum is kept intact when freeing up the insertion to ensure sufficient length of the transferred tendon.
- The PT muscle is freed up proximally to improve excursion.
- The PT muscle and tendon is then passed subcutaneously around the radial border of the forearm.
- The tendon is inserted into the ECRB just distal to the musculotendinous junction through a second incision if needed (TECH FIG 5).
- The transfer is secured with PT in maximum tension and the wrist in 45 degrees of extension.

Flexor Digitorum Superficialis Transfer for Multiple Extensor Disruption
- A transverse incision is made in the distal palm to expose the long and ring superficialis tendons.
- The flexor digitorum superficialis (FDS) tendons to III and IV in the distal palm are divided proximal to the chiasma.
- A longitudinal incision is made on the volar-radial mid-forearm and the interosseous membrane is exposed.
- The two tendons are then delivered into the proximal wound.
- Two openings are excised from the interosseous membrane, large enough to pass the muscle bellies through to minimize adhesions.

TECH FIG 4 • (continued) C–F. Patient demonstrating restored digital and hand extension.

TECH FIG 5 • FCR to EDC and pronator teres to extensor carpi radialis brevis tendon transfer.

TECH FIG 6 • A. Flexor digitorum superficialis (FDS) III and IV transferred to reconstruct segmental injuries of extensor digitorum communis (EDC) II, III, IV, and V. B. FDS III and IV to EDC II–V tendon transfers. The FDS is transferred through a rent created in the interosseous membrane.
In patients with loss of soft tissue over the dorsum of the hand and forearm, appropriate soft tissue coverage is obtained first. At the time of coverage, the proposed path of the tendon transfer or graft is preserved with the use of a silicone tendon rod. Once maturation of soft tissue has occurred, the appropriate tendon transfer or graft may be performed 2 to 3 months after silicone rod placement (TECH FIG 7).

**PEARLS AND PITFALLS**

**POSTOPERATIVE CARE**

- Initial splinting should immobilize the wrist in about 30 degrees of extension, the MP joints in about 15 degrees of flexion, and the IP joints in full extension.
- If transferred tendons originate proximal to the elbow, the elbow should be immobilized in 90 degrees of flexion with appropriate forearm rotation.
- The thumb IP and MP joints should be immobilized in full extension.
- After 4 weeks, active range of motion is started under the supervision of a certified hand therapist and with a protective splint. Active-assisted and passive range of motion follows 2 weeks later.

**OUTCOMES**

- Staged extensor tendon reconstruction using a silicone implant followed by tendon grafting for restoration of PIP joint extension was reported to have good results in six fingers with severe dorsal soft tissue injuries, improving hand function in all cases.¹

**COMPPLICATIONS**

- Extrinsic tightness
- Intrinsic tightness
- Rupture
- Donor deficits
- Joint stiffness

**REFERENCES**

DEFINITION
- Instability of the extensor digitorum tendons at the metacarpophalangeal (MCP) joint has been subdivided into two categories: subluxation and dislocation.
- Subluxation of the extensor digitorum tendons at the MCP joint is defined as lateral displacement of the tendon with its border reaching beyond the midline, but remaining in contact with the condyle during full MCP joint flexion.
- Dislocation describes the condition in which the extensor tendon is located in the groove between the metacarpal heads.\(^\text{12}\)
- Instability of the extensor digitorum tendons at the MCP joint usually occurs in patients with underlying inflammatory conditions (ie, rheumatoid arthritis).
- Traumatic injury to the sagittal bands, particularly the radial sagittal band, can cause instability of the extensor tendon. Although ulnar-sided injuries have been reported, the overwhelming majority of injuries occur to the radial sagittal band.
- Instability of the extensor tendon is relatively rare in non-rheumatoid patients.
- The sagittal bands are sometimes referred to as the “shroud” ligament because of the way they cover, or wrap, the MCP joint.
- Sagittal band injuries are classified as type I, II, or III depending on the degree of extensor tendon instability.\(^\text{12}\)
- Traumatic extensor tendon subluxation at the MCP joint level is classified as type II injury; dislocation is type III. These injuries have been given the eponym “boxer’s knuckle.”\(^\text{5}\)
- Not all injuries to the sagittal bands result in extensor tendon subluxation. Clinical examination will identify those patients in which extensor tendon instability has occurred.
- Factors influencing treatment include symptoms and time elapsed since injury.

ANATOMY
- The digital extensor mechanism at the level of the MCP joint consists of the extensor tendon, sagittal bands, and volar plate. The sagittal bands are part of a complex extensor retinacular system that includes the triangular ligament between the lateral bands, the transverse retinacular ligament, and the oblique retinacular ligament at the proximal interphalangeal (PIP) joint level (FIG 1A).
- The sagittal bands are dynamic structures that envelop the extensor tendons, centering them over the MCP joint during flexion, preventing bowstringing during hyperextension, and controlling tendon excursion. The sagittal bands insert onto the volar plate overlying the MCP joint (FIG 1B).\(^\text{13}\)
- The sagittal bands are the primary stabilizers of the extensor digitorum tendons at the MCP joints, and their integrity is essential for normal extensor tendon function.\(^\text{10,13,15,18}\)
When the MCP joint is maintained in neutral extension, the sagittal bands are oriented perpendicular to the tendon.
- The sagittal bands are anatomically and physiologically distinct from the deeper collateral ligaments.
- The radial sagittal band is often thinner and longer than its ulnar counterpart.
- The greatest tension on the sagittal bands occurs with wrist and MCP flexion and radioulnar deviation.
- The lumbrical muscles function to flex the MCP joint and extend the interphalangeal (IP) joint through the lateral bands. They originate on the flexor digitorum profundus (FDP) tendon and traverse on the radial aspect of the digit inserting into the extensor expansion.
- The intermetacarpal ligaments are stout ligaments that originate and insert on adjacent metacarpal necks. These ligaments pass dorsal to the lumbrical tendons and volar to the interosseous tendons.

PATHOGENESIS
- The mechanism of sagittal band injury commonly involves a direct blow to a flexed MCP joint.
- Injury may result indirectly from forced flexion or directly from shear forces across the sagittal band.
- Other described mechanisms include forceful deviation of the digit against resistance, usually with the MCP joint extended.
- In open injuries, the sagittal band is usually lacerated.
- Sometimes laceration of the junctura tendonum can also lead to extensor tendon subluxation.
- Extensor tendon subluxation typically occurs with at least 50% disruption of the proximal sagittal band. The extensor tendon no longer remains centralized over the MCP joint through flexion, but rather subluxates ulnarly.
- It has been suggested that frequency of injury among the digits is related to the cross-sectional diameter of the sagittal band, the extent of distal attachment, and the length of the sagittal band. The long finger is most commonly injured.
- It has been suggested that traumatic subluxation occurs when there is tearing of both the superficial and deep layers of the sagittal band enveloping the extensor tendon.
- When underlying inflammatory conditions are present, the sagittal bands become attenuated and atrophic, allowing for atraumatic subluxation of the extensor tendons into the troughs (usually ulnar) between metacarpal heads.

NATURAL HISTORY
- Symptoms from acute injuries typically resolve within 3 weeks with appropriate treatment. However, pain can persist for up to 9 months before fully dissipating.
- When sagittal band injuries associated with discomfort, swelling, and subluxation are neglected, patients will experience ongoing symptoms that may worsen over time. The extensor tendon may become fixed in the valley between the metacarpal heads, leading to loss of extension and deviation of the digit. These patients will require surgical treatment for resolution of their symptoms.

PATIENT HISTORY AND PHYSICAL FINDINGS
- This chapter deals with traumatic subluxation. Treatment protocols for inflammatory subluxation differ and are beyond the scope of this chapter.
- A critical aspect of treatment involves understanding the circumstances surrounding the injury. This information will help identify those at risk for infection in open injuries (eg, clean laceration, fight bite), or the possibility of underlying systemic disease contributing to closed injuries caused by low-energy trauma.
- Shortly after injury soft tissue swelling may obscure the alignment of the tendon over the MCP joint.
- Initially after traumatic injury to the sagittal bands with subsequent extensor tendon instability, symptoms and signs include the following:
  - Localized pain
  - Swelling over the involved MCP joint
  - Limited motion (FIG 2A)
  - Limited or deviated MCP joint extension, or both (FIG 2B)
  - Weak MCP extension
  - A potentially painful snapping of the tendon over the MCP joint with active flexion (FIG 2C)
  - Ulnar deviation deformity and difficulty adducting (or abducting in the case of the index) the affected finger early or late
  - Chronic cases of tendon instability often exhibit pain during MCP joint flexion, such as during grip, along with localized tenderness and swelling over the injured sagittal band.
- MCP extension can be actively maintained when the joint is passively placed into extension; however, difficulty is usually encountered when attempts are made to extend the MCP joint from flexion or when flexing the MCP joint from full extension.

![FIG 2](image)

**FIG 2**

- **A.** Lack of complete active digital extension at the metacarpophalangeal joint associated with a sagittal band disruption.
- **B.** Ulnar deviation of the long finger associated with a radial sagittal band disruption.
- **C.** Dislocation of the long finger extensor tendon into the ulnar trough of the fourth web space (arrow). (A,B: Courtesy of Brian Hartigan.)
Methods for examining extensor tendon instability over the MCP joint include the following:
- Assess sagittal bands throughout MP range of motion.
- Assess swelling, open injuries, and so forth. Determine location of pathology.
- Palpate over the MCP joints and in the groove between the metacarpal heads.
- Sagittal band injuries will exhibit pain with superficial palpation. In contrast, pain associated with collateral ligament injury is usually deeper, within the groove between the metacarpal heads.
- Perform tendon instability examination.
- Ask the patient to flex the MCP joint and wrist. This position places the maximum amount of ulnar force on the extensor tendon at the MCP joint. This will help to determine the amount of instability.
- Pain provocation test: With the distal and proximal IP joints extended and the MCP joint flexed, ask the patient to try to extend the MCP joint against resistance.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- A standard radiographic series, including posteroanterior, lateral, and oblique views of the MCP joints, is obtained.
- These views will exclude any mechanical or bony pathology limiting extension of or predisposing the sagittal band to dislocate.
- A Brewerton view (AP view with dorsal surface of the fingers touching the cassette and the MCP joints flexed 45 degrees) or stress views may be needed to rule out collateral ligament avulsion injury.
- Magnetic resonance imaging (MRI) has been used with success to identify patients with sagittal band injuries, especially when the physical examination is obscured by swelling and patient discomfort. MRI with the injured MCP joint flexed facilitates the diagnosis.
- Acute injuries demonstrate morphologic and signal intensity abnormalities within and around the sagittal bands on axial T1- and T2-weighted images, together with poor definition, focal discontinuity, and focal thickening.4
- Dynamic ultrasound has been reported as a useful modality for diagnosis of extensor tendon subluxation when swelling obscures the physical examination.9

**DIFFERENTIAL DIAGNOSIS**
- MCP joint collateral ligament injury
- Trigger finger
- Ulnar nerve palsy
- Congenital sagittal band deficiency
- Extensor digitorum communis tendon rupture
- Radial nerve injury
- Junctura tendinum disruption
- MCP joint arthritis

**NONOPERATIVE MANAGEMENT**
- In our experience, most symptomatic patients presenting within 3 weeks of injury with acute sagittal band disruptions and extensor tendon instability can be treated successfully nonoperatively with a splint.12
  - Success in the literature varies, however. Studies have shown that 44% to 100% of patients treated conservatively will be asymptomatic at an average of 13.5 months.2,3,6,12
  - Certainly, except in special circumstances such as the professional athlete, conservative therapy should initially be attempted.
  - Although several different protocols and splints have been described, most share one common objective: maintaining the MCP joint in neutral (full extension) for a period of weeks. In all situations, motion of the IP joint should be accommodated and encouraged.
  - A hand-based, custom orthoplast splint holding the involved digit in 0 to 20 degrees of MCP joint flexion (FIG 3) is worn for 4 to 6 weeks, depending on the patient’s progress at the 2- and 4-week follow-up visits.
  - After 6 weeks of MCP immobilization in extension, the splint is weaned except for sporting endeavors and other heavy activities, in which case the splint is used for another 2 weeks. Buddy taping can provide long-term support as may be indicated.
  - Active range-of-motion activities are initiated and slowly progressed to gentle passive flexion of the involved MCP joint.
  - Thereafter, unrestricted use of the hand is promoted. It is unusual to need formal hand therapy; however, when excessive joint stiffness is present and radiographs fail to document any bony pathology, a short course of therapy along with modality use can be helpful.
  - If the injury clearly is not responding to immobilization, surgery is recommended.

**SURGICAL MANAGEMENT**
- Operative indications
  - Patients with painful extensor tendon instability more than 3 weeks after the injury
  - Patients whose injury has failed to respond to nonsurgical management and have persistent, painful tendon instability beyond 6 weeks of conservative care
  - Professional athletes5 and other high-demand individuals

**FIG 3** Typical splint used for the conservative treatment of sagittal band disruption. The interphalangeal joints are free and no more than 30 degrees of metacarpophalangeal joint flexion is allowed.
When possible, direct repair of the sagittal band should be performed.
- Although we believe that this is usually not possible more than 8 weeks after injury, Hame and Melone\(^5\) reported on 11 direct repairs at an average of 3.3 months out from time of injury. No patient had prior splinting. All patients were asymptomatic with full recovery of range of motion and return to professional sports at an average of 5 months.
- Carroll et al\(^2\) reported on five patients who underwent reconstruction after failed conservative management. All patients regained full, asymptomatic range of motion.
- If tissue deficiency or scarring exists, reconstruction as opposed to primary repair will be required.

**Preoperative Planning**
- With open injuries, the surgeon should determine if the cause was related to a bite. In this situation, MCP joint contamination is likely and surgical irrigation and débridement as well as antibiotic treatment is warranted. When severe contamination is present, delayed sagittal band repair is indicated.
- Concomitant MCP joint capsular injury is possible. Once surgically exposed, methylene blue injection into the joint, out of the zone of injury, can help to reveal any rents in the MCP joint capsule. These defects should be débrided with subsequent irrigation of the joint. Afterward, no capsular repair is necessary.\(^5\)
- The surgeon should be prepared to perform either a repair or a reconstruction.
- Local anesthesia with sedation is preferred, but regional or general anesthesia is acceptable.

**Positioning**
- The patient is placed supine on the operating table with the affected hand outstretched onto a hand table.
- A tourniquet is applied to the arm and inflated to the appropriate pressure before starting the procedure.

**EXPOSURE**
- A curvilinear incision is placed dorsally over the ulnar aspect of the affected MCP joint.
  - This is used for primary sagittal band repair.
- A longitudinal incision is centered dorsally over the affected MCP joint.
  - This is used for reconstructive cases requiring greater exposure.
- Sensory branches of the radial or ulnar nerves, or both, are identified and protected.

**PRIMARY REPAIR**
- The sagittal band disruption is identified and the extensor tendon centralized (TECH FIG 1A, B).
- Excess tissue is excised from the area between the torn sagittal band and the common extensor tendon.
- The extensor tendon is exposed, the tear identified, and scar tissue débrided.
- The MCP capsule, which is deep to the extensor tendon, is usually left undisturbed; however, when MCP joint pathology needs to be addressed, the capsule may be incised.
- The sagittal fibers are then repaired using 4-0 or 5-0 non-absorbable suture (Ethibond). The knots are buried where possible.
- The repair is performed with the joint in 60 to 70 degrees of flexion to avoid tension on the repair and stiffness of the joint.
- The joint is flexed and extended to ensure midline stability (TECH FIG 1C–E).
- The wound is closed with interrupted 4-0 nylon sutures.

**TECH FIG 1**
- A. Traumatic extensor tendon dislocation (ulnar) over the metacarpophalangeal (MCP) joint (arrowhead) with the MCP joint extended. B. Extensor tendon subluxation over the MCP joint with the joint flexed. (continued)
Release of the ulnar sagittal band may be necessary to mobilize the scarred tendon dorsally and radially (TECH FIG 2A,B).

A distally based radial or ulnar slip of extensor tendon (about one third) is fashioned and routed deep to the intact extensor tendon (TECH FIG 2C).

In a distal-to-proximal direction, the tendon graft is then looped around the radial collateral ligament (if subluxed ulnarly) (TECH FIG 2D).

Once proper tension is determined, the slip is then sutured back to the main tendon with interrupted, nonabsorbable suture or woven through the tendon in a Pulvertaft fashion (TECH FIG 2E,F).

As with all reconstruction techniques, tension is determined by taking the joint through a full range of motion and documenting stability dorsally.

The wound is closed with interrupted 4-0 nylon sutures.
TECH FIG 2 • (continued) E. The distally based slip of extensor tendon has been secured to the extensor tendon proximal to the MCP joint (black arrowhead). The remaining ulnar sagittal band was repaired to prevent radial subluxation of the extensor tendon (red arrowhead). F. Reconstruction of the sagittal band using a distally based radial slip of extensor tendon wrapped around the radial collateral ligament (RCL) and reattached to the extensor tendon (with a weave).

DYNAMIC LUMBRICAL MUSCLE TRANSFER (SEGALMAN\textsuperscript{16})

- The lumbrical muscle is identified on the radial side of the joint and mobilized (TECH FIG 3A,B).
- Begin proximally by separating the lumbrical muscle from the more dorsal interossei.
- Once the lumbrical muscle is separated, continue distally to identify its tendinous insertion.
- The lumbrical tendon is harvested just proximal to its insertion into the lateral band (TECH FIG 3C).
- With the extensor tendon reduced, an isometric point in the extensor tendon must be identified. This is achieved by gently ranging the finger or asking the patient to flex. Once it is identified, a small longitudinal slit is made and the lumbrical tendon is passed through from volar to dorsal (TECH FIG 3D).
- Tension is set appropriately while gently ranging the finger to confirm the absence of subluxation. The tendon is sutured back to itself using interrupted, nonabsorbable suture.
- The wound is closed with interrupted 4-0 nylon sutures.

TECH FIG 3 • Technique using the lumbrical muscle for dynamic extensor tendon stabilization. A. Ulnar dislocation of the extensor tendon over the long finger metacarpophalangeal (MCP) joint (arrow). B. Surgical exposure identifying the extensor dislocation (black arrow) with a large chronic defect in the radial sagittal band (white arrow). (continued)
**SAGITTAL BAND RECONSTRUCTION TO THE DEEP TRANSVERSE INTERMETACARPAL LIGAMENT (WATSON)**

- A 4-cm, distally based slip of extensor tendon consisting of no more than one-third the tendon width is harvested starting proximal to the MCP joint on the affected side (TECH FIG 4A).
- This segment of tendon is then passed through a small slit in the remaining tendon at the level of the deep transverse metacarpal ligament to prevent further propagation of the tendon split.
- The segment is then passed around or through the deep transverse intermetacarpal ligament using a curved clamp (TECH FIG 4B).
- The free end of the tendon graft is then woven through and sutured to the remaining extensor tendon once it has been centralized and properly tensioned using non-absorbable suture (TECH FIG 4C).
- Wounds are closed with interrupted 4-0 nylon sutures.

**CENTRALIZATION USING JUNCTURA TENDINUM**

- A longitudinal incision is centered dorsally over the affected MCP joint.
- The extensor tendon is identified and held in a centralized position.
- The MCP joint is flexed to reveal the more proximal, ulnar-sided junctura tendinum to the adjacent tendon.
- The junctura tendinum is released from its ulnar-sided insertion into the adjacent tendon.
- It is then brought over to the radial side of the affected finger, still in continuity with the tendon, and sutured to the palmar portion of the remaining sagittal band after correct tension has been set to centralize the tendon.
- Wounds are closed with interrupted 4-0 nylon sutures.
PEARLS AND PITFALLS

| Range of motion | - Preoperatively, ensure that there is good passive range of motion of the MCP joint.  
| - Avoid overtensioning and malpositioning of the repair or reconstruction. A reconstruction too proximal will limit extension. A reconstruction too distal will lead to recurrent subluxation. |
| Anesthesia | - Local anesthesia will enable the patient to actively flex the MCP joint during the procedure, allowing the surgeon to intraoperatively assess centralization after the repair or reconstruction.  
| MCP joint capsule | - Identify and débride rents in the MCP joint capsule. Repair is unnecessary. Also be aware of any injury to the junctura tendinum; this should be repaired.  
| MCP flexion | - Range the MCP joint once the tendon is exposed, both before and after repair or reconstruction. The repair or reconstruction should be performed with the MCP joint in 60 to 70 degrees of flexion.  
| Additional releases | - Sometimes the sagittal band, as well as the junctura tendinum, on the uninjured side will require release to centralize the tendon. |

POSTOPERATIVE CARE

- Wounds are sterilely dressed immediately after the procedure and a splint is applied.
  - A volar and dorsal splint is used with the wrist slightly extended, the MCP joints at 0 to 30 degrees flexion, and the IP joints extended.
  - On postoperative day 5, the patient is seen in the office. Sutures are removed and a short-arm cast is applied with the wrist slightly extended, the MCP joints at 0 to 30 degrees of extension, and the IP joints free.
  - Sometimes, in the compliant elderly patient, we favor a hand-based splint fabricated to include the MCP joints in 30 degrees of flexion and the IP joints free.
  - Several postoperative protocols have been described for nondynamic reconstructions.
    - Inoue and Yukihsia placed the involved finger in a plaster cast for 3 weeks with the MCP joint in neutral or slightly flexed, allowing active IP joint motion.
    - Carroll et al splinted the MCP joint neutral for 6 weeks. At 2 weeks after surgery they began PIP joint range of motion, and at 6 weeks active range of motion at the MCP was initiated.
    - Watson et al used a splint and Kirschner wire to immobilize the MCP joint at 15 to 20 degrees of flexion for 3 weeks.
    - Hame and Melone used cast immobilization of the MCP joint in 60 to 70 degrees of flexion for 6 weeks, with active flexion, but not extension, allowed.
  - For dynamic transfers, the patient is immobilized for 4 weeks in a short-arm cast with the wrist in neutral, MCP joints in extension, and the PIP joints free. Active motion is begun 4 weeks after surgery and strengthening at 6 weeks. Therapy is then continued for 6 to 8 weeks.

OUTCOMES

- Rayan et al treated three type II injuries nonoperatively with 3 weeks of splinting the MCP joint at 0 degrees of extension, followed by 2 to 3 weeks of protected range of motion out of the splint three times a day, with a final 4 weeks of buddy splinting. They reported full range of MCP joint motion and no tenderness or pain with resisted digital abduction in all three patients. However, one patient did experience residual painless subluxation.
  - Carroll et al treated nine subluxed extensor tendons. Four were treated nonoperatively with 6 weeks of splinting the MCP joint in 0 degrees of extension, followed by range-of-motion therapy. Five were treated operatively using a slip of extensor tendon looped around the collateral ligament. After splinting and therapy, all patients were pain-free with full extension and active flexion to 90 degrees or more. There were no recurrences of symptoms in either group and no complications in the surgical group.
  - Watson et al described 16 patients treated operatively with a slip of extensor tendon looped through the deep transverse metacarpal ligament. They reported an average MCP joint flexion of 90 degrees postoperatively, with no subluxation of the tendon. All patients were pain-free. There were no complications and no need for further surgery.
  - Hame and Melone reported on eight professional athletes who underwent immediate repair of sagittal band injuries with subluxation of the extensor tendon. There were 11 injured fingers in total. Seven of the 11 had capsular injuries; they were all debrided but not repaired. Each athlete demonstrated full range of motion postoperatively and all returned to professional sport at 5 months on average. No additional intervention was necessary and there were no complications.

COMPLICATIONS

- Complications are rare. Most series in the literature do not report any complications.
  - With nonoperative therapy, possible complications include joint stiffness, skin irritation from splinting, and failure of treatment.
  - With operative therapy, possible complications include infection, joint stiffness, injury to neurovascular structures, and failure of treatment with recurrent subluxation or dislocation either in a radial or ulnar direction.

REFERENCES

DEFINITION
- Synovium lines the joint spaces and tendon sheaths.
- It secretes lubricant (synovial fluid) needed for tendon gliding and reduces friction in synovial joint motion.
- Tendons may be both extra- and intrasynovial.
- Flexor tendons in the carpal tunnel have the added feature of subsynovial connective tissue, which can become inflamed.
- Tenosynovitis is inflammation of the tendon sheath in extrasynovial tendons, and inflammation of the synovial lining in intrasynovial tendons.³

ANATOMY
- The extensor tendons lie under the dorsal retinaculum in six separate compartments. These may be divided into the extensor tendon zones. The portion of the extensor tendon that lies under the dorsal retinaculum is lined with a synovial sheath (FIG 1A).
- The first extensor tendons originate as outcropper muscles from the distal third of the forearm and cross over the second extensor compartment tendons—the extensor carpi radialis longus (ECRL) and the extensor carpi radialis brevis—distally at the level of the wrist about 4 cm proximal to the radial styloid.
- The extensor pollicis longus (EPL) in the third extensor compartment makes an acute angle at the Lister’s tubercle at the level of the wrist.
- The fourth extensor compartment tendons—the extensor digitorum communis and the extensor indicis proprius—lie under a broad retinaculum. The deep branch of the posterior interosseous nerve courses deep to the fourth extensor compartment.
- The extensor digitorum quinti in the fifth extensor compartment often is the only tendon to motor the small finger metacarpophalangeal (MCP) joint in the act of extension.
- The extensor carpi ulnaris (ECU) tendon in the sixth compartment lies in a fibro-osseous tunnel and is intimately held in the ulnar groove by a subsheath that is critical for distal radioulnar joint stability.
- The wrist flexor tendons—the flexor carpi radialis (FCR), the palmaris longus, and the flexor carpi ulnaris—are extrasynovial tendons.
- The FCR passes through a tight fibro-osseous tunnel in the trapezium before inserting on the base of the second metacarpal (FIG 1B,C).
- The digital flexor tendons lie under the transverse carpal ligament in the carpal tunnel. Unlike digital extensor tendons, flexor tendons are almost entirely intrasynovial.
- The flexor tendons in the digits lie in a fibro-osseous canal formed by the annular and cruciate ligaments.²

PATHOGENESIS
- Rheumatoid arthritis is a disease of synovial tissue that can lead to inflammatory tenosynovitis.
- Flexor and extensor tenosynovitis is most commonly a sequela of rheumatoid arthritis.
- Rheumatoid arthritis causes formation of hypertrophic synovium in the joint spaces, thereby destabilizing joints. The hypertrophic synovium invades the tendon sheaths and synovial lining of all tendons.³

NATURAL HISTORY
- Inflammatory tenosynovitis usually is painless and can be the first sign of rheumatoid arthritis.
- The dorsal and volar wrist, as well as the volar digits, are most commonly affected.
The synovial tissue proliferates in the tendon sheath and eventually may invade the tendon. The end result is weakening and rupture of the tendon.\(^3\)

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Tenosynovitis of the first extensor compartment reveals thickening of the extensor pollicis brevis and abductor pollicis longus tendon sheaths at the radial styloid.
  - This thickening can produce a positive Finkelstein’s test: ulnar wrist abduction of a hand in a fist position, causing pain along the first extensor compartment.
  - Second compartment extensor tenosynovitis presents with painless swelling of the dorsum of the wrist 4 cm proximal to the radial styloid. There is focal tenderness to palpation with swelling and positive Tinel sign of the sensory branch of the radial nerve.
  - Third extensor compartment tenosynovitis usually presents with rupture of the EPL tendon.
    - This results in inability to raise the thumb when the hand is placed flat on a table.
  - Fourth extensor compartment tenosynovitis presents with focal swelling in extensor zone 7 along with multiple tendon ruptures (FIG 2).
  - Fifth extensor compartment tenosynovitis usually is accompanied by dorsal distal ulna instability and tendon rupture.
  - Sixth extensor compartment tenosynovitis is manifested as ECU instability in addition to significant intrasynovial inflammation at the level of the ulnar styloid.
  - Pain at the wrist indicates that the radiocarpal or radioulnar joint is affected.
  - Flexor tenosynovitis at the wrist can cause median nerve compression in the carpal tunnel, as well as decreased active and passive range of motion of the fingers.
  - Flexor tenosynovitis of the digits can cause triggering.\(^2\)
  - The flexor tendon that most commonly ruptures due to rheumatoid arthritis is the flexor pollicis longus. This is termed the Mannerfelt lesion and results in loss of thumb interphalangeal joint flexion.
  - The following examinations, all of which may detect weakness or rupture, are graded on a scale of 0 to 5:
    - First dorsal compartment (abductor pollicis longus and extensor pollicis brevis): abduct the thumb radially.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- MRI may be useful to evaluate low-grade tenosynovitis and mechanical dysfunction of the fibro-osseous digital pulley system.
- In general, flexor or extensor tenosynovitis is a clinical diagnosis made on physical findings.

**DIFFERENTIAL DIAGNOSIS**

- Extensor tendon weakness
- Rupture of sagittal bands
- Posterior interosseous nerve palsy
- Intrinsic muscle tightness or contracture
- Extensor tendon rupture
- Flexor tendon weakness
- Flexor tendon rupture
- Nerve palsy (median nerve, anterior interosseus nerve, ulnar nerve)

**NONOPERATIVE MANAGEMENT**

- Medical control of rheumatoid arthritis
- Splinting
- Cortisone injections are only very rarely indicated due to the risk of tendon rupture.
SURGICAL MANAGEMENT
- Tenosynovectomy is indicated if no improvement is observed after 4 to 6 months of adequate medical treatment or if tendon ruptures are detected.⁵
- Flexor tenosynovectomy is relatively indicated if active digit motion becomes worse than passive motion.³

Preoperative Planning
- Consider withholding rheumatoid medications (e.g., methotrexate, Etanercept, Imuran) 1 week before and 1 week after surgery.³

Positioning
- The patient is positioned supine with an armboard.

Approach
- For an extensor tenosynovectomy, the wrist dorsal midline approach is used (FIG 3A).
- For a flexor tenosynovectomy, the wrist volar approach to the carpal tunnel is chosen (FIG 3B).
- A digital tenosynovectomy is done using the volar zigzag approach to the digits (FIG 3C).

EXTENSOR TENOSYNOVECTOMY
- A straight longitudinal incision is made.
- Full-thickness skin flaps are created, exposing the extensor retinaculum (TECH FIG 1A).
- A straight longitudinal incision is made of the extensor retinaculum over the third compartment.
- Transverse incisions are made over the proximal and distal borders of the retinaculum, creating a radially based flap.
- Divide the vertical septum, opening each extensor compartment.
- Remove hypertrophic synovium from each tendon sheath with a rongeur or by sharp dissection (TECH FIG 1B).
- Frayed tendons are repaired with fine interrupted sutures.
- Tendons at risk for rupture are sutured to adjacent tendons.
- If synovitis of the wrist is encountered, wrist synovectomy is performed, and, if possible, the capsule is closed.
- The distal ulna is resected if it is prominent dorsally or if significant distal radioulnar joint arthrosis is noted.
- The retinaculum is passed deep to the extensor tendons and sutured (TECH FIG 1C,D).
  - Suturing a portion of the retinaculum over the extensor tendons prevents bowstringing.²
FLEXOR TENOSYNOVECTOMY

- Use a standard carpal tunnel approach with a mid-palm incision parallel to the thenar crease in line with the long finger.
- Extend the incision proximally 4 cm in a zigzag fashion when crossing the wrist crease.
- Protect the palmar cutaneous branch of the median nerve at the wrist flexion crease.
- Divide the volar antebrachial fascia and protect the median nerve in the forearm.
- Divide the palmar fascia and transverse carpal ligament longitudinally.
- Excise hypertrophic synovium surrounding the flexor tendons (TECH FIG 2).
  - A complete synovectomy is not required when the excess synovium involves more than half of the tendon diameter. Synovectomy in this case would lead to loss in function.

DIGITAL FLEXOR TENOSYNOVECTOMY

- Use a volar zigzag incision to explore the flexor tendons in the digit.
- Extend the incision proximally and distally for more exposure.
- Excise all hypertrophic synovium (TECH FIG 3).
- Carefully preserve the annular second and fourth pulleys to prevent bowstringing.
- Excise nodules in the tendon and close defects with fine suture.
- Check tendon excursion for smooth gliding.
- Passive flexion of the finger should equal the flexion obtained when pulling on the tendon (simulating active flexion).
  - If passive and active flexion are not equal, additional synovectomy is required.²

Inspect the floor of the carpal tunnel. Any bony spicules (commonly originating from the scaphoid) are removed with a rongeur.

Check flexor tendons for decreased excursion, indicating digit tenosynovitis.²
PEARLS AND PITFALLS

### Indications
- Failed adequate medical management for 4–6 months

### Extensor tenosynovectomy
- Débride radiocarpal synovitis if present.
- Resect the distal ulna if prominent or dislocated.

### Flexor tenosynovectomy
- Débride bony spicules on the carpal tunnel floor (ie, scaphoid).

### Digital flexor tenosynovectomy
- Preserve annular pulleys to prevent bowstringing.
- Passive flexion of the finger should be the same as the flexion observed when the surgeon pulls on the tendon.

POSTOPERATIVE CARE
- Splint the wrist in neutral position.
- Early (within 48 hours) active and passive digit range of motion exercise is key to maintaining motion.¹

OUTCOMES
- Long-term studies show less than 10% tendon rupture and recurrent tenosynovitis at 5 years.

COMPLICATIONS
- Wound dehiscence
- Tendon adhesions
- Tendon rupture¹

REFERENCES
Rheumatoid arthritis is a progressive disease that, if uncontrolled, leads to joint destruction, secondary to progressive synovitis, ligament instability, joint dislocation or subluxation, and attrition of adjacent tendons either by bony erosion or direct tenosynovial infiltration. When tendon rupture occurs on the dorsum of the hand or wrist, patients cannot extend their fingers and have difficulty grasping objects. The most common tendon ruptures on the dorsum of the hand begin on the ulnar side and usually are a result of subluxation of the distal radial ulnar joint (DRUJ), the so-called Vaughan-Jackson or caput ulnae syndrome.

On the volar side of the wrist, the most common tendons to rupture are the flexor pollicis longus and the adjacent flexor digitorum profundus (FDP) tendon to the index finger or possibly the long finger. This is referred to as Mannerfelt syndrome.

DEFINITION

Rheumatoid arthritis is a progressive disease that, if uncontrolled, leads to joint destruction, secondary to progressive synovitis, ligament instability, joint dislocation or subluxation, and attrition of adjacent tendons either by bony erosion or direct tenosynovial infiltration.

When tendon rupture occurs on the dorsum of the hand or wrist, patients cannot extend their fingers and have difficulty grasping objects.

The most common tendon ruptures on the dorsum of the hand begin on the ulnar side and usually are a result of subluxation of the distal radial ulnar joint (DRUJ), the so-called Vaughan-Jackson or caput ulnae syndrome.

On the volar side of the wrist, the flexor pollicis longus may become involved in the pathology of rheumatoid arthritis.

PATHOGENESIS

Tendon rupture on the dorsum of the wrist is usually the result of instability in the DRUJ, leading to secondary subluxation and bony erosion through the capsule of the joint and then the tendon.

The tendon initially affected is the EDQ. As the carpus supinates and subluxates volarly, causing the distal ulna to be more dorsal, tendons typically rupture sequentially in an ulnar to radial direction.

The tendons may also be compromised by direct infiltration from the tenosynovium.

While the ulnar tendons are involved most commonly, it is possible for all of the tendons crossing the dorsum of the wrist to rupture, making reconstruction more difficult.

On the volar side of the wrist, the flexor pollicis longus may become compromised through erosion by osteophytes and rough bony surfaces at the level of the trapeziometacarpal joint of the thumb or the scaphotrapezial articulation. The adjacent profundus tendon to the index and occasionally the long finger can rupture as well.

While the ulnar tendons are involved most commonly, it is possible for all of the tendons crossing the dorsum of the wrist to rupture, making reconstruction more difficult.

Tendons of the flexor surface of the wrist and forearm are also subject to rupture via direct tenosynovial infiltration, but this is less common.

ANATOMY

The extensor tendons of the hand and forearm pass beneath the extensor retinaculum at the wrist. The retinaculum is divided into six separate compartments lined by tenosynovium, which can become involved in the pathology of rheumatoid arthritis.

The first compartment contains the tendons of the abductor pollicis longus and the extensor pollicis brevis. The former tendon often contains multiple slips, which can contribute to limited space in its respective compartment and secondary De Quervain tenosynovitis.

The second compartment consists of the extensor carpi radialis longus (ECRL) and brevis (ECRB), the former tendon inserting at the base of the index metacarpal and the latter at the base of the long finger.

The third compartment contains only the tendon of the extensor pollicis longus (EPL), which passes around the tubercle of Lister at a fairly sharp angle. While frequently involved in tendon ruptures in rheumatoid arthritis, the EPL may also present as an isolated tendon rupture after nondisplaced fractures of the distal radius.

The fourth compartment contains the extensor indicis proprius (EIP) and the extensor digitorum communis (EDC), sending tendons from the common extensor muscle in the forearm to each of the fingers. The EIP is a separate muscle tendon unit located within the fourth compartment. It can be differentiated by its distal muscle belly.

The fifth extensor compartment contains the extensor digiti quinti (EDQ), often consisting of two slips and passing almost directly over the DRUJ.

The sixth compartment contains only the extensor carpi ulnaris.

On the palmar side of the wrist, the flexor pollicis longus is located most radially and passes over the radiocarpal joint adjacent to the trapeziometacarpal joint of the thumb. The flexor pollicis, along with the median nerve and the profundus and sublimis tendons to each digit, passes beneath the deep transverse carpal ligament and represents the contents of the carpal canal.

Tenosynovial proliferation can exist within the carpal tunnel, arising from the undersurface of the ligament but more commonly proliferating along the tendons themselves.

The worst-case scenario is secondary rupture of all of the wrist extensors, with subluxation of the extensor carpi ulnaris volar to the axis of wrist motion such that it becomes more of a wrist flexor and ulnar deviator than a wrist extensor. The radial wrist extensors may also rupture; however, in part as a result of the more robust nature of the tendons themselves, they tend to remain intact even with progressive disease.

NATURAL HISTORY

Before the advent of treatment for rheumatoid arthritis, the natural history was one of relentless progression. The disease would occasionally “burn itself out,” however, with the radiocarpal joint subluxing in a volar and radial direction, leading to instability and loss of function.

Also, before the development and routine use of antitumor necrosis factor drugs, patients were occasionally refractory to nonsteroidal medication, corticosteroids, and stronger anti-inflammatory drugs such as methotrexate. When these drug combinations failed, proliferative tenosynovitis occasionally occurred on the dorsum of the wrist, leading to direct tendon rupture as a result of tenosynovial ingrowth into the tendon and collagen destruction and rupture (FIG 1).

The worst-case scenario is secondary rupture of all of the finger extensors, with subluxation of the extensor carpi ulnaris volar to the axis of wrist motion such that it becomes more of a wrist flexor and ulnar deviator than a wrist extensor. The radial wrist extensors may also rupture; however, in part as a result of the more robust nature of the tendons themselves, they tend to remain intact even with progressive disease.
The French Impressionist painter Pierre Auguste Renoir was said to have had such severe rheumatoid arthritis that in his later years he would tape a brush to his hand to paint.

PATIENT HISTORY AND PHYSICAL FINDINGS

Patients often note a spontaneous loss of finger motion, but there may be minimal swelling and discomfort. Patients occasionally report a snap or twinge of discomfort as the tendon ruptures.

With an extensor tendon rupture, patients cannot actively extend the metacarpophalangeal (MCP) joints of the involved digit.

In the case of isolated rupture of the extensor digiti quinti, an intact EDC to the small finger may make it difficult to confirm the diagnosis.

The proximal and distal interphalangeal joints of the finger may be extended through the intrinsics even when the extensors are ruptured.

Wrist flexion should result in MCP joint extension through tenodesis if the extensor tendons are intact. When the finger extensors are ruptured, this tenodesis effect is absent (FIG 2A,B).

On the volar side of the wrist, the examiner should check closely for the possibility of associated tenosynovial proliferation proximal and deep to the transverse carpal ligament.

Active digital motion may cause palpable crepitance at this level.

Such proliferation may result in coexisting carpal tunnel syndrome (CTS). The examiner should question the patient regarding symptoms of CTS and should assess for signs of CTS.

The patient should also be examined carefully for active flexion at the distal interphalangeal joints of the index and long fingers as well as the interphalangeal joint of the thumb.

Absence of flexion should alert the surgeon to the possibility of rupture of the flexor pollicis longus and the FDP to the index and occasionally the long finger.

These tendons are particularly vulnerable when subluxation and spur formation are present at the trapeziometacarpal or scaphotrapezial joints as well as the volar radiocarpal joint.

Tendon rupture at this level is referred to as Mannerfelt syndrome (FIG 2C) and needs to be differentiated from an anterior interosseous nerve palsy.

Direct pressure on the flexor pollicis longus muscle in the forearm should lead to passive flexion in the interphalangeal joint of the thumb if the tendon is intact.

The tenodesis test also is effective for the flexor pollicis longus and profundus and sublimis tendons to the fingers; however, in patients with progressive rheumatoid arthritis, the radiocarpal joint and the interphalangeal joints may become arthritic, making passive motion of the wrist and fingers somewhat more difficult and therefore the test more unreliable.

FIG 1 • Exposure of the extensor tendons of the wrist shows proliferative tenosynovitis originating from the tenosynovial lining of the extensor retinaculum. If left unchecked, such proliferative tenosynovitis can contribute to extensor tendon rupture at the level of the wrist.

FIG 2 • A. Passive wrist extension results in passive finger flexion with intact finger flexors. B. Passive wrist flexion should result in passive finger extension when the finger extensor tendons are intact. In this situation, however, those tendons are not intact and passive wrist flexion results in the long, ring, and small extensor fingers remaining in a flexed position. C. In a patient with Mannerfelt syndrome, attempted active flexion of the thumb and fingers results in absent flexion of the interphalangeal joint of the thumb and in this situation the distal interphalangeal joint of the index finger. Clinically this is similar to anterior interosseous nerve syndrome and must be distinguished clinically and often by electromyography.
IMAGING AND OTHER DIAGNOSTIC STUDIES

- AP and lateral radiographs of the hand and wrist should be obtained to look for subtle changes of the DRUJ, such as subluxation or a small osteophyte (FIG 3), which may be consistent with the physical findings of tendon rupture (FIG 4).
- Similar attention should be paid to the volar surface of the radiocarpal joint and the trapeziometacarpal joint of the thumb as well as the scaphotrapezial and trapezoidal joints.
- Radiographs may reveal arthrosis and deformity in the digits themselves responsible for motion loss.
- Radiographs of the cervical spine may reveal subluxation, possibly causing nerve compression and secondary digital motion loss or weakness.
- CT and MRI are not routinely needed.
- Electromyography and nerve conduction studies are crucial in the evaluation of the patient with potential tendon ruptures, particularly if tenodesis testing is normal in the face of a loss of active finger extension or flexion.
- Compression of both the anterior interosseous and posterior interosseous nerves can occur in rheumatoid arthritis, usually secondary to ganglion cyst formation at the level of the elbow joint.

DIFFERENTIAL DIAGNOSIS

- In the case of tendon ruptures on the dorsum of the hand and wrist, the differential diagnosis is primarily with that of posterior interosseous nerve compression or posterior interosseous nerve syndrome.
- Compression of the posterior interosseous branch of the radial nerve, or the radial nerve itself more proximally, needs to be considered as the cause of the patient’s inability to extend the fingers. Diagnosis can be suspected by history and clinical examination. Electrophysiologic testing may also prove helpful.
- Cervical disc disease or rheumatoid arthritis of the cervical spine with subluxation or instability may also be the cause for weakness of the finger or wrist extensors, and the cervical spine should also be imaged.
- With respect to Mannerfelt syndrome, absence of flexion at the interphalangeal joint of the thumb and the distal interphalangeal joints in the index and long fingers should be differentiated from the anterior interosseous nerve syndrome, which when present in rheumatoid arthritis is usually due to a large ganglion originating on the volar surface of the elbow.

NONOPERATIVE MANAGEMENT

- Nonoperative management probably is more feasible with respect to Mannerfelt syndrome than with the Vaughn-Jackson or caput ulnae syndrome. While the functional deficit is generally greater with loss of finger extensors than loss of active flexion of the interphalangeal joint of the thumb and distal interphalangeal joints of the index and long fingers, some patients may still function remarkably well.
- Supportive measures in patients who for one reason or another are not deemed suitable surgical candidates may be provided by a certified hand therapist or occupational therapist able to assist the patient with his or her activities of daily living.
- With median nerve entrapment and compression from the proliferative tenosynovitis at the level of the radiocarpal joint, disability becomes more progressive and nonsurgical treatment more difficult. There may be a role for corticosteroid injection at the level of the radiocarpal joint, and certainly referral to a rheumatologist is crucial for the control and management of the disease before any surgical intervention.
- In the case of wrist or finger extensor tendon rupture, non-surgical treatment may be beneficial in terms of resting the radiocarpal joint and interphalangeal joints of the fingers to prevent further tendon rupture by attrition. Splinting the wrist or hand may prove beneficial, particularly if motion in the radiocarpal joint or fingers is painful.
SURGICAL MANAGEMENT

Extensor Tendon Rupture

A variety of tendon transfers are available for reconstruction of single and multiple extensor tendon ruptures.

It is important for the surgeon to locate the site of tendon rupture, and identify as well as treat the cause.

Usually, rupture is secondary to the distal ulna subluxing dorsally through the attenuated fibers of the DRUJ. When subluxation occurs at this level, it erodes through the floor of the fourth and fifth extensor compartments.

Tendon reconstruction is therefore not complete unless it involves removal of the dorsal osteophyte by a modified Darrach procedure and coverage of the distal ulna with a flap of extensor retinaculum.

When the distal ulna is unstable, the pronator quadratus may be brought dorsal to stabilize the bone.

Small finger extension loss

Single tendon rupture of the EDQ may go unnoticed, particularly if there is a strong EDC to the small finger. Often, however, this common extensor to the small finger is hypoplastic or absent and all that is present is a junctura tendinosa from the small finger to the adjacent ring finger. Isolated loss of function in the EDQ is manifest by weakness or lack of extension of the small finger.

The distal stump of the ruptured tendon is sewn end to side to the intact ring finger EDC tendon. The risk of this transfer, however, is excessive abduction of the small finger when the distal tendon is short (FIG 5A).

Alternatively, an EIP transfer may be performed (FIG 5B, C).

Ring and small finger extension loss (FIG 4)

In addition to the EDC tendons to the ring and small fingers, the EDQ usually will have ruptured.

The EIP is transferred to the EDQ.

The distal ring finger EDC tendon is transferred end to side to the adjacent intact long finger EDC tendon (FIG 6).

Long and ring finger extension loss (FIG 7A)

Although two fingers are seemingly involved, the EDC tendon to the small finger is usually ruptured as well. The EDQ remains intact.

In cases of double rupture in the ring and small fingers, transfer of the extensor indicis proprius to the distal extensor digiti quinti, with end-to-side transfer of the distal extensor digitorum communis of the ring finger to the adjacent extensor digitorum communis to the long finger, is a standard transfer.
If the index finger EDC tendon is intact, EIP transfer to the long and ring finger EDC tendons is performed (FIG 7B).

If the EDC tendon to the index finger has ruptured, end-to-side transfer of the distal tendon of the long finger EDC to the adjacent intact EIP and transfer of the distal tendon of the ring finger EDC to the adjacent intact EDQ may be considered (FIG 7C).

Long, ring, and small finger extension loss

- If the EIP and EDC tendons to the index finger are intact, the EIP can be transferred to the distal stumps of the ring and small finger EDC tendons using end-to-end or end-to-side techniques, depending on the length of the distal stumps.

- The EDC to the long finger is transferred end to side to the adjacent intact index EDC tendon (FIG 8).

- If only the EIP is intact and all remaining tendons on the dorsum of the wrist have ruptured, transfer of the flexor digitorum sublimis (FDS) of the ring finger around the radial or ulnar border of the forearm is the next logical choice.

- In patients with partial or complete wrist fusion, or in patients with limited wrist motion, transfer of the ECRL may be considered. Although not “in phase” with the finger extension, the line of pull matches reasonably well.

- Index, long, ring, and small finger extension loss

- The two most common transfers are the FDS around the radial and ulnar sides of the forearm or through the interosseous membrane (FIG 9A,B).
Chapter 61  TENDON TRANSFERS USED FOR TREATMENT OF RHEUMATOID DISORDERS 2613

Transfer of one of the radial wrist extensors is a suitable alternative (FIG 9C).

Loss of thumb extension
- EPL rupture is common and often results in minimal loss of function.
  - If diagnosed early, an interposition graft may be used.² The palmaris tendon, a strip of the flexor carpi radialis, and a slip of the EDQ are suitable choices.

Late or chronic ruptures require transfer of the EIP to the distal end of the EPL. The proximal muscle will usually begin to atrophy and become nonfunctional by 6 months after the injury.
- If the EIP is not available, transfer of the FDS from the long or ring finger can be considered. The FDS can be routed through the interosseous membrane or around the radial side of the forearm as described for transfer to restore finger extension.⁷
- Chronic synovitis at the thumb MCP joint may lead to attritional rupture of the dorsal capsule and the extensor pollicis brevis.
  - This boutonnière deformity of the thumb is a type I as described by Nalebuff⁴ and Nalebuff and Millender⁵ (FIG 10).
  - The deformity usually progresses after extensor pollicis brevis rupture. The EPL shifts ulnarward, the collateral ligaments weaken, and the thumb metacarpal becomes abducted radially. The interphalangeal joint hyperextends as a reciprocal response to the MCP joint flexion.
  - Transfer of the EPL to the extensor pollicis brevis and dorsal capsule is performed. Local anesthesia is typically adequate.

Flexor Tendon Rupture
- Tendon transfer for the treatment of flexor tendon disruption in the rheumatoid patient is much less common than for extensor tendon rupture.
- Mannerfelt syndrome should be treated by transfer of the brachioradialis tendon to the flexorpollicis longus.
- Associated disruption of a FDP tendon is usually treated by transferring the distal stump end to side to the adjacent digit’s FDP tendon.

FIG 8 • Rupture of the common extensors to the long, ring, and small fingers with extensor digiti quinti rupture can be treated, as shown here, with transfer of the extensor indicis proprius to the distal stumps of the ring and small finger with distal end-to-side transfer from the extensor digitorum communis to the long finger to the adjacent index extensor digitorum communis.

FIG 9 • A. Rupture of all four finger extensors may be treated alternatively with transfer of the flexor digitorum superficialis (FDS) to the long and ring fingers, harvested in the distal palm and transferred around the radius and ulna, with the two forearm bones serving as pulleys for the transferred tendon. B. Alternatively, both FDS tendons may be transferred around the radial side of the forearm and sutured to the distal stumps of the extensor digitorum communis tendons. C. With rupture of all common extensor tendons to the fingers as well as the extensor indicis proprius and the extensor digiti quinti, extension may be restored through transfer of one of the radial wrist extensors. This is ideal when a partial wrist fusion is being planned, as shown.
Preoperative Planning

- All patients with rheumatoid arthritis require a thorough general physical examination as well as careful evaluation of their cervical spine, including posteroanterior and lateral radiographs, often with flexion and extension views to evaluate cervical spine instability.
- Limited joint mobility is a contraindication to tendon transfer.
- Brachioradialis tendon transfer to the flexor pollicis longus is an ideal transfer and is likely to yield an excellent result, but only if there is adequate passive motion at the interphalangeal joint and MCP joint as well as the basal joint and the thumb. If these joints are stiff, the brachioradialis might be better saved for other needs as the patient’s arthritis progresses.
- The carpus should be examined for stability. In particular, the DRUJ on the ulnar side of the wrist should be checked for dorsal instability and subluxation and the volar, radial side of the wrist for palmar subluxation.

EXTENSOR INDICIS PROPRIUS TENDON TRANSFER

- Isolate the EIP through a 1-cm longitudinal or curvilinear incision on the dorsal ulnar aspect of the index MCP joint.
- The EIP is usually the ulnar tendon of the two located dorsal to the MCP joint of the index finger.
- Make a second 2- to 3-cm incision over the mid-dorsal wrist (unless a dorsal wrist incision has already been made for another procedure).
- Incise the retinaculum overlying the fourth extensor compartment and locate the EIP tendon ulnar and deep to the EDC tendons.
- The EIP muscle belly is the most distal in the fourth extensor compartment.
- Once the identity of the EIP is confirmed proximally and distally, suture the index EIP and EDC tendons together as far distal as possible using 4-0 nonabsorbable, usually braided nylon, suture.
- Invert or bury the knot to void prominence under thin rheumatoid skin.
- Incise the EIP just proximal to the stitch, then free any tendinous interconnections over the dorsum of the hand.
- Use a blunt instrument or Penrose drain to pull the EIP tendon into the wrist wound.
- Transfer the EIP to the exposed recipient tendon using a Pulvertaft weave.
- A single weave, while usually sufficient for smaller tendons, should be supplemented with an additional one or two weaves if possible. This will significantly strengthen the repair site.
- If insufficient distal tendon is present for a weave, either an end-to-end repair or a weave in which the transferred tendon is brought through a transverse incision in the distal recipient stump from volar to dorsal is an effective option.
- Skin incisions are closed and a splint is applied.

FLEXOR DIGITOTORUM SUPERFICIALIS TENDON TRANSFER

- In the case of rupture of all of the extensor tendons on the dorsum of the wrist, and when wrist motion is still intact, tendon transfer of the FDS, as suggested by Boyes,¹ is a reliable method to restore finger extension.
- The FDS and FDP to each of the donor fingers must be intact.
- Pre-existing swan-neck deformity in a donor digit may worsen after harvest of the FDS tendon.
- Long and ring FDS tendons are used most often.
Chapter 61  TENDON TRANSFERS USED FOR TREATMENT OF RHEUMATOID DISORDERS

Make a transverse incision in the distal palm and divide the FDS tendon proximal to the bifurcation, leaving the chiasm of Camper intact to provide proximal interphalangeal stability and help prevent development of a swan-neck deformity (TECH FIG 1).

Splinting the proximal interphalangeal joint in flexion postoperatively will also help to minimize the risk of developing a swan-neck deformity.

Isolate the FDS tendon proximally through a Henry-type incision in the distal forearm and atraumatically deliver it into that incision.

Pass the tendon deep to the median nerve, the FDP, the flexor carpi radialis, the flexor pollicis longus, and the radial artery and the nerve at the wrist with a blunt tendon passer, hemostat, or Kelly clamp.

The transferred tendon sits on the radius using the bone as a pulley to enhance the effectiveness of the transfer.

If the FDS to the ring finger is too short to pass around the radial side of the wrist, an alternative route is beneath the FDP, flexor carpi ulnaris, and ulnar artery and nerve around the ulnar side of the forearm using the ulna as the pulley.

In general the radial path is preferred to minimize ulnar deviation of the digits.

Alternatively, the FDS tendon is passed volar to dorsal though an incision in the interosseous membrane just proximal to the DRUJ.

The membrane functions as the pulley.

Weave the smaller distal tendon stumps through the larger transferred FDS tendon in the manner described by Pulvertaft.

Adjust tension such that with slight wrist flexion, the fingers are maintained in full extension.

Immobilize the hand and wrist with the wrist in 40 degrees of extension and the fingers flexed until tension is noted at the suture line (TECH FIG 2).

Ideally, this should be close to the “safe position” with slight MCP joint flexion and relative interphalangeal joint extension.

TECH FIG 1 • Transfer of the flexor digitorum sublimis to the long and ring fingers. The distal incision in the palm is used to isolate the sublimis tendon as far distal as possible by flexing the finger so that the chiasm of Camper is visible in the wound. The tendon is divided just proximal to the chiasm, leaving enough distal tendon to contribute to the stability of the proximal interphalangeal joint in extension and thereby avoiding a secondary instability of that joint and possible swan-neck deformity.

TECH FIG 2 • The ideal splint for transfer to the extensor tendons of the finger immobilizes the wrist in the so-called safe position. With wrist extension, tension at the site of transfer is usually minimal. Finger flexion at the metacarpophalangeal joint is ideal to prevent scarring of the collateral ligaments and secondary loss of finger flexion. The amount of flexion possible is judged in the operating room by passive flexion of the finger until a minimum amount of tension is seen at the repair site. (From Williams DP, Lubahn JD. Reconstruction of extensor tendons. Atlas Hand Clin 2005;10:209–222.)

EXTENSOR CARPI RADIALIS LONGUS OR BREVIS TRANSFER

When all of the finger extensors have ruptured, wrist motion is severely limited (ie, after a partial or complete wrist fusion), and the radiocarpal joint is stable, the wrist extensors become potential muscles for use as transfers.

The ECRL and the ECRB are located in the second dorsal compartment of the wrist adjacent to the fourth compartment and are separated only by the tubercle of Lister and the EPL.

Expose the ECRL or ECRB using a straight dorsal incision or a limited transverse incision over the base of the index and long metacarpals, at their respective insertion sites.

Divide the tendon selected for transfer, usually the ECRL, at its insertion and transfer it ulnarward to the recipient tendon stump.
BRACHIORADIALIS TENDON TRANSFER (RECONSTRUCTION OF MANNERFELT SYNDROME)

- Expose the forearm muscles and the brachioradialis tendon insertion on the distal radial aspect of the radius through a Henry-type incision.
- Confirm the tendon rupture by direct exposure of the slightly more distal and radial tendon of the flexor pollicis longus.
- Mobilize the distal tendon stump and perform a tenolysis to remove adhesions.
- Weave the distal flexor pollicis longus through the brachioradialis in a Pulvertaft fashion. Sharp tendon passers facilitate this technique (TECH FIG 3).
- Adjust tension such that with wrist flexion, the MCP and interphalangeal joints of the thumb extend fully, and with wrist extension, they flex 30 to 40 degrees.
- Secure the weaves with 3-0 or 4-0 braided nonabsorbable sutures.
- If the index or long FDP tendons also are ruptured, isolate the distal tendon stumps and repair them end to side.

EXTENSOR POLLICIS LONGUS TENDON TRANSFER (RECONSTRUCTION OF THUMB BOUTONNIÈRE DEFORMITY)

- Make a longitudinal incision to expose and identify the EPL tendon at its insertion onto the base of the distal phalanx.
- Incise the tendon at that level and mobilize it proximally (TECH FIG 4A).
- Carefully protect the intrinsic tendon, which will now be the sole extensor for the thumb interphalangeal joint.
- Expose the dorsal base of the proximal phalanx and weave the EPL tendon through the dorsal capsule, securing it using a 3-0 or 4-0 nonabsorbable braided suture (TECH FIG 4B).
- Alternatively, secure the EPL tendon in place using drill holes or a suture anchor in the proximal phalanx (TECH FIG 4C,D).
- The thumb is splinted or casted for 4 weeks and a protective splint is worn for strenuous activities for 6 to 8 weeks.
TECH FIG 4 • Extensor pollicis brevis rupture. A,B. Tendon transfer of the extensor pollicis longus proximally to the site of insertion of the extensor pollicis brevis, allowing the hyperextended interphalangeal joint to drop into a more flexed position and allowing active extension at the level of the metacarpophalangeal joint. C,D. Extensor pollicis longus is anchored through drill holes to the base of the proximal phalanx. (From Lubahn JD, Wolfe TL. Surgical treatment and rehabilitation and tendon ruptures in the rheumatoid hand. In: Mackin EJ, Callahan AD, Skirven TM, et al, eds. Rehabilitation of the Hand and Upper Extremity, ed 5. St. Louis: Mosby, 2002:1598–1607.)

PEARLS AND PITFALLS

EIP harvest

■ Obtain the EIP transfer by tracing the ulnarmost inserting tendon in the MCP joint region of the index finger proximally at the level of the wrist. In a certain percentage of patients, the ulnarmost tendon is in fact the EDC rather than the EIP. The EIP, however, is always the deeper, more volar tendon at the level of the wrist. Tracing this independent muscle tendon unit from the wrist to the index finger MPJ will help assure the surgeon that the correct tendon is being released for transfer.

■ Distal repair of the dorsal apparatus at the site of EIP harvest is somewhat controversial. While some experts recommend repair, others feel confident that the defect can be left with no risk of extensor lag. The surgeon needs to be aware of the potential risk of extensor lag, and we recommend attention to the defect by suture repair.

EDQ transfers

■ Sufficient length of the distal segment of the EDQ should be available to allow tendon transfer to the adjacent EDC without abducting the small finger. If this transfer is tight, the side-to-side transfer of EDQ to the EDC of the ring finger should be abandoned and tendon transfer to the EIP or another suitable donor pursued.

Unstable DRUJ

■ At the time of tendon transfer, inspect the DRUJ to be certain that any osteophytes have been débrided and a localized flap rotated to cover the exposed bone created. If the DRUJ is deemed unstable, transfer of the pronator quadratus dorsally may be used to stabilize the distal ulna.

Suturing

■ When suturing tendon grafts at the site of tendon weave (ie, where a graft or transfer is passed through another tendon), one or two sutures should be sufficient. Take care that the needle does not pass through the tendon near the thread from another suture. If this occurs, the suture is weakened or possibly cut in two by the needle, and the graft or transfer is predisposed to rupture. Cutting needles should never be used as they place both the suture and the tendon at risk.
POSTOPERATIVE CARE
- Postoperative care for each of these tendon transfers is similar.
- In the case of tendon transfer to restore loss of finger extensors, the hand and wrist are immobilized with the wrist extended about 40 degrees. More may be desirable in certain instances, but too much extension could damage already fragile joints.
  - The MCP joints are brought into flexion until tension is noted at the suture line. Forty degrees or more is ideal to maintain the desired length of the collateral ligaments and prevent MCP joint extension contractures.
  - Immobilization is continued for 3.5 to 4 weeks, and gentle active motion is begun, maintaining the hand in a splint for protection.
  - At 6 weeks, some resistive exercises may be added to the program. By 12 weeks, the patient should be able to resume normal activities.
- In the case of flexor tendon rupture, the hand and wrist are immobilized with the wrist in 60 degrees of flexion, the MCP joints in 40 degrees of flexion, and the interphalangeal joints allowed to extend until tension is noted at the suture line. Immobilization is continued for 6 weeks, at which time a gentle active range-of-motion program is begun without resistance.
  - At 12 weeks resistive exercises are added and the patient is permitted to gradually resume normal activity.

OUTCOMES
- Outcomes in tendon transfer surgery in rheumatoid arthritis are highly dependent on the patient’s medical condition and ability to cooperate with the postoperative splinting and rehabilitation program. Most patients who are supervised by a therapist achieve a better result than those who try to make it on their own.
  - With good medical management of rheumatoid arthritis, when the disease is well controlled, and in cooperative patients who are motivated to improve, good results should be expected.
- Tendon transfer should always be delayed in patients with active disease as results will be poor.
- The only surgical procedure to be performed in poorly controlled patients is synovectomy, and with the caveat that success hinges on eventual good medical control of the disease.

COMPLICATIONS
- Infection
- Skin or surgical wound breakdown
- Attenuation of the transferred tendon
- Rerupture of the tendons
- Loss of motion due to improper tensioning of the transferred tendon
- Joint stiffness

REFERENCES
DEFINITION
- Rheumatoid arthritis is a poorly understood systemic disease affecting the synovium of joints and tendon sheaths. The synovial tissue in rheumatoid arthritis is characterized by a proliferation of synovial lining cells, angiogenesis, and relative lymphocytosis.\textsuperscript{14}
- A combination of cartilage degeneration, synovial expansion and periarticular erosion, and ligamentous laxity creates an imbalance within the extrinsic and intrinsic tendon systems of the digit to cause progressive deformity.
- A boutonnière (“buttonhole”) deformity involves disruption of the central slip. It results in a characteristic deformity involving hyperextension at the metacarpophalangeal (MCP) joint, flexion at the proximal interphalangeal (PIP) joint, and hyperextension at the distal interphalangeal (DIP) joint.
- Swan-neck deformity is characterized by hyperextension of the PIP joint and flexion of the DIP joint. MCP joint flexion may also be present.
- In the posttraumatic setting, it results from laxity of the PIP joint volar plate and inability of the terminal slip to extend the DIP joint.
- Chronic deformity may be associated with progressive digital contracture.

Classification
- Rheumatoid thumb deformity\textsuperscript{26,33}
  - Type I: Boutonnière deformity: MCP joint flexion and interphalangeal joint hyperextension. Carpometacarpal (CMC) joint is not primarily involved.
  - Type II: Rare; a combination of types I and III involving MCP joint flexion and interphalangeal joint hyperextension and associated CMC joint subluxation or dislocation
  - Type III: Swan-neck deformity: MCP joint hyperextension, interphalangeal joint flexion, and thumb metacarpal adduction, resulting from progressive CMC joint pathology
  - Type IV: Gamekeeper’s deformity. Attenuation of the ulnar collateral ligament of the thumb MCP joint results in radial deviation through the MCP joint and secondary metacarpal adduction deformity or contracture.
  - Type V: Results from attenuation of the MCP volar plate with progressive MCP joint hyperextension and secondary interphalangeal joint flexion. There is no metacarpal adduction deformity.
- Boutonnière deformity
  - Stage I—mild: PIP joint synovitis and a mild, fully correctable extension lag
  - Stage II—moderate: Marked flexion deformity of the PIP joint, either flexible or fixed
  - Stage III—severe: PIP joint articular destruction
- Swan-neck deformity
  - Type I: PIP joint is fully mobile and flexible.
  - Type II: Active and passive motions of the PIP joint are limited, with the MCP joint held in extension due to intrinsic tightness.
  - Type III: Decreased PIP joint motion in all positions of MCP joint flexion and extension
  - Type IV: Fixed PIP joint hyperextension with advanced destruction of the PIP joint articular surfaces

ANATOMY

Bone and Joint
- The MCP joint is a condyloid joint with average range of motion from 15 degrees hyperextension to 90 degrees flexion.
- A cam effect for collateral ligaments is due to the shape of the metacarpal head; collateral ligaments are taut with MCP joint flexion and lax with MCP joint extension.
- The PIP joint (FIG 1A) is a hinge joint with greater inherent osseous stability than the MCP joint due to the configuration of the two condyles of the head of the proximal phalanx, which articulates with the median ridge at the base of the middle phalanx.
- The collateral ligaments are taut throughout the joint arc of motion.
- The volar plate is a thick, fibrocartilage structure that serves to resist PIP joint hyperextension; the volar plate originates within the A2 pulley on the proximal phalanx and inserts into the “rough area” at the base of the middle phalanx.
- The DIP joint is stabilized by the collateral ligaments, the terminal extensor tendon insertion, the flexor digitorum profundus insertion, and the volar plate.

FIG 1 • A. Proximal interphalangeal (PIP) joint relationships. The flexor tendons (flexor digitorum superficialis [FDS] and profundus [FDP]) have been removed from the proximal digital flexor sheath at the A2 pulley. The FDP and FDS tendon orientation is demonstrated before they re-enter the flexor sheath at the A4 pulley. The PIP joint collateral ligament (cl) and the insertion of the central slip (cs) at the dorsal base of the middle phalanx have been reflected distally to highlight the volar plate (vp) and its proximity within the flexor sheath. P1, proximal phalanx; P2, middle phalanx. (continued)
Dorsal Restraining Structures of the Digit (FIG 1B-D)
- The sagittal bands originate on both sides of the MCP joint, from the volar plate and the base of the proximal phalanx, and insert into the lateral margins of the extensor tendon over the dorsal MCP joint.
  - They stabilize the extrinsic extensor tendon over the MCP joint to prevent lateral subluxation.
  - They contribute indirectly to MCP joint extension and prevent extensor bowstringing.
- The triangular ligament stabilizes the two conjoined lateral bands over the dorsal aspect of the middle phalanx and prevents volar subluxation of the conjoined lateral bands.
- The transverse retinacular ligament is composed of fibers oriented in a volar–dorsal direction at the level of the PIP joint. It prevents dorsal subluxation of the conjoined lateral bands.
  - The oblique retinacular ligament (ORL) is a static restraining ligament, linking the PIP and DIP joints. It runs from the fibro-osseous gutter at the A2 flexor pulley and the middle third of the proximal phalanx to insert into the terminal extensor tendon and couples PIP joint and DIP joint extension.

Flexor Tendon: Digit
- At the level of the A1 pulley, the flexor digitorum superficialis (FDS) tendon flattens and bifurcates to allow the more dorsal flexor digitorum profundus (FDP) tendon to pass distally within the flexor sheath to insert at the volar base of the distal phalanx.
- The FDS tendon slips rotate laterally and dorsally around the FDP and then divide again into medial and lateral slips. The medial slips rejoin dorsal to the FDP tendon and insert into the distal aspect of the proximal phalanx. The lateral slips continue distally to insert into the base of the middle phalanx.

Extensor Tendon: Digit
- At the base of the proximal phalanx, the extrinsic extensor tendon trifurcates with the central portion inserting into the dorsal base of the middle phalanx as the central slip.
- The lateral slips are joined by the oblique fibers of the lumbrical tendons to form the conjoined lateral band. The conjoined lateral bands converge over the middle phalanx to form the terminal tendon, which inserts at the dorsal base of the distal phalanx, where it functions to extend the DIP joint.
- The interosseous muscles contribute to the dorsal extensor apparatus through their deep muscle belly, which travels superficial to the sagittal band as the lateral tendon, becoming the transverse fibers of the extensor hood (MCP joint flexion).
PATHOGENESIS

Posttraumatic Boutonnière Deformity
- Disruption of the central slip is the inciting pathology in the development of the boutonnière deformity.
- Injury patterns can be grouped into two broad categories, closed and open.
  - Closed injuries: Forceful hyperflexion of the PIP joint may result in a detachment of the central slip from its insertion. An associated avulsion fracture involving the insertion of the central slip may be identified from the dorsal base of the middle phalanx.
  - Volar dislocations of the PIP joint or digital crush injuries may disrupt the central slip.
  - Open injuries: Dorsal laceration or deep abrasions over the PIP joint may disrupt the central slip.
- Disruption of the central slip and attenuation of the triangular ligament allows for the migration of the lateral bands volar to the PIP joint axis of rotation. This results in flexion at the PIP joint and extension at the DIP joint through the action of the displaced lateral bands.
- The displaced lateral band becomes a flexor of the PIP joint and an extensor of the DIP joint.

Posttraumatic Swan-Neck Deformity
- Unrecognized volar plate injury at the PIP joint may result in volar plate insufficiency. This leaves the action of the central slip unchecked by the volar plate, resulting in a progressive PIP joint hyperextension deformity.
- Recurrent dorsal dislocation of the PIP joint is an example of an injury pattern that may result in volar plate incompetence.
- Avulsion of the terminal tendon from its insertion at the base of the dorsal distal phalanx results in an imbalance in the extensor mechanism. Extension forces are concentrated at the central slip, producing a progressive hyperextension deformity of the PIP joint.
- Patients predisposed to volar plate laxity (such as from generalized ligamentous laxity, inflammatory conditions, and collagen vascular disorders) are particularly susceptible to the development of deformity.
- An extension malunion of the middle phalanx or periteninous adhesions secondary to previous digital fracture or injury may contribute to the development of a swan-neck deformity.
- Hyperextension of the PIP joint and attenuation of the transverse retinacular ligament permits dorsal migration of the lateral bands relative to the PIP joint axis of rotation. The displaced lateral bands act to extend the PIP joint and to flex the DIP joint.

Rheumatoid Boutonnière Deformity

Fingers
- Boutonnière (“buttonhole”) deformity results from pathologic synovitis of the PIP joint that causes progressive attenuation of the central slip, transverse retinacular ligaments, and triangular ligament. The PIP joint essentially “buttonholes” through the extensor mechanism. Characteristic flexion of the PIP joint and hyperextension deformities of the MCP and DIP joint prevail due to the extensor imbalance (FIG 2A).
- Subluxation of the lateral bands, volar to the axis of PIP joint rotation, occurs due to the loss of these restraints. The lateral bands become flexors of the PIP joint rather than extensors.
- It is important to differentiate this pathologic involvement of the extensor mechanism from a flexion contracture of the PIP joint.
- Due to persisting PIP joint flexion, the volar plate, collateral ligaments, and oblique retinacular ligaments become increasingly contracted, resulting in a stiff and subsequently fixed boutonnière deformity.

Thumb
- Type I boutonnière deformity is the most common rheumatoid deformity of the thumb. It is characterized by MCP joint flexion and interphalangeal joint hyperextension (FIG 2B).
- The pathologic changes affecting the thumb typically involve synovitis of the MCP joint with resulting attenuation of the extensor mechanism (dorsal joint capsule, extensor pollicis brevis tendon insertion, extensor hood). This relative extensor imbalance results in MCP joint flexion and possible joint subluxation.
- Attenuation of the sagittal band permits ulnar and volar subluxation of the extensor pollicis longus (EPL) tendon, which accentuates MCP joint flexion and interphalangeal joint hyperextension as it translates volar to the axis of MCP joint rotation.
- The destructive influence of prolific MCP joint synovitis can cause progressive articular erosion and altered joint surface mechanics, resulting in progressive joint instability and deformity.
As the MCP joint flexion posturing increases in severity, compensatory radial abduction deviation of the thumb metacarpal ensues.

- Rupture of the EPL tendon at the wrist can result in a similar “extrinsic-minus” deformity of the thumb.20,25
- Boutonnière deformity can result, also, from a hyperextension deformity of the thumb interphalangeal joint secondary to joint synovitis with attenuation of the volar plate or to rupture of the flexor pollicis longus tendon.19
  - Generally, these primary interphalangeal joint etiologies present with less dramatic MCP joint flexion deformity.33

**Rheumatoid Swan-Neck Deformity**

**Fingers**

- Swan-neck deformity may result from pathologic rheumatoid synovitis of the MCP, PIP, or DIP joints and is characterized by PIP joint hyperextension and MCP and DIP flexion deformities.
  - Progressive attenuation of the volar plate, collateral ligaments, and insertion of the FDS tendon results in the development of a PIP hyperextension deformity.
  - Attenuation of the transverse retinacular ligaments may occur from synovitis, thereby resulting in a loss of the normal restraints to dorsal translocation of the lateral bands. As the lateral bands subluxate dorsal to the axis of PIP joint rotation, they become a constant hyperextension force on the PIP joint.
  - The DIP joint may be the primary cause of swan-neck deformity where synovitis results in the attenuation and possible rupture of the terminal extensor tendon. This leads to a concentration of the extensor forces at the PIP joint and a resultant hyperextension deformity.
  - Pathologic alterations in MCP joint mechanics may initiate the development of a swan-neck deformity. Progressive flexion deformity and ulnar drift of the digit results in an imbalance of the extensor mechanism whereby the lateral bands are drawn dorsally, concentrating an extension–hyperextension force at the PIP joint. Flexion deformity at the MCP joint may be secondary to several causes (**FIG 3A,B**):
    - Chronic synovitis and associated attenuation of the sagittal bands
    - Articular destruction with associated joint deformity and volar joint subluxation
    - The influence of intrinsic tightness or contracture
    - Persisting PIP hyperextension results in contracture of the extensor apparatus, particularly the triangular ligament, as well as the skin. These progressive changes result in a stiff and subsequently fixed PIP joint hyperextension contracture.
    - Digital flexor tenosynovitis may contribute to poor initiation of digital flexion and an increased extension imbalance at the PIP joint.
    - Chronic synovitis of the PIP joint, combined with altered joint mechanics, may result in progressive articular destruction that leads to greater joint deformity, a progressively fixed contracture, and, potentially, painful dysfunction of the digit.

**Thumb**

- Type III rheumatoid thumb deformity is the second most common thumb deformity after boutonnière deformity.25,29
  - The deformity occurs as the result of CMC joint synovitis and associated alterations in thumb mechanics.
  - Progressive dorsal and radial subluxation of the thumb CMC joint occurs with the deleterious effects of chronic synovitis, including capsular attenuation and articular erosions.
  - The force vectors associated with pinch and grasp activities accentuate the CMC deformity and accentuate a progressive thumb metacarpal adduction contracture due to a loss of thumb abduction.
  - As the adduction contracture worsens, hyperextension of the MCP joint (permitted by volar plate laxity) and interphalangeal joint flexion becomes a functional compensation (**FIG 3C,D**).
NATURAL HISTORY

Traumatic Injury
- Early diagnosis is critical for achieving satisfactory outcomes. Reconstructive options become limited as the deformity becomes rigid.

Boutonnière Deformity
- Deformity may not be evident immediately after injury but may develop over 2 to 3 weeks.
- The pathologic finger posture develops through five stages:1
  - Disruption of the central slip results in resting flexion of the PIP joint and weak extension of the middle phalanx via the lateral bands.
  - Attenuation of the triangular ligament and contracture of the transverse retinacular ligaments results in volar migration of the lateral bands. Active PIP joint extension is absent.
  - Extension forces are transmitted through the lateral bands, causing hyperextension at the DIP joint.
  - Progressive contracture of the PIP joint volar plate and the oblique retinacular ligament results in fixed flexion contracture at the PIP joint.
  - Progressive articular degeneration occurs after prolonged and untreated pathology.

Swan-Neck Deformity
- The deformity may be subclassified into four groups that describe the natural history:2
  - Presence of full passive range of motion at the PIP joint
  - Prolonged hyperextension of the PIP joint results in intrinsic tightness. The PIP joint exhibits full range of motion when the MCP joint is flexed. However, with the MCP joint extended, PIP flexion becomes limited.
  - As the transverse retinacular ligament attenuates and the triangular ligament contracts, the subluxated lateral bands become fixed dorsal to the PIP joint axis of rotation. Hyperextension of the PIP joint becomes fixed regardless of MCP joint position.
  - Progressive PIP joint articular degeneration occurs with chronic, fixed deformity.

Rheumatoid Deformity
- The rate of progressive rheumatoid arthritis-related upper extremity deformity appears to be slowing due to improved medical management of this systemic disease process.
- The incidence of uncorrectable boutonnière and swan-neck deformities during the first 2 years after the onset of systemic disease is about 16% and 8%, respectively.7
- The prevalence of finger deformities in patients with established rheumatoid arthritis is about 36% for boutonnière and 14% for swan-neck deformities.7
- The wrist, MCP, and PIP joints are the most commonly affected joints of the upper extremity, and pathologic proliferation of the flexor and extensor tenosynovium may influence digital function and deformity.

PATIENT HISTORY AND PHYSICAL FINDINGS

Posttraumatic Injury

Boutonnière Deformity
- A history of blunt trauma to the digit with swelling and tenderness over the PIP joint should arouse suspicion as to the condition. Often, patients report “jamming” or spraining the digit. History of a dorsal digital laceration is similarly concerning.
- Deformity may not develop until 10 to 21 days after the injury, making early diagnosis challenging and diligent follow-up imperative. Laceration, ecchymosis, or tenderness over the dorsum of the PIP joint may be diagnostic when a PIP joint extension lag is present.
- If the examination is limited due to pain, a digital block should be considered to facilitate a comfortable examination.
- The following physical findings are supportive in confirming an early diagnosis:
  - 15- to 20-degree PIP joint extension lag with the wrist and MCP joint fully flexed8
  - Weak extension of the middle phalanx against resistance18
  - Elson test: Effort to extend the PIP joint accompanied by rigidity of the DIP joint suggests that the central slip is ruptured and forces are being transferred by the lateral bands.
  - The Elson test is most reliable in diagnosing early boutonnière deformities.31
  - Boyes test: When the central slip is disrupted, passive extension of the PIP joint causes tension across the lateral bands, resulting in loss of active flexion at the DIP joint. When flexion at the PIP joint is restored, motion at the DIP joint returns.

Swan-Neck Deformity
- A history of unrecognized or undertreated trauma or multiple dorsal PIP joint dislocations is common. A patient who presents with a longstanding “mallet” deformity should arouse suspicion, particularly if there is associated hypermobility in the PIP joint of unaffected digits.
- Physical examination begins with inspection of the involved digit.
  - Typically, the PIP joint is hyperextended and the DIP joint is flexed. MCP joint flexion may be present also.
  - Active and passive range of motion of the PIP joint should be assessed.
  - In the presence of a flexible deformity, a Bunnell test for intrinsic tightness should be performed.
  - This test assists the examiner in determining the relative contribution of intrinsic tightness to the deformity.
  - Increased resistance to passive PIP flexion with the MCP joint in extension compared with flexion indicates a relative shortening of the intrinsic muscle–tendon units.

Rheumatoid Deformity
- Diagnostic criteria for rheumatoid arthritis are based on the American College of Rheumatology’s 1988 recommendations.2
- Current medications and medical comorbidities may influence decision making for treatment and the timing for surgical intervention.
- The evaluation of digital deformities associated with rheumatoid arthritis requires careful global assessment, including neurologic assessment (cervical spine, peripheral compressive neuropathy); appreciation for shoulder, elbow, and wrist involvement; and the awareness of lower extremity deformities that will need reconstructive surgery for which the use of ambulatory aids might be necessary.
- As progressive deformity of the wrist occurs, its pathologic influence on digital function and deformity should be recognized.
- The carpus typically collapses into supination, with concomitant volar translation and ulnar translocation.4

Relative dorsal prominence of the distal ulna may involve a loss of distal radioulnar joint (DRUJ) congruity and may be associated with ruptures of the extensor carpi ulnaris tendon and extensor tendons to the small and ring fingers (caput ulnae syndrome). Inspection of the extrinsic digital extensors, including the EPL, should be done, particularly in the presence of active synovitis of the radiocarpal joint and DRUJ (FIG 4).

The MCP joint should be assessed for active synovitis and for characteristic volar subluxation and ulnar drift.

Just as pathologic changes to both the wrist and MCP joints may influence the development of swan-neck and boutonnière deformities of the digits, these changes may adversely affect the outcomes of digital reconstruction if they are not addressed.

Evaluation of the digits should be performed individually with inspection of the resting posture of each digit, assessment of the active and passive motion of each digital joint, and inspection for joint synovitis or tenosynovitis. Skin integrity is assessed for attenuation and for its contribution to joint contracture.

Flexor tenosynovitis may be identified by a palpable fullness in the distal volar forearm or along the digital flexor sheath. Swelling, palpable crepitus along the digital flexor sheath, and a discrepancy between active and passive digital motion are hallmarks of flexor tenosynovitis of the digit.

Flexor tendon rupture may be present, often secondary to attenuation at the volar carpus, and should be addressed in the presence of a loss of active digital joint flexion.

Extensor tenosynovitis at the wrist may be determined by palpable tenosynovial hypertrophy, or fullness, and crepitus along the dorsal extensor compartments, proximal and distal to the extensor retinaculum.

Tendon ruptures may be identified by a lack of active digital extension despite active muscular contraction, by palpable tendon deficit, and by a lack of digital extension through tenodesis with passive wrist flexion.

The adhesion of a ruptured tendon to the surrounding tissues and the influence of the junctura tendinea may limit the accuracy of these evaluations.

As described above, the Bunnell intrinsic tightness test should be performed for all fingers of patients with rheumatoid arthritis, particularly for patients with swan-neck deformity of the digits. This test assists the examiner in determining the relative contribution of intrinsic tightness to the development of the deformity.

Tightness of the oblique retinacular ligament, often appreciated in digits with early boutonnière deformity, is evaluated by assessing the relative degree of resistance to passive DIP joint flexion with the PIP joint held by the examiner in maximum extension.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs (three views) are the mainstay of hand and wrist evaluation in the patient with either a traumatic or rheumatoid cause for deformity.
- Staging of arthritis-related joint pathology and identification of joint subluxation or dislocation, important for diagnostic and management considerations, is performed using plain radiographs (FIG 5A).
- Avulsion fractures from the dorsal base of the middle phalanx, volar subluxation of the PIP joint, or both suggest a central slip injury (FIG 5B).
In the presence of a fixed PIP joint flexion deformity, concomitant avulsion fracture of the volar plate suggests pseudo-boutonnière pathology.

Fluoroscopic imaging or stress views may be helpful in differentiating collateral ligament injury from disruption of the central slip.

Avulsion fractures from the dorsal base of the distal phalanx suggest terminal tendon injury.

The presence of volar plate avulsion fractures in the setting of PIP joint hyperextension suggests volar plate incompetence.

MRI may be useful in assessing for soft tissue pathology such as tenosynovitis and tendon rupture, especially in rheumatoid patients.

**DIFFERENTIAL DIAGNOSIS**

**Posttraumatic Injury**

- Pseudo-boutonnière deformity
- Collateral ligament injury
- Mallet finger
- Volar plate avulsion fracture

**Rheumatoid Deformity**

- Osteoarthritis
- Psoriatic arthritis
  - Similar deformities as seen in rheumatoid arthritis, but skin lesions are common and DIP joint “pencil-in-cup” deformities may be present
- Connective tissue disorders (scleroderma, systemic lupus erythematosus)
  - Systemic lupus erythematosus primarily affects soft tissue structures (ligamentous laxity, tendon subluxation) rather than joint destruction. Radiographs typically demonstrate joint deformities with well-preserved joint spaces. The thumb may be the first digit affected; lateral subluxation of the interphalangeal joint and flexion deformity of the MCP joint (secondary to extensor tendon subluxation) are common.
- Patients with scleroderma often develop PIP joint flexion contractures and compensatory hyperextension posturing of the MCP joints.
- Crystal-induced arthropathy (gout, calcium pyrophosphate deposition disease)
- Hemochromatosis
- Remitting symmetric seronegative synovitis

**NONOPERATIVE MANAGEMENT**

**Posttraumatic Injury**

**Boutonnière Deformity**

- Nonoperative management is indicated if correction of the deformity restores the anatomic length relationship between the central slip and the lateral bands. It is most appropriate in those with closed injuries who present within 8 to 12 weeks of injury. It may be attempted in those with central slip avulsion fractures or volar dislocation if satisfactory reduction and PIP joint stability can be obtained.

- For patients with full passive extension of the PIP joint, PIP joint extension splinting is the treatment of choice.
  - A transarticular Kirschner wire maintaining the PIP joint in full extension is an alternative or adjunct to external splinting.
  - For patients with a PIP joint flexion contracture without secondary joint degenerative changes, progressive static or dynamic extension splinting should be pursued.

- Full passive extension of the PIP joint should be sought before surgical intervention is considered.
- Active and passive DIP joint range of motion should be emphasized while the PIP joint is being treated. Restoration of active DIP joint flexion while the PIP joint is extended suggests successful treatment. Restoration of full active extension at the PIP joint is the goal.
- For most injuries, PIP joint extension splinting should be maintained for 6 to 8 weeks at all times, transitioning to protective buddy straps for daily activity and nighttime extension splinting for an additional 4 to 6 weeks.

**Swan-Neck Deformity**

- Once the deformity has developed, nonoperative treatment is rarely effective.
- Some patients with flexible deformities are capable of initiating PIP joint flexion with little impairment. They may complain of “snapping” or “cogwheeling” as the lateral bands relocate volarly during PIP joint flexion. These patients may benefit from a digital splint, such as a figure 8 ring splint, to prevent continued PIP joint hyperextension and to maintain the lateral bands in their anatomic position (**FIG 6**).

**Rheumatoid Deformity**

**Boutonnière Deformity**

- Nonoperative management of an early boutonnière deformity includes low-profile PIP joint extension splinting.
- Oral anti-inflammatory medications, intra-articular corticosteroid injection of the PIP joint, or both are used to minimize joint synovitis.

**Type I Swan-Neck Deformity**

- The goals of treatment for the flexible swan-neck deformity are prevention of PIP joint hyperextension and improvement in PIP joint flexion.
- In the presence of minimal PIP joint synovitis, use of digital splints, such as a figure 8 ring splint, is advocated to prevent PIP joint hyperextension (**Fig 6**).

**SURGICAL MANAGEMENT**

**Posttraumatic Injury**

**Boutonnière Deformity**

- Surgical intervention is indicated for patients who fail to respond to at least 3 months of extension splinting, patients with open injuries, and patients with fixed deformity with associated degenerative joint changes.

**FIG 6** A figure 8 ring splint (Silver Ring Splint; Charlottesville, VA) used to prevent proximal interphalangeal joint hyperextension in a mild, flexible swan-neck deformity. (Photographs © Copyright of Fraser J. Leversedge, Charles A. Goldfarb, and Martin Boyer.)
Surgical decision making should be tempered by the observations of Burton and Melchior:

- Boutonniere reconstructions are most successful on supple joints. If necessary, joint contracture release can be performed as a first stage. If the release is followed by an intensive exercise and splinting program, the second stage may be avoided.
- An arthritic joint usually precludes soft tissue reconstruction. The surgeon should consider either a PIP joint fusion or arthroplasty with extensor reconstruction.
- Boutonniere deformities rarely compromise PIP joint flexion and grip strength. The surgeon should not trade extension at the PIP joint for a stiff finger and a weak hand.

Swan-Neck Deformity

- Surgery is indicated for patients with a flexible deformity who cannot actively initiate PIP joint flexion and in those with fixed deformities.
- Patients with flexible deformities benefit from volar mobilization of the lateral bands and tenodesis to prevent PIP joint hyperextension.
- Patients with fixed deformities have difficulty grasping objects. Often, functional contact is limited to the volar surface of the hyperextended PIP joint.
- If the articular surfaces are well preserved, PIP joint release with concomitant procedures to restore flexion may be beneficial.
- If the articular surfaces are damaged, PIP arthrodesis is a practical option.

Rheumatoid Deformity

- Principles of surgical correction of rheumatoid deformities in the hand should be guided by the relief of pain and the improvement of function.

Boutonniere Finger Deformity

- Stage I—mild
  - For progressive boutonniere deformity associated with persistent PIP joint synovitis unresponsive to oral medication and intra-articular corticosteroid injection, PIP joint synovectomy may be considered. Concomitant slip reconstruction and lateral band repositioning may be indicated due to soft tissue attenuation over the dorsal PIP joint.
  - Functional limitation due to DIP joint hyperextension may be treated by sectioning the terminal extensor tendon over the dorsal middle phalanx.
- Stage II—moderate
  - For patients with moderate boutonniere deformity and preservation of the articular cartilage of the PIP joint, central slip reconstruction and terminal extensor tendon release may be indicated.
- Stage III—severe
  - If articular destruction is evident or if a severe fixed flexion contracture of the PIP joint is present, even without articular changes, then arthrodesis of the PIP joint is a reliable option for reducing pain and for improving function.
  - Implant arthroplasty of the PIP joint and concomitant terminal extensor tendon release is a less reliable option, particularly when there is attenuation of the dorsal extensor apparatus.

Swan-Neck Finger Deformity

- Type I
  - The primary cause of the flexible swan-neck deformity must be determined before proceeding with surgical inter-
MCP joint through EPL attachment to the dorsal MCP joint capsule.26

- **Moderate: Fixed MCP joint deformity**
  - The condition of the adjacent CMC and interphalangeal joints must be considered to determine whether to proceed with MCP arthrodesis or arthroplasty. Often, treatment at this stage of disease reduces the progression of thumb deformity.
  - If the extent of interphalangeal joint involvement warrants intervention, treatment of the interphalangeal joint is limited to arthrodesis. Therefore, preservation of motion at the MCP joint may be optimal through MCP implant arthroplasty, although function after MCP and interphalangeal arthrodesis is generally good.
  - Arthroplasty of the thumb MCP joint involves resection of the involved joint surfaces and prosthetic placement, most commonly with a flexible silicone implant. Extensor reconstruction, including EPL rerouting, is considered to augment extensor forces acting at the MCP joint. Postoperatively, the thumb MCP joint is splinted in extension for 4 to 6 weeks, allowing for controlled CMC and interphalangeal joint exercises. Good functional results with minimal progression of CMC or interphalangeal joint arthritis have been reported.33
  - Arthrodesis of the MCP joint is accomplished by one of several methods, including tension band wire fixation, crossing Kirschner wires, a headless compression screw, or plate and screw fixation. The joint is typically placed in 15 degrees of flexion and the arthrodesis site may be augmented with bone graft as needed to maximize bone surface contact area. The arthrodesis site is protected in a splint until radiographic union is confirmed. Early interphalangeal joint range of motion is encouraged to minimize extensor adhesions and stiffness.

- **Severe: Fixed deformities of MCP and interphalangeal joints**
  - In this advanced stage, the treatment rationale is similar to that for moderate deformity, except that interphalangeal joint contracture or joint deterioration requires intervention. Rarely, interphalangeal joint capsular release may be indicated to improve motion, in the absence of articular deterioration. For cases involving interphalangeal joint instability or progressive arthritis, interphalangeal arthrodesis is indicated.

- **Carpometacarpal joint involvement**
  - As rheumatoid arthritis has the potential to involve greater numbers of joints, motion-sparing procedures of the CMC joint are preferred compared to arthrodesis.
  - While total trapezial implant arthroplasty is relatively contraindicated in the rheumatoid patient due to the higher risk for implant failure or dislocation, resection or hemiresection arthroplasty with ligament reconstruction and soft tissue interposition arthroplasty should be considered.33

- **Type III: Swan-neck deformity**

  - **Mild: Isolated CMC joint involvement**
    - In the absence of symptomatic relief from conservative treatment, CMC hemi-trapeziectomy or trapeziectomy and ligament reconstruction with soft tissue interposition arthroplasty is indicated.
  - **Moderate: CMC joint pathology with mild MCP joint involvement (flexible deformity)**
    - For CMC joint pathology with progressive MCP joint hyperextension deformity, CMC hemi-trapeziectomy or trapeziectomy and ligament reconstruction with soft tissue interposition arthroplasty and simultaneous MCP joint volar plate capsulodesis, sesamoidectomy, or volar tenodesis are considered. Temporary transarticular pin stabilization of the MCP joint in 20 degrees of flexion for 3 to 4 weeks postoperatively permits early motion of the interphalangeal joint.
  - **Severe: CMC joint dislocation with metacarpal adduction contracture and fixed MCP joint hyperextension deformity**
    - Treatment for this advanced stage requires:
      - CMC joint reconstruction with resection arthroplasty and ligament reconstruction or tendon interposition arthroplasty
      - Correction of the metacarpal adduction contracture
      - MCP arthrodesis
    - Often, addition contracture of the thumb metacarpal may be adequately treated with resection of the thumb metacarpal base and release of the restraining ligaments of the CMC joint during resection arthroplasty. If the aduction contracture persists, then fasciotomy of the first dorsal interosseous and adductor muscles may be completed.33 Web space reconstruction with Z-plasties is rarely indicated.

### Preoperative Planning

- The surgeon must plan ahead. Extended procedures associated with multiple digital reconstructions or the combined treatment of multiple joints should warrant careful and efficient use of tourniquet time.
  - Regional anesthesia (axillary block, IV regional) may be preferred for the reconstruction of digital deformities. This form of anesthesia may provide a greater duration of postoperative pain control and may minimize the systemic effects of general anesthesia.
  - Avoidance of general anesthesia may minimize the potential risks of cervical spine positioning in patients with cervical instability secondary to rheumatoid arthritis.
  - Procedures that may require the use of bone grafting should involve preoperative discussion with the patient to explain the potential need for bone grafting and to identify potential sources for the graft (i.e., iliac crest, olecranon, distal radius, allograft or synthetic bone substitutes).

### Posttraumatic Injury

- A detailed history and physical examination should be performed.
  - Active and passive PIP joint range of motion should be assessed. Chronic, rigid deformities may require staged procedures with surgical release of the PIP joint before subsequent reconstructive procedures.
  - Radiographs should be reviewed for fractures, joint subluxation or dislocation, and degenerative joint changes.
  - Adjacent joint injuries and pre-existing degenerative changes should be considered during surgical planning.

### Rheumatoid Deformity

Before surgical reconstruction of rheumatoid swan-neck or boutonnière deformities of the digits, a global assessment is completed to characterize the systemic involvement of rheumatoid disease.

- Coordination of medical clearance and perioperative care may be pertinent for patients with medical comorbidities and for patients taking perioperative medications such as corticosteroids.
Preoperative cervical spine evaluation may be indicated to confirm stability of the spine for safe anesthesia administration.

Timing of rheumatoid swan-neck or boutonnière reconstruction should account for other musculoskeletal pathology as reviewed above. Postoperative protocols and anticipated prognosis for recovery should be reviewed carefully with patients to minimize potential conflicts with other medical or surgical management.

**Positioning**

- Surgical reconstruction of the hand is performed typically in a supine position with the upper limb placed on a well-padded hand table.
- A brachial tourniquet is used.
- Preoperative shoulder and elbow assessment will minimize potential difficulties with surgical positioning, particularly for patients with severe limitations to joint mobility or joint instability.

**Approach**

- Careful soft tissue handling is observed to minimize the risk of wound or soft tissue complications. Full-thickness skin flaps are raised during operative exposure.
- A longitudinal midline or curvilinear incision from the proximal phalanx to the DIP joint provides excellent visualization of the extensor mechanism.

**Dorsal Approach**

- For smaller fragments inappropriate for Kirschner wire or screw fixation, the fragment may be excised and the central slip repaired directly into the dorsal base of the middle phalanx using a pullout suture or suture anchor method.
- If the fracture fragment is larger, reduce the fragment, preserving the attachment of the central slip.
- The lateral bands must be restored to their anatomic location, dorsal to the axis of rotation of the PIP joint. Mobilize them by excising the triangular ligament and incising both transverse retinacular ligaments as necessary.
- Approximate the lateral bands distal and dorsal to the axis of rotation of the PIP joint and suture them together using 4-0 nonabsorbable, braided suture.
- The repair is protected and the PIP joint is held fully extended, usually using a transarticular Kirschner wire, for 6 weeks.

**Volar Approach**

- Access to volar structures may be necessary to release the PIP joint. This can be accomplished via a midlateral or a Brunner incision centered at the PIP joint.
- Dissection is carried down to the flexor sheath, elevating full-thickness flaps and preserving the digital neurovascular bundles.
- Between the A2 and A4 pulleys, the membranous portion of the flexor sheath can be elevated to expose the flexor tendons and the underlying volar plate of the PIP joint.
- Arthrodesis and arthroplasty techniques are detailed in separate chapters.

---

**BOUTONNIÈRE RECONSTRUCTION**

**Primary Central Slip Repair**

- Primary repair is accomplished through a dorsal approach.
- After isolating the central slip, assess the redundant tissue with the PIP joint held in full extension.
- Excise a chevron-shaped segment of redundant fibrous tissue, permitting repair of the free tendon edges with 4-0 braided suture using a multistrand, grasping or locking repair method.
- V-Y advancement may be necessary to facilitate repair.
- In the case of an avulsion fracture, identify and carefully elevate the fragment, preserving the attachment of the central slip.
- For smaller fragments inappropriate for Kirschner wire or screw fixation, the fragment may be excised and the central slip repaired directly into the dorsal base of the middle phalanx using a pullout suture or suture anchor method.
- If the fracture fragment is larger, reduce the fragment anatomically and stabilize it using appropriate fixation such as small screws or two small Kirschner wires.
- The lateral bands must be restored to their anatomic location, dorsal to the axis of rotation of the PIP joint. Mobilize them by excising the triangular ligament and incising both transverse retinacular ligaments as necessary.
- Approximate the lateral bands distal and dorsal to the PIP joint and suture them together using 4-0 nonabsorbable, braided suture.
- The repair is protected and the PIP joint is held fully extended, usually using a transarticular Kirschner wire, for 6 weeks.

**Central Slip Reconstruction Using Local Tissue**

- Central slip reconstruction using local tissue may be considered for patients with a flexible deformity and insufficient central slip for direct primary repair. Several methods have been described using a dorsal approach to the extensor apparatus.

**Snow’s Technique**

- Identify the proximal stump of central slip and dissect it free of the surrounding tissues.
- Elevate a distally based flap of extensor tendon sharply, preserving sufficient length to span the tendinous defect.
- Turn the flap down on itself and suture it to any distal tissue as well as the lateral bands using 4-0 braided, nonabsorbable suture.
- After repair, passive PIP joint flexion of no less than 60 degrees must be possible without excessive tension across the repair site.

**Aiche’s Technique**

- Isolate the radial and ulnar lateral bands and divide them longitudinally from the trifurcation of the extrinsic tendon to the triangular ligament.
- Mobilize the dorsal half of each lateral band dorsally and suture them together using 5-0 nonabsorbable, braided suture.
- Lateral band relocation is recommended when the lateral bands are fixed volar to the PIP joint axis of rotation.
Littler and Eatron’s Technique\(^{17}\)
- Carefully isolate the radial and ulnar lateral bands.
- Incise the lateral bands over the middle phalanx. Preserve at least one ORL; otherwise, DIP joint extension will be compromised.
- Mobilize the incised lateral bands dorsally and suture them into the insertion of the central slip.
- If excessive attenuation of the central slip precludes suture stabilization, this repair method is contraindicated.

Matev’s Technique\(^{22}\)
- After isolating the lateral bands from the surrounding soft tissue, incise the ulnar lateral band at the level of the DIP joint and incise the radial lateral band at the mid-point of the middle phalanx.
- Suture the proximal stump of the ulnar lateral band to the distal stump of the radial lateral band over the dorsal digit, thereby lengthening the terminal slip (TECH FIG 1).
- Weave the proximal stump of the radial lateral band into the remnants of the central slip and suture it to the base of the middle phalanx to restore PIP joint extension.
- Postoperatively, the PIP joint is held in full extension for 6 weeks. A temporary transarticular Kirschner wire may be placed to protect the repair.

Central Slip Reconstruction Using Tendon Graft
- When a flexible deformity is present but there is insufficient local tissue for use in central slip reconstruction, a tendon graft reconstruction may be considered.

Extensor Tenotomy
- Hyperextension deformity of the DIP joint may be addressed with extensor tenotomy.\(^{23}\)
- Tenotomy is indicated in the presence of mild, flexible deformities and for patients who have failed prior surgery directed at the PIP joint.
- Extensor tenotomy may be considered as an adjunct to PIP joint arthrodesis performed for chronic boutonnière deformity with associated PIP joint arthritis.
- Make a dorsal incision over the distal two thirds of the middle phalanx.
- Identify the terminal tendon and elevate it proximally over a distance of 1.5 cm from the underlying phalanx and DIP joint.
- Incise the terminal tendon distal to the triangular ligament.
- Preserve the radial ORL so that DIP joint extension is not compromised.
- Passively extend the PIP joint and passively flex the DIP joint to separate the incised tendon ends.

Oblique Retinacular Ligament Reconstruction\(^{16,39}\)
- Reconstruction of the ORL is indicated when a flexible swan-neck deformity develops secondary to an untreated mallet finger. This procedure is suited for patients with a well-preserved DIP joint.
- Make an incision from the ulnar margin of the MCP joint flexion crease and continue it volarly and distally along the radial midaxial line before curving it dorsally to end over the DIP joint.
- Isolate the radial neurovascular bundle from the surrounding tissue. Proximally, identify the A2 pulley. Distally, identify the terminal slip.

TECH FIG 1 • Boutonnière reconstruction using Matev’s technique of lengthening the terminal tendon and reconstructing the central slip using the lateral bands. The ulnar lateral band is incised slightly proximal to the distal interphalangeal joint and the radial lateral band is incised more proximally, at the level of the mid-aspect of the middle phalanx. The proximal stump of the ulnar lateral band is then sutured into the distal stump of the radial lateral band as shown here. The free proximal stump of the radial lateral band (rlb) is then repaired into the dorsal base of the middle phalanx. (Photographs © Copyright of Fraser J. Leversedge, Charles A. Goldfarb, and Martin Boyer.)

TECH FIG 2 • Boutonnière reconstruction using a tendon graft. The tendon graft is passed through a transverse osseous tunnel in the dorsal base of the middle phalanx (P2) and the limbs of the graft are woven into the lateral bands (lb). (Photographs © Copyright of Fraser J. Leversedge, Charles A. Goldfarb, and Martin Boyer.)
Proximal Interphalangeal Joint Flexor Tenodesis

- Creation of a check-rein to PIP joint hyperextension can be accomplished by PIP joint flexor tenodesis or by lateral band tenodesis (described below).
- Via a Brunner or midaxial incision, elevate full-thickness skin flaps to expose the digital flexor sheath, protecting the digital neurovascular bundles.
- Raise as a flap the membranous portion of the flexor sheath, from the distal aspect of the A2 pulley to the proximal edge of the A4 pulley, to expose the underlying flexor tendons.
- Identify one slip of the FDS tendon and divide it proximally at the level of the decussation, leaving its insertion into the base of the middle phalanx intact (TECH FIG 4A,B).
- Pass the divided tendon end from dorsal to volar through a transverse incision in the A2 pulley, about...
3 mm from the pulley’s distal margin, and suture it back onto itself with the PIP joint held in about 20 degrees of flexion (TECH FIG 4C,D).

- Postoperative immobilization with a dorsal block splint maintains the joint in more than 20 degrees of flexion for 6 weeks. Flexion exercises for the PIP and DIP joints are started at 3 weeks postoperatively.

**Lateral Band Tenodesis**\(^{42,45}\)

- The lateral band is rerouted so that it lies volar to the PIP joint axis of rotation and forms a restraint to PIP hyperextension.
- Approach the extensor apparatus via a dorsal curvilinear incision. Expose the Cleland ligament and divide it to access the flexor sheath with preservation of the digital neurovascular bundles.
- Leaving its proximal and distal attachments intact, dissect the dorsally subluxated lateral band free from the central slip and from its distal attachment to the triangular ligament overlying the base of the middle phalanx. Translocate the lateral band volar to the PIP joint axis of rotation, assisted by flexion of the PIP joint.
- At the level of the PIP joint, elevate a dorsally based flap of the flexor sheath 0.5 to 1 cm wide and place the mobilized lateral band volar to the flap. Repair the flap to its anatomic position, restraining the lateral band as an effective pulley.
- Alternatively, the lateral band may be detached from its insertion into the terminal tendon slip and rerouted within a roughly 0.5- to 1-cm segment of the flexor sheath at the A2 pulley before repairing it to the terminal tendon distally (Tech Fig 4A,B).
  - Confirm unimpeded gliding of the lateral band beneath the flexor sheath by gentle proximal and distal traction on the translocated lateral band.\(^{45}\)
  - Postoperatively, a dorsal block splint maintains the joint in more than 30 degrees of flexion. Digital flexion exercises are encouraged early in the postoperative period. Full active PIP joint extension is not allowed for 6 weeks.

**Type III Swan-Neck Reconstruction**

- Reconstruction of a type III swan-neck deformity must address the fixed translocation of the lateral bands dorsal to the PIP joint rotation axis and the associated PIP joint soft tissue contracture.
- Management of these pathologic changes includes lateral band release from the central tendon and from the triangular ligament; translocation of the lateral bands to a position volar to the PIP joint rotation axis; dorsal PIP joint contracture release, with dorsal capsulectomy and collateral ligament release; extensor tenolysis of the digit; and possible limited flexor tenolysis, as indicated, for flexor tenosynovitis.
- Via a dorsal curvilinear incision, raise full-thickness skin flaps to expose the underlying extensor apparatus.
- Release the lateral bands along their dorsal attachment to the central tendon, from the proximal phalanx to their confluence over the dorsal aspect of the middle phalanx.
- Complete a dorsal PIP joint capsulectomy and gradually release the radial and ulnar collateral ligaments, from dorsal to volar, until the PIP joint can be passively flexed to 90 degrees.
- Because the mobile lateral bands will passively translate volar to the PIP joint axis of rotation with passive joint flexion, the lateral bands do not require stabilization.
- After soft tissue releases, the PIP joint is stabilized in 20 degrees of flexion with a temporary transarticular Kirschner wire. The digital reconstructions are protected in a forearm-based splint, removed to permit MCP and DIP joint motion. The wire is removed 2 to 3 weeks postoperatively.

**PEARLS AND PITFALLS**

**Patient selection**

- The PIP joint should be assessed for flexibility.
- Reconstructive options are limited in the presence of PIP joint degenerative changes. Arthrodesis may be the only practical solution.
- Assess for intrinsic tightness in all patients with digital deformity.
- In rheumatoid patients, carefully evaluate the wrist and MCP joint before surgical reconstruction of the interphalangeal joints.
- Tendon ruptures may not be clinically apparent in rheumatoid patients with severe deformity.

**Boutonnière deformity**

- The deformity develops from injury to the central slip.
- Delayed development of the deformity may occur after injury to the central slip.
- Early diagnosis is important. The Elson test is useful in confirming early diagnosis.
- Extension splinting is effective treatment in those who present within 2 to 3 months from the time of injury. A transarticular Kirschner wire holding the PIP joint in extension may serve as an effective internal splint.
- It is important to differentiate boutonnière deformity from PIP joint contracture (pseudo-boutonnière deformity).

**Swan-neck reconstruction**

- In rheumatoid patients a swan-neck deformity can arise from any of the MCP, PIP, or DIP joints. It is critical to identify which type of deformity is present in order to guide treatment.

**Thumb CMC reconstruction**

- Implant interposition arthroplasty may have an increased failure rate due to poor soft tissue restraints and an increased risk of implant dislocation.

**PIP joint implant arthroplasty**

- Avoid implant arthroplasty in patients with a severe PIP joint flexion contracture (more than 45 to 50 degrees).
- Consider arthrodesis for the index PIP joint due to lateral stresses on the joint with pinch.
OUTCOMES

Traumatic Deformity Reconstruction

- Surgery for established boutonnière and swan-neck deformities is technically challenging.
- A variety of surgical options exist; there is little consensus regarding a preferred technique.
- There are relatively few studies evaluating the long-term results after surgery for posttraumatic boutonnière and swan-neck deformities. Direct comparisons may be difficult due to the variations in clinical stage at the time of presentation.

Boutonnière Deformity

- Towfigh and Gruber reported on the results of surgical treatment of 114 flexible posttraumatic boutonnière deformities. The central slip was repaired directly, with local tissue, or reconstructed with a tendon graft. Follow-up averaged 40 months. Seventy-eight patients report good or excellent results. Satisfactory results were observed in 22 patients and poor results in 14 patients.
- Meadows et al. reported on the results of extensor tenotomy performed on 14 fingers with posttraumatic boutonnière deformity. The average preoperative PIP joint flexion contracture was 36 degrees. All the digits had DIP joint extension contractures with an average arc of motion from 6.5 degrees of hyperextension to 4.2 degrees of flexion. Postoperatively, DIP flexion improved to 44 degrees. Ten of the digits had an extension lag averaging 13 degrees. Seven digits had improved extension at the PIP joint by an average of 27 degrees.

Swan-Neck Deformity

- Tonkin et al. reported outcomes of lateral band tenodesis for swan-neck deformity. Thirty digits with swan-neck deformity of various causes were included. Preoperative PIP joint deformity averaged 16 degrees of hyperextension; this was improved to 11 degrees of flexion postoperatively.
- Reconstruction of the oblique retinacular ligament was first described by Thompson et al. They reported improvement in PIP joint hyperextension and DIP joint flexion with this technique. Kleinman and Peterson described similar results with reliable correction of DIP joint flexion and secondary PIP joint hyperextension.

Rheumatoid Deformity Reconstruction

- There is a relative lack of clinical outcomes studies evaluating the long-term results of surgical management for swan-neck and boutonnière deformities in patients with rheumatoid arthritis.
- Kiefhaber and Strickland reported on the results of surgical treatment for type III swan-neck and stage II boutonnière deformities. In 92 patients undergoing lateral band release, extensor tenolysis, and PIP joint dorsal capsulotomy for type III swan-neck deformity, the authors reported an initial increase of 55 degrees flexion at the PIP joint; however, of 15 fingers assessed at 3 and 12 months postoperatively, there was a 17-degree loss of the early postoperative motion gains. Despite this deterioration of postoperative results, the arc of PIP motion shifted toward flexion, improving functional grasp.
- In 19 patients undergoing central slip reconstruction for stage II boutonnière deformity, the authors found unpredictable results and reported that the deterioration of postoperative correction was greater with time. Four of 19 patients were able to extend the PIP joint beyond 20 degrees of flexion and 11 of 19 patients had a PIP joint extension deficit of greater than 45 degrees.
- Tonkin et al. published two separate studies assessing the outcomes of treatment for swan-neck deformities with lateral band translocation and with synovectomy and lateral band release and translocation. While these studies are limited in their conclusions because of the varying stages of disease and their small patient populations, the trend toward positioning the arc of motion into flexion was observed, similar to the study results of Keifhaber and Strickland.
- Several long-term clinical outcomes studies of PIP and MCP joint implant arthroplasties have demonstrated poor correction of preoperative swan-neck or boutonnière deformities and in general have reported poorer results with respect to pain relief and range-of-motion recovery as compared to arthroplasties done for conditions of osteoarthritis or posttraumatic arthritis.
- A review of surgical treatment of varying stages of thumb boutonnière deformity by Terrono et al. concluded that MCP joint synovectomy and EPL rerouting for early, correctable boutonnière deformity had a high rate of deformity recurrence (64%). The authors recommend MCP joint arthrodesis for cases of moderate severity with isolated joint involvement, but in severe cases, MCP joint arthroplasty and interphalangeal arthrodesis is considered.

COMPLICATIONS

- Perioperative complications in the treatment of posttraumatic boutonnière and swan-neck deformities can be avoided by careful patient selection, appropriate intervention, and adherence to proper surgical technique.
- Thorough perioperative patient counseling and education is imperative to avoid unrealistic patient expectations and unanticipated outcomes.
- A successful operative result and the avoidance of perioperative complications in the treatment of a boutonnière or swan-neck deformity in the rheumatoid hand is largely dependent on a thorough preoperative evaluation, correct staging of the pathologic condition, and appropriate timing of operative intervention. While the goals of reducing pain and improving function are primary, patient education is critical for avoiding unrealistic expectations and unanticipated results.

REFERENCES

Chapter 62 OPERATIVE RECONSTRUCTION OF BOUTONNIÈRE AND SWAN-NECK DEFORMITIES

DEFINITION
- Medial epicondylitis involves tendinosis at the origin of the flexor–pronator mass.
- It is commonly referred to as “golfer’s elbow,” although there is a stronger association with racquet sports and manual labor.4

ANATOMY
- The common flexor–pronator origin is primarily on the anterior aspect of the medial epicondyle.
- The common flexor–pronator origin includes the humeral head of the pronator teres, the flexor carpi radialis (FCR), the flexor carpi ulnaris, and a small portion of the flexor digitorum superficialis.
- The palmaris longus also shares the origin, although this is not likely to be clinically relevant.

PATHOGENESIS
- Epicondylitis results from repetitive microtrauma followed by an incomplete reparative response that results in tendinosis, a pathologic state in which the degenerative tendon cannot heal itself effectively.
- Epicondylitis can be seen with medial collateral ligament instability whereby myotendinous overload occurs in an attempt to dynamically stabilize the ulnohumeral joint. In this scenario, ulnar neuropathy often is part of a trio of pathology.

NATURAL HISTORY
- Most patients improve with conservative treatment.
- However, a greater percentage of patients with medial epicondylitis go on to surgical treatment when compared to patients with lateral epicondylitis.3

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients commonly complain of forearm pain rather than elbow pain. At times the inflammation is significant enough to cause irritation of the ulnar nerve as it enters the flexor carpi ulnaris, causing ulnar nerve symptoms (eg, local irritability and distal numbness and tingling).
- Onset usually is insidious, but the patient may recall an inciting event.
- Medial epicondylitis can be present simultaneously with lateral epicondylitis.
- Examination methods include the following:
  - Palpation of the medial epicondyle for tenderness, a universal finding in medial epicondylitis
  - Resisted pronation is highly sensitive for medial epicondylitis.1
  - A decreased ROM suggests intra-articular pathology such as arthritis.
  - If resisted wrist flexion reproduced symptoms, it supports a diagnosis of medial epicondylitis.
  - Tap the ulnar nerve in the cubital tunnel and along its path into the ECU. Presence of a tingling sensation locally prompts further nerve investigation.
  - Flex patient’s elbow maximally, then compress the ulnar nerve just proximal to the cubital tunnel. Presence of hand numbness or tingling prompts further nerve investigation.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs may show calcifications at the flexor–pronator origin.
- MRI will reliably demonstrate increased intratendon signal on T2-weighted sequences. Most will also show increased intratendon signal and/or tendon thickening on T1-weighted sequences.
  - A small percentage of patients may show increased T2 signal in the medial epicondyle or anconeus edema.2
  - Periosteal reaction is not commonly seen on MRI.2
- Electrophysiologic testing (electromyography and nerve conduction studies) are warranted if patients have ulnar nerve symptoms, but with mild ulnar neuropathy these tests have a very low sensitivity.

DIFFERENTIAL DIAGNOSIS
- Pronator syndrome
- Medial collateral ligament injury
- Ulnar neuropathy
- Arthritis
- Cervical radiculopathy
- Malingering

NONOPERATIVE MANAGEMENT
- Appropriate initial treatment includes avoidance of painful activities and symptomatic relief with nonsteroidal anti-inflammatory drugs and ice.
- Daytime wrist bracing for exertional activities
- Physical or occupational therapy to supervise and instruct on stretching and strengthening protocol for patients not otherwise inclined to comply with those instructions
- Although corticosteroid injection at the medial epicondyle has been shown to provide temporary symptomatic relief, it does not affect the natural history.2 Repeat injections should be avoided to avoid tendon weakening and rupture.
- Ulnar nerve injury has been reported with injection, so careful attention should be paid to the location of the nerve and whether or not it is subluxed.

SURGICAL MANAGEMENT
- A minority of patients fail nonoperative management.
- Careful patient selection will ensure an excellent outcome with surgical management.
Preoperative Planning
- Be prepared to address concurrent ulnar nerve pathology. If necessary, ulnar nerve decompression should be performed in situ, using subcutaneous or submuscular transposition.
- In thin patients, and especially those who have lifestyles in which the inner elbow is struck frequently, we prefer submuscular transposition with flexor pronator lengthening, which definitively treats epicondylitis as well.
- Be prepared to address flexor pronator tears or avulsion. These typically will present more abruptly, with acute or chronic pain, ecchymosis, and swelling.
- It will be necessary to débride the ruptured degenerative tissue (Fig 1) and repair it by retensioning it close to the origin and closing the gap with healthier medial and lateral portions of the flexor pronator origin down to the medial epicondyle (as shown in Tech Fig 2D).

Positioning
- The patient is placed in the supine position.
- The arm is externally rotated at the shoulder and padding is placed under the elbow.
- The arm should rest in a position allowing ready access to the medial aspect of the elbow without requiring constant holding by an assistant.

Approach
- The elbow should be examined after the administration of anesthesia to ensure stability, and the result documented in the operative note.
- The goal of surgery is to débride the degenerative tissue at the flexor–pronator origin and create an environment conducive to proper healing of the tendon.

Incision and Dissection
- A 3- to 5-cm incision through the skin only is made beginning just proximal to and in the center of the medial epicondyle and extending distally along the axis of the forearm (Tech Fig 1A).
- Blunt dissection with scissors is carried through the subcutaneous tissues, taking care to preserve medial antebrachial cutaneous nerve branches, which commonly cross the field (Tech Fig 1B).
- The subcutaneous tissues are gently swept away, exposing the fascia of the flexor–pronator mass.
- The ulnar nerve is palpated, and the elbow is put through a range of motion to check for ulnar nerve subluxation. The result is documented in the operative note.
- The fascia overlying the interval between the pronator and FCR is then incised in line with the fibers to expose the tendon origin (Tech Fig 1C). The exact location can be altered depending on clinical examination and the point of maximal tenderness.

**FIG 1** The common flexors can be seen ruptured and retracted distal to the medial epicondyle.
TECH FIG 2 • A. Degenerative tissue is excised. The remaining healthy tendon is stable and cannot be scraped away with a no. 15 blade. B. The anterior portion of the medial epicondyle is scraped or rongeured to remove any remaining degenerative tendon. C. The bony cortex is not violated, however. D. The muscle interval is closed with a running size 0 Vicryl suture and tied with inverted knots. E. Skin closure is done with a running 3-0 Prolene suture.

The pronator is reflected anteriorly and the FCR posteriorly, exposing the abnormal, deeper tendon tissue (TECH FIG 1D).

**Fasciectomy and Partial Ostectomy**

- The abnormal tissue is excised. It can be identified by its grayish, unorganized mucoid appearance. Abnormal tissue will scrape away with a no. 15 blade, but normal tendon will remain attached (ie, Nirschl scratch test).
- The pathologic tissue is débrided to margins showing an organized, tendinous appearance.
- The area of excision usually is 1 to 1.5 cm long and 3 to 5 mm wide (TECH FIG 2A).
- A rongeur is used to roughen the anterior portion of the medial epicondyle to a bleeding surface without removing cortical bone (TECH FIG 2B,C).
- The defect in the tendon is closed with a running absorbable suture, using 0 or 1-0 suture material with a tapered needle (TECH FIG 2D).
- The subdermal layer is closed with buried, interrupted absorbable sutures, followed by a subcuticular skin closure and Steri-strips (TECH FIG 2E).
POSTOPERATIVE CARE

- Postoperatively, the patient is placed in a soft dressing and a removable cock-up wrist brace.
- The elbow is not immobilized, and gentle ROM is allowed immediately.
- The dressing is removed in 3 to 5 days. The patient may perform activities of daily living as tolerated with the wrist brace, removing the wrist brace several times daily for ROM.
- Exertion is avoided.
- A strengthening program is initiated in 6 weeks with a counterforce brace.
- All restrictions are removed at 3 months, but impact activities are not allowed until 4 to 6 months postoperatively. Return of full, pain-free activity can take 6 to 24 months.

OUTCOMES

- Over 85% of all patients will have return to full activities with no pain or only mild, occasional pain. Among high-level athletes, 75% to 85% will return to their previous level. In patients with mild or no ulnar nerve symptoms, the success rate is greater than 95%.1,6
- In patients with more than moderate ulnar nerve symptoms, there is a trend toward less favorable and less predictable outcomes, although a satisfactory result still is possible.
- It is uncommon for a patient to have absolutely no improvement in pain after surgery, even if the subjective outcome is unsatisfactory. Such a result should prompt consideration of incorrect diagnosis or the possibility of secondary gain issues.

COMPLICATIONS

- Medial antebrachial cutaneous nerve injury
- Grip weakness
- Weakness with wrist flexion or pronation
- Hematoma
- Infection
- Ulnar nerve injury
- Medial collateral ligament injury

REFERENCES

DEFINITION
- Lateral epicondylitis involves tendinosis at the origin of the common wrist extensors.
- It is commonly referred to as “tennis elbow” and is likely more correctly termed “lateral elbow tendinopathy.”

ANATOMY
- The common extensor origin is located on the lateral epicondyle.
- The common extensor origin includes the extensor carpi radialis brevis (ECRB), extensor digitorum communis (EDC), extensor digiti minimi, and extensor carpi ulnaris.
- The ECRB is the primary muscle–tendon unit affected, followed by the EDC, but an isolated origin does not exist.

PATHOGENESIS
- Epicondylitis results from repetitive microtrauma followed by an incomplete reparative response, resulting in chronic tendinosis.
- Functionally, this condition can more correctly be described as “gripper’s elbow,” as synergistic wrist extension increases finger flexion strength. Patients afflicted with lateral epicondylar tendinopathy commonly engage in repetitive forceful gripping activities as they lift, pull, twist, and push objects.

NATURAL HISTORY
- Lateral epicondylitis is a self-limiting condition that resolves in over 80% of patients over the course of 1 year.
- Most patients receiving active treatment (eg, anti-inflammatory medication, orthotics, ultrasound, physical or occupational therapy, injections) improve with nonoperative treatment.
- Typically, fewer than 10% of patients require surgical intervention.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Acute phase: lateral elbow pain or ache with activities that typically resolves with rest, ice, or anti-inflammatory medication
- Intermediate phase: lateral elbow pain or ache occurs at rest and may not resolve without prolonged activity restriction
- Chronic phase: pain or ache occurs with sleep and often is unresponsive to rest, medication, and injections.

Examination methods include the following:
- Palpation of the lateral epicondyle for tenderness, a universal finding in lateral epicondylitis
- Pain either at the epicondyle or radiating distally along the ECRB is a positive finding in any of these circumstances:
  - Passive stretch test: With the elbow in full extension, the wrist is flexed and the forearm is pronated.
  - Mill’s test: With the elbow flexed, the forearm slightly pronated, and the wrist slightly dorsiflexed, the patient actively supinates against the examiner, who resists this rotation.

Thompson test: With the elbow extended, the wrist in slight dorsiflexion, and making a fist, the patient dorsiflexes against the examiner, who resists this motion.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs may show calcifications at the extensor origin.
- MRI
  - Increased intratendon signal is reliably demonstrated on T2-weighted sequences.
  - Most also show increased intratendon signal or tendon thickening on T1-weighted sequences.
  - A small percentage of patients may show increased T2 signal in the lateral epicondyle or anconeus edema.
  - Periosteal reaction is not commonly seen on MRI.
- Lateral collateral ligament tears often are overcalled on MRI, but this possibility must be ruled out by an accurate history and pre- and intraoperative examinations.

DIFFERENTIAL DIAGNOSIS
- Synovial plica
- Lateral collateral ligament tear
- Radial tunnel syndrome
- Loose bodies
- Degenerative joint disease (typically early radiocapitellar joint)
- Avascular necrosis of the capitellum

NONOPERATIVE MANAGEMENT
- Appropriate initial treatment includes avoidance of painful activities and symptomatic relief with nonsteroidal anti-inflammatory drugs (NSAIDs) and ice.
- Daytime strapping is biomechanically and clinically effective.
- Nighttime wrist bracing to prevent palmar wrist flexion and prolonged tension on the extensor tendons
- Physical or occupational therapy to supervise and instruct on stretching and strengthening protocol for patients not otherwise inclined to perform these exercises
- Corticosteroid injection has had good response in the early stages of the condition.
- Platelet-rich plasma or blood clot tendon injection and botulinum toxin muscle injection currently are under investigation.

SURGICAL MANAGEMENT
- A minority of patients fail nonoperative management.
- Careful patient selection is critical to ensure an excellent outcome following surgical management.
- No prospective randomized studies have yet been done to examine the advantages of open versus arthroscopic techniques for the treatment of lateral epicondylitis. However, I choose arthroscopic treatment if there are any signs of a plica or synovial irritation (endpoint pain) that will allow direct examination and treatment.
Preoperative Planning
- Be prepared to address concurrent extensor tendon rupture.
- Be prepared to address lateral collateral ligament rupture.

Positioning
- The patient is placed in the supine position.
- The arm is internally rotated at the shoulder, and padding is placed under the elbow.
- The arm should rest in a position that allows ready access to the lateral aspect of the elbow without requiring constant holding by an assistant.
- The elbow should be examined after the administration of anesthesia to ensure stability, and the result documented in the operative note.
- The goal of surgery is to débride the degenerative tissue at the extensor origin and create an environment conducive to proper healing of the tendon.

OPEN LATERAL EPICONDYLAR FASCIECTOMY AND PARTIAL OSTECTOMY
- A 3- to 5-cm incision through skin only is made beginning at the proximal edge of the center of the lateral epicondyle and extending distally through the mid-radiocapitellar joint plane along the axis of the forearm (TECH FIG 1A).
- Blunt dissection with scissors is carried out through the subcutaneous tissues to expose the EDC aponeurosis and the ECRL.
- The more anterior and reddish ECRL and the more tendinous EDC originating on the epicondyle are identified (TECH FIG 1B).
  - The interval between the ECRL and the EDC aponeurosis is then split in line with the mid-radiocapitellar joint plane. Distally, a fat stripe along the aponeurosis typically is seen along this dissection plane.
  - A small posterior EDC flap is created for later closure and the ECRL is elevated anteriorly revealing the underlying ECRB origin. The origin may be obliterated by degenerative tissue.
- The abnormal tendon tissue to be excised can be identified by its grayish, unorganized mucoid appearance and should be sharply excised. Care is taken to dissect the ECRB off the underlying capsule.
- Abnormal tissue typically will scrape away with a no. 15 blade, but normal tendon will not (Nirschl scratch test). Sometimes the ECRB tissue cannot be dissected free from the underlying capsule or it has already ruptured from its origin, and the underlying joint becomes exposed (TECH FIG 1C). This will not affect outcome.
- If exposed, the joint should be inspected for degenerative change, which, if present, typically is found beneath a plica. The plica should be removed (TECH FIG 1D).
- The pathologic tissue is débrided to margins showing an organized, tendinous appearance. Complete resection of the ECRB origin is not necessary if healthy viable portions remain (TECH FIG 1E).
- The proximal stump of the ECRB should not be repaired, because it has ample attachments and will not retract significantly.
- The area of excision usually is 1 to 2 cm long and 5 to 10 mm wide.
- The undersurface of the EDC often is affected, and degenerative tissue should be similarly removed.
- A rongeur is used to roughen the anterior portion of the lateral epicondyle to a bleeding surface without removing cortical bone.
- In some cases, patients have a significantly prominent epicondylar tip. This can be removed, especially if patients are focused on this finding and they are very thin, but the early recovery period will be more painful (TECH FIG 1F).
- The defect in the tendon is closed with a running absorbable suture, using 0 or 1-0 suture material with a tapered needle. If a capsular rent occurs, there is no need to make a separate capsular closure, but the proximal tendon repair should be close to the epicondyle and watertight to avoid a postoperative ganglion (TECH FIG 1G).
- The subdermal layer is closed with buried, interrupted absorbable sutures, followed by a subcuticular skin closure and Steri-strips.

**TECH FIG 1** • A. Surgical approach uses a 3-cm incision over the lateral epicondyle and can be extended in line with the forearm axis to avoid injury to the lateral collateral ligament. B. The interval between the tendinous EDC aponeurosis and the darker muscle of the ECRL is entered, and the ECRL is elevated off the underlying ECRB. (The patient’s hand is to the right.) (continued)
TECH FIG 1 (continued) C. The degenerative ECRB is sharply excised. At times, as in this example, it is not possible to separate the ECRB and capsule, and a portion of the capsule also is excised. Neighboring tendon of the EDC is scraped with a no. 15 blade to remove loose degenerative tissue. D. In this example, it was possible to excise the degenerative portion of the ECRB without the underlying capsule. E. The anterior portion of the lateral epicondyle is scratched clean of degenerative tissue with a no. 15 blade or rongeur but not decorticated. F. Some intact, normal ECRB fibers are left if they are present. G. Closure is done with an inverted-stitch size 0 Vicryl suture on a tapered needle in a running fashion.

TECH FIG 2A

ARTHROSCOPIC LATERAL EPICONDYLAR FASCIECTOMY AND PARTIAL OSTECTOMY

- The patient is positioned according to surgeon preference for elbow arthroscopy.
- We prefer the lateral decubitus position with the aid of the Tenet Spider Arm Holder (Smith & Nephew Inc., Andover, MA).
- If prone or lateral, it is advantageous to keep the elbow well above the plane of the chest wall to optimize anterior superomedial portal camera positioning.
- The elbow is filled with 30 to 50 mL of irrigating solution until distended. An anterior superomedial portal is established.
- A small longitudinal portal incision is made about 2 cm proximal to the medial epicondyle and just anterior to the medial intermuscular septum. A curved hemostat is used to spread underlying tissues and feel the medial intermuscular septum, and then is slid along its anterior surface to the lateral, then anterior humerus.
- This is repeated with the scope trocar, which is then passed distally along the anterior humerus toward the radiocapitellar joint, piercing the capsule and entering the joint.
- Documentation of intra-articular (eg, loose bodies, plica [TECH FIG 2A], osteochondritis dissecans, arthritis) and lateral capsular or tendon pathology (TECH FIG 2B) is made, and they are treated appropriately.
- A 25-gauge needle is placed from outside in to choose an optimal radiocapitellar portal at the upper rim of the radial head at or just proximal to the joint level (TECH FIG 2C).
- A shaver is used to débride the abnormal capsule lining the EDC origin. Abnormal ECRB is débrided until normal superficial tendon fibers are identified and protected. If ruptured, all degenerative portions of the ECRB are excised. Normal, shining ECRL fibers can be seen superficially as well as the dark muscular appearance (TECH FIG 2D).
- Débridement should not proceed posterior to the mid-radiocapitellar plane, to avoid injury to the lateral collateral ligament.
- A bone-cutting shaver or a less aggressive burr used in reverse will roughen, but not decorticate, the anterior aspect of the lateral epicondyle from the capitellum back to the portal entry site (TECH FIG 2E).
- A hooked electrocautery probe is useful to divide a plica to facilitate its resection.
- Lateral and posterior portals are closed with 3-0 Prolene sutures, and the medial portal is left open for rapid resolution of fluid distention and pain relief.
POSTOPERATIVE CARE

- Postoperatively, the patient is placed in a soft dressing and a removable cock-up wrist brace.
- The elbow is not immobilized, and gentle range of motion is allowed immediately.
- The dressing is removed in 2 to 5 days. The patient may perform activities of daily living as tolerated with the wrist brace, removing the wrist brace several times daily for range of motion exercises.
- Exertion is avoided.
- A strengthening program is initiated at 6 weeks.
- All restrictions are removed at 3 months, but impact activities are not allowed until 4 to 6 months postoperatively. Pain-free full activity may require 6 to 12 months.
OUTCOMES

- Over 85% to 90% of all patients will have return to full activities with no pain. The remaining 10% to 15% have significant pain relief and strength, but do not return to normal preinjury levels. These outcomes hold true for both short follow-up and more than 10 years of follow-up.\textsuperscript{4,5,7} Future prospective randomized trials will elucidate whether the reported more rapid recovery of the arthroscopic treatment is realized.

- It is uncommon (\(<5\%\) of cases) for a patient to have absolutely no improvement in pain after surgery, even if the subjective outcome is unsatisfactory. Such a result should prompt consideration of incorrect diagnosis or the possibility of secondary gain issues.

COMPLICATIONS

- Hematoma
- Infection
- Lateral collateral ligament injury
- Weakness in grip strength

REFERENCES

DEFINITION
- Extensor carpi ulnaris (ECU) subluxation occurs when the separate subsheath of the sixth dorsal compartment is torn or attenuated.
- Incompetence of the ECU subsheath permits subluxation or dislocation of the ECU tendon out of the ulnar groove of the ulna, with a painful click noted on resisted supination, ulnar deviation, and palmar flexion.

ANATOMY
- The dorsal extensor retinaculum of the wrist is composed of two primary layers (FIG 1).
  - The supratendinous retinaculum originates 2 to 3 cm proximal to the radiocarpal joint and ends distinctly at the carpometacarpal joints. The most radial attachment on the distal radius forms the radial septum for the first extensor compartment. The supratendinous retinaculum courses medially, surrounding the ulna.¹⁰
  - The supratendinous retinaculum participates as a block to tendon subluxation for the first through fifth extensor compartments but does not function to prevent subluxation of the ECU.
  - The infratendinous retinaculum runs from the radiocarpal to the carpometacarpal joints. It is found deep to the fourth and fifth extensor compartments on the radius. The ECU lies in its own separate fibro-osseous subsheath, which represents a duplication of the infratendinous retinaculum.
  - The ECU sheath is separated from the supratendinous retinaculum by loose areolar tissue.
- The fibro-osseous subsheath of the sixth dorsal compartment overlies 1.5 to 2.0 cm of the distal ulna and arcs from the radial to ulnar wall of the ECU osseous groove. It ensheathes the ECU and maintains the tendon tightly in the groove (FIG 2).
  - The ECU subsheath contributes to the dorsal portion of the triangular fibrocartilage complex (TFCC).

PATHOGENESIS
- The mechanism of a traumatic injury most commonly is active ECU contraction combined with forced supination, palmar flexion, and ulnar deviation.
  - Injuries resulting from trauma can range from simple attenuation to complete rupture of the ECU fibro-osseous sheath.
  - Traumatic ECU subluxation is commonly reported in association with racket sports, baseball, and golf.

NATURAL HISTORY
- Chronic subluxation of the ECU tendon over the ulnar prominence of the groove in the distal ulna can lead to painful snapping of the tendon with supination and pronation. This can progress to ECU tendinopathy.
  - An injury to the ECU sheath resulting in volar dislocation of the ECU tendon can result in distal radioulnar joint (DRUJ) instability. This joint laxity may cause pain and dysfunction, eventually leading to degenerative changes.
  - Dislocation of the ECU tendon removes a dynamic stabilizer of the DRUJ.
The subsheath of the sixth extensor compartment represents a component of the dorsal peripheral TFCC. Disruption can result in static instability of the DRUJ.

Some patients may experience relatively minor ECU subluxation and related symptoms that do not progress and often improve with minimal intervention.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

Patients may present following an acute injury or, more commonly, in the subacute phase, complaining of persistent ulnar wrist pain aggravated by activities requiring pronation and supination. They may relate the sensation of a “click.”

A complete physical examination of the patient’s ulnar-sided wrist complaints should be conducted to elucidate associated pathology and rule out confounding conditions in the differential diagnosis.

- Palpation and inspection of sixth dorsal compartment and ECU tendon helps to localize the area of discomfort and focus the physical examination. Most acute sheath ruptures and tendinopathies will be tender to palpation at the level of the distal ulna and groove. Tenderness at the joint line may indicate an associated TFCC tear.
- In range-of-motion testing, an inflamed ECU tendon usually will be most painful with full passive radial wrist flexion, although motion most often is full except in the acute setting.
- If the tendon dislocates with passive supination, palmar flexion, and ulnar deviation, the ECU is grossly unstable. If the addition of ECU contraction is required for frank dislocation, some inherent stability remains. Pain with subluxation is a critical finding when contemplating surgical treatment.
- In resisted finger abduction, pain over the wrist and ECU tendon signifies an inflammatory ECU condition, possibly due to subluxation or overuse.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Routine anteroposterior (AP), lateral, and oblique radiographs in neutral rotation are important.
- Pronated grip views and other specialized plain radiographs of the wrist can provide information on other pathologies that contribute to ulnar-sided wrist pain (see Differential Diagnosis).
- MRI is the most sensitive and specific imaging modality to detect ECU subluxation (FIG 3A).
  - The sensitivity increases in studies with both wrists positioned in pronation, neutral, and supination. This allows side-by-side comparison with the asymptomatic wrist and adequately shows the position of the ECU relative to the ulnar osseous groove in all three positions.
  - The actual subsheath tear may or may not be visualized.
  - Often, inflammation and partial interstitial tendon disruption are visualized.
- An MRI arthrogram may depict a subsheath tear and, therefore, an injury to the peripheral TFCC.
  - Contrast may extravasate into the sixth extensor compartment (FIG 3B).
  - The study will also provide additional information concerning the remainder of the TFCC and the integrity of the intercarpal ligaments.
- Ultrasound allows dynamic assessment of ECU stability and can be useful in quantifying the degree of ECU tendon subluxation.

**DIFFERENTIAL DIAGNOSIS**

- ECU tenosynovitis
  - Fullness and pain with palpation of the sixth dorsal compartment
  - The patient often can reproduce a painful snap or click with supination and ulnar deviation, even in the absence of ECU subluxation.
- TFCC injury
  - Tenderness with direct palpation of the TFCC
  - Pain with axial loading and rotation of the ulnar-deviated wrist (TFCC compression test)
  - Instability of the DRUJ with manual manipulation when compared to the contralateral wrist
- Lunotriquetral ligament injury
  - Tenderness to palpation over the dorsal lunotriquetral articulation
  - The patient may also describe pain and crepitance with ulnar deviation of the wrist.
  - Provocative maneuvers for lunotriquetral ligament injuries (ie, ballottement test, ulnar sniff box test) have sufficient sensitivity but poor specificity.
- Ulnocarpal impaction syndrome
  - More common in patients with ulna-positive variance
  - Usually a dynamic phenomenon occurring during forceful activity or pronated gripping
The physical examination findings will be similar to those of TFCC injury, with pain on forced ulnar deviation of the wrist (TFCC stress test) that increases with rotation through the loaded ulnocarpal articulation. Tenderness will be elicited along the ulnar border of the triquetrum and the distal ulna.

Ulnar styloid nonunion
- Uncommon; occurs more commonly with widely displaced styloid fractures at the time of injury
- The intimate relationship with the ulnar TFCC attachment means that symptomatic nonunion can be associated with TFCC dysfunction and DRUJ instability.

DRUJ arthrosis
- Patients present with complaints of pain, swelling, and stiffness. The pain is exacerbated by forearm rotation, particularly when performed with manual compression of the DRUJ.

NONOPERATIVE MANAGEMENT
- In the acute setting (less than 3 weeks since injury), immobilize the patient in an above-elbow cast. The wrist should be in neutral to slight pronation, neutral to slight radial deviation, and neutral to slight extension.
- The cast is removed about 4 to 5 weeks later, and therapy is initiated. A sugartong splint is fabricated with the forearm in slight pronation, and a progressive active and active-assisted ROM protocol is initiated.
- Three weeks later, a forearm-based splint is provided and the patient slowly progresses back to activities.
- Unprotected, full activity is allowed 3 to 4 months after the initiation of treatment.

The literature does not agree on the efficacy of nonoperative treatment. Rowland produced a compelling case report of surgical treatment in acute, traumatic ECU subluxation.

In this case, the intraoperative findings showed the edges of the ruptured subsheath to be separated by a minimum of 7 mm, regardless of the position of the wrist.

These findings suggest that nonoperative treatment could routinely lead to clinical ECU subluxation and persistent symptoms.

SURGICAL MANAGEMENT
- Surgical reconstruction of the ECU subsheath should be considered in patients with clinically significant symptoms related to painful subluxation of the ECU tendon, especially if the injury is more than 3 weeks old. Treatment must be individualized based on the needs and expectations of the patient.
- The guiding principles for surgical repair depend on the essential osteofibrous sheath lesion present at the time of surgery.
- Inoue and Tamura classified three distinct patterns of injury (TABLE 1).

Treatment of type C lesions
- Separation of the fibro-osseous sheath from bone necessitates repositioning of the tissue at the ulnar margin of the groove (see False Pouch Reconstruction and Imbrication for Type C Lesions).
- Stretching and attenuation of the sheath without separation from bone may be effectively treated by suture imbrication, depending on the quality of the tissue.

Although this chapter describes reconstruction of traumatic ECU subluxation, reconstruction also may be considered in the patient with inflammatory arthropathy and secondary volar dislocation of the ECU tendon. The opportunity to stabilize the ulnar wrist and DRUJ while forestalling progression of deformity may lead the patient and surgeon toward surgical care even in the absence of pain.

Preoperative Planning
- All preoperative information obtained from the history, the physical examination, and imaging studies should be thoroughly reviewed and synthesized into the operative plan. For example, a patient with joint line tenderness and an MRI indicating a TFCC injury might benefit from wrist arthroscopy before any open procedure is done.
- Dorsal synovitis or tenosynovitis requiring débridement
- The existence of a shallow ulnar osseous groove and the need to deepen the groove surgically for added stability
- The paucity of soft tissue for reconstruction and the need for another graft choice for subsheath reconstruction. Graft options include the palmaris and flexor carpi ulnaris tendons.

Positioning
- The patient is positioned supine on the operating table with the injured extremity extended on an armboard in the usual manner.
- Initially, the procedure is performed with the arm extended and pronated. If the wrist must be placed in a neutral or supinated position, the elbow is flexed.

Approach
- A precise incision is chosen to allow for the predetermined method of reconstruction.
- Make a Brunner zigzag incision over the sixth extensor compartment.
- The incision begins 1 to 2 cm distal to the ulnocarpal joint and is carried proximally 5 cm.
- Identify and protect the dorsal cutaneous branch of the ulnar nerve in the distal incision.
- Incise the extensor retinaculum on its far ulnar border and carefully separate it from the underlying sixth extensor compartment fibro-osseous sheath (see Fig 2).
- Conservation of and planned incision in the extensor retinaculum is critical to allow for its use as a sling to stabilize the ECU tendon (see Retinacular Sling Reconstruction for Type A and B Lesions)
- Following exposure, inspect the separate fibro-osseous sheath of the ECU and note the position of the tendon through pronosupination.
- Perform a tenosynovectomy as indicated.

RETINACULAR SLING RECONSTRUCTION\(^2\) FOR TYPE A AND B LESIONS
- Retinacular sling reconstruction\(^2\) is performed when the sheath is ruptured and not repairable.
- At the level of the ulnar groove, create a rectangular flap of tissue, 2 to 3 cm wide, based on the septum separating the fifth and sixth extensor compartments (TECH FIG 1A).
- Pass this radially based sling in an ulnar direction, volar to the ECU tendon, then fold it back radially over the tendon and secure it to the ulnar portion of the fifth compartment (TECH FIG 1B).
- This places the superficial surface of the retinaculum in contact with the ECU tendon.
- Avoid constricting the ECU tendon by ensuring that the sling is wide and loose, which still prevents subluxation of the tendon.
- The portion of the extensor retinaculum not used for the sling is repaired anatomically.
ALTERNATE RETINACULAR SLING RECONSTRUCTION FOR TYPE A AND B LESIONS

- An alternate retinacular sling reconstruction\(^9\) requires the development of an ulnarly based, rectangular flap, 2 to 3 cm wide, of supratendinous retinacular tissue, beginning at Lister’s tubercle or over the second extensor compartment if more length is required (TECH FIG 2A).
  - The flap is based on the ulnar septum of the fifth extensor compartment.
- Pass the tissue ulnarly, deep to the ECU tendon, then back over the tendon to create the sling.
- This places the deep surface of the retinaculum in contact with the ECU tendon.
- Insert suture anchors on the radial and ulnar margins of the ulnar groove, and use this suture to stabilize the flap (TECH FIG 2B).
- Avoid constricting the ECU tendon, as discussed previously.

RETINACULAR GRAFT AUGMENTATION FOR TYPE A AND B LESIONS

- Retinacular graft augmentation\(^4\) is performed when the sheath is ruptured and not repairable.
- Harvest a 2 × 2-cm square graft from the distal supratendinous retinaculum (TECH FIG 3A).
- Secure this graft to the periosteum on the ulnar and radial borders of the ulnar osseous groove to maintain the ECU tendon within the groove.
- Roughen the bone surface to encourage attachment, and place suture anchors at the anatomic attachment sites along the radial and ulnar borders of the ulnar osseous groove.
- Secure the harvested graft to the margins of the ulnar groove, allowing bony contact between the graft and the ulna (TECH FIG 3B).
  - Place the deep surface of the graft against the tendon.
  - This provides secure fixation and does not rely on questionable soft tissue for early fixation.

FALSE POUCH RECONSTRUCTION AND IMBRICATION FOR TYPE C LESIONS

- False pouch reconstruction and imbrication\(^6\) is done when the fibro-osseous sheath of the ECU tendon is attenuated and stretched, but intact. The tendon subluxates out of the ulnar groove during forearm rotation (TECH FIG 4A, B).
- Incise the sheath on its ulnar margin (TECH FIG 4C).
- If the sheath has separated from the deep periosteum, roughen the medial surface of the ulna deep to the false pouch (TECH FIG 4D).
Insert suture anchors at the site of the true ulnar attachment of the sheath (TECH FIG 4E).

- Use suture from the bone anchors to capture and repair the fibro-osseous sheath, securing it to the prepared bone bed (TECH FIG 4F).

- The effect is to imbricate the attenuated sheath and obliterate the false pouch.

- Place additional permanent sutures to complete the repair (TECH FIG 4G).

TECH FIG 4 • Type C lesion. A. The supratendinous retinaculum has been incised, revealing the ECU subsheath. The subsheath is inflamed, stretched, and attenuated, allowing tendon subluxation. B. Diagrammatic representation of a type C lesion in which the sheath has pulled away from the bone. C. An incision is made in the attenuated subsheath, allowing visualization of the tendon. Despite MRI findings that indicate potential intrasubstance injury (see Fig 3A), the tendon itself appears normal. D. The bone underlying the ulnar subsheath flap is roughened with a rasp. E,F. Mini–bone anchors are used to secure the tissue to the ulnar border of the groove and imbricate the subsheath. G. Additional permanent sutures complete the repair.

DEEPENING OF THE ULNAR OSSEOUS GROOVE

- Deepening of the ulnar osseous groove is an optional technique that may be used to address all lesion types.
- This technique is added to the reconstruction when preoperative studies or intraoperative findings suggest that a shallow ulnar osseous groove contributes significantly to subluxation of the ECU tendon (TECH FIG 5A).
- Retract the ECU tendon out of its groove.
- Carefully elevate the periosteum and a thin layer of bone along the ulnar 2 to 3 cm of the ulnar osseous groove using a sharp, curved osteotome (TECH FIG 5B).
  - The radial border is used as a hinge to expose the underlying cancellous bone.
  - Precise elevation of the osteoperiosteal flap ensures adequate coverage of the raw bony surfaces.
- Remove cancellous bone using a small curette (TECH FIG 5C), no deeper than 2 to 3 mm.
- The cortical bone flap is then returned to its position and tamped down using a small bone tamp (TECH FIG 5D).
  - The periosteum is repaired (TECH FIG 5E).
- Treat any remaining exposed bony surface with bone wax.

TECH FIG 5 • Deepening of the ulnar osseous groove. A. ECU tendon in a shallow ulnar groove. B. A sharp curved osteotome is used to create an osteoperiosteal “trapdoor” with a hinge of periosteum radially. C. A curette is used to remove cancellous bone. D. A bone tamp is used to close the trapdoor gently and deepen the osseous groove. E. The periosteum is then secured using 4-0 suture if feasible.
CLOSURE AND SPLINTING
- Perform passive motion testing to ensure that the ECU tendon is stable in its groove following reconstruction or repair.
- Close the extensor retinaculum in a side-to-side fashion using absorbable suture.
- Deflate the tourniquet and obtain hemostasis.
- Following routine skin closure and dressing placement, place a sugartong splint with the forearm mildly pronated and the wrist in mild extension and radial deviation.

PEARLS AND PITFALLS

| Indications | Symptomatic subluxation of the ECU tendon at the ulnar osseous groove
| Acute injuries often are effectively treated with immobilization. |
| Approach | Protect against injury to the dorsal cutaneous branch of the ulnar nerve.
| Incise the supratendinous retinaculum along its ulnar border, remembering that the sixth extensor compartment is a separate, deeper structure. |
| Carefully inspect the ECU subsheath for rupture or attenuation, and adjust the reconstruction based on those findings. |
| Evaluate the ECU subsheath looking for a concomitant TFCC disruption. |
| Inspecting the ulnar osseous groove | Consider deepening the ulnar groove to augment stability. |
| Subsheath repair versus reconstruction | Repair the subsheath if the tissues appear substantial. |
| Reconstruct the sheath if in doubt. |
| Perform passive motion testing in the extremes of supination mild wrist flexion and ulnar deviation following the procedure to ensure that the problem has been addressed. |
| Pitfalls | Avoid injury to the dorsal cutaneous branch of the ulnar nerve. |
| Do not repair the supratendinous retinaculum to the ulna, because this will limit forearm rotation. |
| If creation of an ulnar extensor retinaculum sling is required, avoid making it overly tight, inhibiting ECU tendon gliding. This can be easily accomplished by placing a pediatric feeding tube beside the ECU during the sling construction. |
| Return to activity | Full activity is not considered until 3 to 4 months following surgery. |

POSTOPERATIVE CARE
- The sutures are removed 2 weeks after surgery, and an above elbow cast is applied with the forearm and wrist positioned in the manner described.
- This cast is removed 2 weeks later, and therapy is initiated with use of a fabricated sugartong splint and progressive range of motion as described in Nonoperative Management.

OUTCOMES
- No large conclusive studies on which to base outcomes have yet been published.
- A few case reports and smaller series have reported good results following surgical treatment for ECU subluxation.1-4,6,7,9 Our experience mirrors these reports.

COMPICATIONS
- The uncommon nature of ECU subluxation, the uniformly acceptable surgical outcomes, and the lack of large surgical case series result in a sparse list of postoperative complications. Trends with which to define “routine” postsurgical complications are simply not present.
- Complications that have been reported in the literature include the following:
  - Complex regional pain syndrome
  - Decreased wrist motion
  - Decreased grip strength

A1 Pulley Release for Trigger Finger With and Without Flexor Digitorum Superficialis Ulnar Slip Excision

Alexander M. Marcus

DEFINITION
- Trigger finger is an entrapment of the digital flexor tendon(s) by the flexor tendon sheath.
- Trigger finger progressively causes inflammation, pain, catching, locking, and reduced range of motion (ROM).

ANATOMY
- The flexor digitorum profundus and superficialis (flexor pollicis longus in the thumb) pass under (dorsal to) the flexor sheath, which consists of annular and cruciate pulleys.
- The A1 pulley, which is volar to the metacarpophalangeal joint (MCP), is the most proximal pulley (except for a thickening known as the palmar aponeurotic pulley), and is almost always the primary site of entrapment (FIG 1).

PATHOGENESIS
- High angular loads at the A1 pulley and often, other causes of local inflammation result in a flexor tendon sheath whose inner diameter is too narrow to accommodate the flexor tendon(s).
- This size mismatch causes hypertrophy (thickening) of the A1 pulley and tendinous swelling.
- These changes exacerbate the size discrepancy, setting up a cycle in which entrapment causes hypertrophy and hypertrophy causes entrapment.

NATURAL HISTORY
- Trigger digits may develop spontaneously or may occur after swelling, from either trauma or a period of heavy use.
- Trigger digits may:
  - Resolve spontaneously (especially in mild cases)
  - Persist with the same level of symptoms
  - Advance to passively correctable locking
  - Become indefinitely locked in either flexion or extension

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history may include any of the following:
  - Pain in the distal palm, often radiating proximally along the path of the flexor tendon
  - Pain occurring with use, and difficulty grasping objects or flexing the digit
  - Clicking or locking with digital flexion and extension, which is often perceived to be at the proximal interphalangeal joint (PIP)
  - The finger being stuck in flexion, often in the morning, requiring the other hand to straighten it
  - Being unable to flex or extend the digit fully, or at all (FIG 2)
- The history should elicit the following information:
  - Whether the patient has had a trigger finger before, in either the currently involved or any other digit
  - Previous treatments for trigger finger, and the extent and duration of the result

FIG 1 • To understand trigger finger and its release, an appreciation of the flexor tendon pulley system of the finger (A) and thumb (B) is required.

FIG 2 • Reduced flexion caused by ring finger triggering.
A1 PULLEY RELEASE FOR TRIGGER FINGER

Chapter 66

Whether the condition began after a particular incident or period of increased hand use
The patient’s medical history should be evaluated for conditions that may cause trigger fingers and alter treatment, as well as commonly associated conditions, including:
- Diabetes
- Rheumatoid arthritis and other inflammatory arthropathies
- Amyloidosis, most commonly secondary to renal disease requiring dialysis
- Lysosomal storage diseases
- Carpal tunnel syndrome (often seen in patients with trigger finger, but not causally related)

The history and physical examination should exclude other conditions that cause overlapping symptoms, including:
- Nerve compression
- Muscle weakness
- Tendon interruption from laceration (partial or complete) or rupture
- Pulley rupture and bowstringing
- Joint or soft tissue contracture or swelling, or both
- Extensor tendon laceration or subluxation, especially at the MCP joint
- Joint dislocation

The physical examination should include the following:
- ROM test, which is the most objective measure of severity. If the patient has absolutely no active motion at the PIP (or thumb IP), consider tendon interruption.
- Palpation of the palm. If the A1 pulley is not tender, strongly consider other diagnoses. Examine for other causes of the patient’s symptoms, including Dupuytren’s contracture, tendon sheath ganglion, PIP joint injury, and A3 pulley triggering.
- Examination of the extensor apparatus. Rule out extensor mechanism abnormalities that may cause overlapping signs or symptoms, including a popping sensation with ROM.
- Perform a neurovascular examination. Carpal tunnel syndrome often is associated with trigger finger. Muscle weakness may cause similar findings. Any neurovascular deficit should be documented before treatment.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs can exclude some unusual causes of trigger finger symptoms and can assess for arthritis, but are not required to make the diagnosis of trigger finger.
- If other pathology is suspected, MRI can be useful.
- Nerve conduction studies can evaluate for anterior interosseous nerve (AIN) compression, which may mimic a trigger thumb or concomitant carpal tunnel syndrome.

DIFFERENTIAL DIAGNOSIS
- Extensor tendon subluxation at the MCP joint
- Joint contracture or injury, including MCP locking due to collateral ligaments and a swollen PIP joint
- Soft tissue swelling or contracture, including Dupuytren’s contracture
- Partial tendon laceration
- Triggering at the A3 pulley (rare)
- Muscle weakness, including flexor pollicis longus weakness secondary to AIN palsy
- Masses (especially tendon sheath ganglions), which may cause A1 pulley tenderness

NONOPERATIVE MANAGEMENT
- Observation and splinting
  - Mild, early cases often resolve spontaneously or do not bother the patient significantly.
  - Use of a night extension splint may help alleviate swelling and morning locking.
  - Unless the PIP joint remains locked, in either flexion or extension, for several weeks, delayed treatment usually does not significantly change either the options available or their results.
- Injection
  - Long-term relief in most affected digits with one to three injections.²
  - Results in diabetic patients are not as good,¹⁴ but it still is worth trying.
- Injection technique (FIG 3)
  - 1 mL of 2% plain (no epinephrine) lidocaine and 1 mL of a soluble corticosteroid solution (eg, betamethasone or

FIG 3 • Technique for trigger digit injection.
dexamethasone) in a single syringe with a 25-gauge needle is given.
- The A1 pulley area is prepped with an antiseptic solution such as alcohol or betadine.
- A topical spray may be used to reduce discomfort.
- 1 to 2 mL is injected in the sheath and subcutaneously. Avoid injecting into the tendon itself; if increased resistance is encountered, this may be the cause.

**SURGICAL MANAGEMENT**

- Indications for surgical treatment include:
  - Symptoms that persist despite conservative management
  - Inability to flex or extend the finger even passively: this is an indication for earlier release to prevent secondary joint contracture.
- Open A1 pulley release is indicated for any routine trigger finger.
- Percutaneous trigger finger release:
  - Requires an actively triggering digit so the patient can flex to confirm needle placement and pulley release.
  - Is used primarily for the middle and ring fingers. Use in other digits may place digital nerves in jeopardy.
  - In patients with very extensive synovitis, such as that seen in rheumatoid arthritis, lysosomal storage diseases, or amyloidosis associated with end-stage renal disease, releasing the A1 pulley percutaneously or through a routine, small incision is contraindicated. A more extensive tenosynovectomy and sometimes ulnar slip of the flexor digitorum superficialis (FDS) resection (USSR) is required.

**Preoperative Planning**

- Clinical notes and any studies obtained preoperatively should be reviewed.

**Approach**

- Anesthesia is obtained by injecting 2% plain (no epinephrine) lidocaine subcutaneously around the incision and in the tendon sheath.
  - Sedation will mitigate the discomfort associated with the injection and the tourniquet. If sedation is used, the patient should be allowed to wake up in time to demonstrate complete active digital flexion and extension without locking, documenting successful pulley release.
  - A standard volar approach to the A1 pulley is made with either an oblique, transverse, or longitudinal incision.
  - For resection of the ulnar slip of the sublimis, a Bruner-type or midaxial longitudinal incision is used over the distal portion of the proximal phalanx.

**OPEN A1 PULLEY RELEASE**

**Incision and Exposure**

- A 1-cm incision is placed over the A1 pulley.
  - Longitudinal (TECH FIG 1A)
  - If a transverse incision is used, it is placed in a palmar skin crease (TECH FIG 1B):
    - Distal palmar crease for small and ring fingers
    - Proximal palmar crease for index finger
    - An incision between creases may be required for middle finger release
  - Oblique or Bruner-type
  - Avoid crossing palmar skin creases at a right angle with any incision type.
  - Incise only the skin and dermis with a no. 15 blade.
  - Bluntly spread subcutaneous tissue to avoid injury to the digital nerves.
  - The digital neurovascular structures adjacent to the A1 pulley must be retracted and protected.
  - Extensive dissection and exposure of these structures is not required.
  - The radial digital nerve of the thumb is at the greatest risk because it typically crosses the surgical field (TECH FIG 1C).
Chapter 66 A1 PULLEY RELEASE FOR TRIGGER FINGER

**TECHNIQUES**

**Begin the A1 pulley incision with a knife, taking care not to cut deep into the tendon.**

**Complete the release with scissors until the pulley leaflets can be spread completely apart (TECH FIG 2B).**

**Avoid cutting any significant portion of the A2 pulley (or the oblique pulley in the thumb).**

---

**Performing the Release**

- Clear off the A1 pulley with sponge dissection.
- The A1 pulley is not incised until it is clearly visualized (TECH FIG 2A).
  - Use of small right-angle retractors helps provide needed visualization.
- Begin the A1 pulley incision with a knife, taking care not to cut deep into the tendon.
- Complete the release with scissors until the pulley leaflets can be spread completely apart (TECH FIG 2B).
- Avoid cutting any significant portion of the A2 pulley (or the oblique pulley in the thumb).

---

**TECH FIG 1 • (continued)**

B. Position of transverse incisions for trigger finger release in relation to the palmar skin creases and the A1 pulley. C. The digital neurovascular structures are right next to the A1 pulley and must be protected. This schematic demonstrates the proximity of the digital nerves and arteries. Because the radial digital nerve of the thumb may cross at the level of the A1 pulley, it is particularly vulnerable.

**TECH FIG 2 • A.** The digital neurovascular structures are retracted, and the A1 pulley has been cleared of all overlying soft tissue. B. The A1 pulley has been completely released. C. The palmar pulley remaining after A1 release. D. The flexor tendons are bluntly separated and pulled out of the wound, which then flexes the digit. (A–D. Top is proximal.)
The A2 pulley is separated from the A1 pulley either by a space (where there is no sheath) or a section of very thin sheath tissue.9

If the tendons appear constricted by the palmar aponeurotic pulley proximal to the A1 pulley, it should also be released (TECH FIG 2C).

Bluntly separate the tendons (in the fingers) and pull the tendon(s) out of the wound (TECH FIG 2D). Minimize any direct handling of the tendons.

Completion

A limited tenosynovectomy may be performed if required (TECH FIG 3A). Any unusual resected tissue or mass is sent to the pathology department for analysis (TECH FIG 3B).

Confirm that the patient can actively flex and extend the finger (TECH FIG 3C,D). If the active ROM is not full or significantly improved, or if the tendons are not passing under the remaining pulleys, consider ulnar slip of the flexor digitorum superficilias resection (USSR) as well as etiologies other than standard trigger finger.5,7,8,10

Release the tourniquet, and irrigate the wound.

Obtain hemostasis, usually with manual compression. Reinspect the wound, check for any arterial bleeding, and confirm the finger has brisk capillary refill.

Close the skin with interrupted sutures and place a mildly compressive dressing.

PERCUTANEOUS A1 PULLEY RELEASE

- The patient must have active triggering.
- The procedure is performed with a sterile prep in either the office or operating room.
- Hyperextend the MCP joints over a towel to help displace the neurovascular structures dorsally.
- Palpate the A1 pulley.
- Inject the local anesthetic (with or without corticosteroid) as described for nonoperative treatment.
- An 18- or 19-gauge needle is placed through the A1 pulley, centered radial to ulnar, and into the tendon (TECH FIG 4).

Open A1 Pulley Release With FDS Ulnar Slip Excision (USSR)

- The patient actively flexes the finger which moves the needle, confirming location.
- The needle is pulled back slightly so that it remains in the A1 pulley, but not the tendon.
- The needle is rotated so that the bevel is in line with the longitudinal axis of the pulley.
- Sweep the needle proximally and distally until grating is no longer felt.
- The patient should be able to actively flex and extend the finger without triggering, confirming release.

The initial steps are performed in the same manner as described for an open A1 pulley release.

A Bruner-type or ulnar midaxial incision is made over the proximal phalanx.

For a Bruner-type incision, a zigzag skin incision is made with the points over the finger flexion creases (TECH FIG 5).

The skin only is opened with a no. 15 blade, and blunt dissection is used to separate the neurovascular bundles as a unit. Formal dissection of the nerve and artery, or separating them from each other, is not required.

Care should be taken to stay more centrally as the incision proceeds distally (over the PIP and distal interphalangeal joints) because the neurovascular bundles can become less radial and ulnar on the digit.

The skin only is opened with a no. 15 blade, and blunt dissection is used to separate the neurovascular bundles as a unit. Formal dissection of the nerve and artery, or separating them from each other, is not required.

Care should be taken to stay more centrally as the incision proceeds distally (over the PIP and distal interphalangeal joints) because the neurovascular bundles can become less radial and ulnar on the digit.
Inspect the tendon distal to the A2 pulley, confirming that there is no catching under the A3 pulley and that an enlarged, bulbous flexor digitorum profundus is not catching under the distal end of the A2 pulley. In either of these cases, USSR may or may not relieve the problem.

Ulnar slip excision is then performed in either distal-to-proximal fashion or with a proximal-to-distal technique.

**Distal-to-Proximal Ulnar Slip Excision**

- Just distal to the A2 pulley, incise the tendon sheath, creating a radially based flap. This flap may be repaired later with 6-0 Prolene if desired.
- With the PIP joint maximally flexed, isolate and cut the ulnar slip of the flexor digitorum superficialis distally, taking care to preserve the vinculum brevis.
- Pull the tendon into the proximal wound and cut it as far proximal as can be reached safely.
- Confirm that the tendons now pass smoothly under the pulley system through a complete ROM.
- Release the tourniquet. Irrigate the wounds.
- Obtain hemostasis, usually with manual compression. Reinspect the wound, check for any arterial bleeding, and confirm the finger has brisk capillary refill.
- Close the skin with interrupted sutures and place a mildly compressive dressing.

**TECH FIG 5** • A Brunner-type incision. (Courtesy of Dominique Le Viet.)

**Proximal to Distal Ulnar Slip Excision**

- Examine the part of the tendon meant to glide under the A1 and A2 pulleys for enlargement, degeneration, longitudinal splitting, or loss of its smooth surface (**TECH FIG 6A**).
- Fully flex the finger, identify the ulnar and radial slips of the FDS distally, and split them longitudinally in a proximal direction (**TECH FIG 6B**).
- With the finger and wrist flexed, cut the ulnar slip of the FDS as far proximal as possible. Pull the ulnar slip distally, carefully separating it through the chiasm, and, with the PIP joint flexed, cut it distally at the edge of the A3 pulley. The tendon slip is than removed from either direction; a loop of 3-0 wire can be used to separate adhesions if necessary (**TECH FIG 6C**).
- Release the tourniquet. Irrigate the wound.
- Obtain hemostasis, usually with manual compression. Reinspect the wound, check for any arterial bleeding, and confirm the finger has brisk capillary refill.
- Close the skin with interrupted sutures and place a mildly compressive dressing.

**PEARLS AND PITFALLS**

| Satisfactory release | ▪ Confirm that the tendon glides freely after release. |
| ▪ If there was no joint contracture preoperatively, the patient should have significantly improved active (or passive, if the patient is under general anesthesia) ROM. |
| ▪ If not, assess the cause and correct. |

| Avoid injury to A2 pulley | ▪ Release of more than 25% of the A2 pulley may cause bowstringing, reducing flexion ROM, and require pulley reconstruction. |

**POSTOPERATIVE CARE**

- A soft dressing is applied with all of the digits free (**FIG 4**). Active ROM as tolerated is encouraged. Minimize dressing bulk to avoid inhibiting motion.
- Formal therapy is required only if the patient has difficulty regaining ROM.
- Patients whose digits were locked preoperatively are more likely to need therapy. This may be started within the first week.
- Scar massage is encouraged after the wound is sealed.

**OUTCOMES**

- Surgical release of trigger digits has a high success rate with a low complication and recurrence rate.\(^1\),\(^12\)

**COMPlications**

- Injury to digital nerve or artery
- Bowstringing
- Wound infection or dehiscence resulting in a flexor sheath infection

**REFERENCES**

DEFINITION
- Carpal tunnel syndrome (CTS) is the most common nerve compression condition in the upper extremity.
- Carpal tunnel release (CTR) is one of the most commonly performed procedures in the United States.
- CTS is a compressive neuropathy of the median nerve at the wrist.
- Early stages of CTS are reversible with treatment.
- Later or more severe stages of CTS may not be (fully) reversible.

ANATOMY
- The carpal tunnel or carpal canal is a space bounded by the carpal bones dorsally, the trapezium and scaphoid radially, the hook of the hamate ulnarly, and the transverse carpal ligament palmarly (FIG 1A).
- The carpal canal contains the median nerve and nine digital flexor tendons, along with the accompanying tenosynovium (FIG 1C).
- Anatomic anomalies include the following:
  - A persistent median artery
  - Muscle anomalies
  - Median nerve branching anomalies (FIG 1B)
  - Extraneous masses or structures may be found within the carpal canal, including sarcoïd and ganglion cysts.

PATHOGENESIS
- Most cases of CTS are idiopathic.⁹
- Some cases are associated with systemic conditions, such as rheumatoid arthritis, diabetes, thyroid disease, chronic renal failure, and sarcoïdosis. CTS is associated with pregnancy.
- There is an association of CTS with cumulative trauma and repetitive use.⁹
- Increased pressure within the carpal canal is associated with CTS.²,⁶,¹¹
- Peripheral neuropathy and CTS have also been associated with shear forces on the nerve, such as with a traction injury.⁷

FIG 1 • A. Cross-section of the carpal tunnel. B. The carpal tunnel has been fully released and the median nerve motor branch is seen branching from the nerve proximally and penetrating the radial portion of the transverse carpal ligament. C. Cross-section of the carpal tunnel with the ulnar artery and nerve superficial to the TCL. (B: Copyright Thomas R. Hunt III, MD.)
NATURAL HISTORY
- CTS may have a variable course. It can improve, remain stable, or get more severe.
- Patients with severe CTS have motor and sensory changes and may have muscle weakness and atrophy.9
  - Patients with extremely advanced CTS frequently have little pain but constant numbness and weakness.

HISTORY AND PHYSICAL FINDINGS
- Presenting symptoms can be variable: some patients with mild CTS present with moderate to severe pain, numbness, and paresthesias, whereas other patients have minimal symptoms until their syndrome is severe and there is thenar muscle atrophy.
  - A common finding that drives patients toward a remedy is nocturnal waking.
- The surgeon should obtain a full medical history to identify for risk factors for CTS such as hypothyroidism and diabetes.
- The surgeon must understand the patient’s occupational and recreational hand activities and any antecedent trauma that might contribute to symptoms.
  - The surgeon should inquire about activity triggers for the CTS.
- The surgeon should obtain a sense of symptom progression and severity.
  - Questions should be asked about sensory and motor function, pain pattern, and nocturnal waking.
- The physical examination includes the neck and shoulder girdle; the supraclavicular, infraclavicular, and axillary area; the humerus and elbow; the forearm; and the wrist and hand.
  - It is important to generate a list of findings that may be responsible for the pain or paresthesias other than CTS.
  - In addition to the standard joint evaluation with range of motion and assessments of stability, it is important to palpate the course of the nerves and elicit the Tinel sign along the course of the paracervical, brachial plexus, median, ulnar, and radial nerves.
  - The Tinel sign is mild, moderate, or severe subjective findings of radicular pain. The mechanical external stimulus threshold for depolarization–repolarization is lowered in a nerve that has a peripheral neuropathy. Anatomic distribution also is important.
  - Phalen’s sign: Wrist flexion decreases the anatomic volume of the carpal canal and raises pressure in patients with CTS. The pattern of paresthesia can be important.
  - Carpal tunnel compression test: The mechanical external stimulus threshold for depolarization–repolarization is lowered in a nerve that has a peripheral neuropathy.
  - Two-point discrimination: In peripheral neuropathy the ability to distinguish one or two points is diminished.
  - Decreased range of motion and palmar wrist swelling can be indirect indications of tenosynovium in the carpal canal, and also any intra-articular wrist pathology.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- AP, lateral, and oblique radiographs are not mandatory in the workup if the wrist examination is completely normal. If there is any possibility of wrist pathology, these studies should be obtained.
  - Other imaging studies are not indicated in routine cases. In cases of recurrent CTS, MRI should be obtained to gain further information regarding a complete versus incomplete release of the transverse carpal ligament (TCL) or evidence of median nerve compression, tenosynovitis, and scarring.1
- Electrodiagnostics: Nerve conduction studies (NCS) and electromyography (EMG) are important. CTS can be graded based on NCS and EMG findings:
  - CTS mild: Increased sensory or motor distal latency; may see decreased amplitude
  - CTS moderate: Increased nerve conduction velocity
  - CTS severe: EMG shows signs of chronic denervation with positive fibrillations and sharp waves or unobtainable recordings on the electrodes to median innervated muscles.
  - Although some experts believe the absence of any of the above electrodiagnostic findings means that there is no CTS, others believe that false-negatives exist due to sensitivity issues with NCS and EMG.4

DIFFERENTIAL DIAGNOSIS
- Cervical radiculitis
- Cervical pathology, joint disease, disc disease, facet disease with foraminal stenosis
- Thoracic outlet syndrome
- Brachial plexopathy
- Syringomyelia, motor neuron disease, myelopathy
  - “Double crush syndrome”
- Shoulder pain related to instability, intra-articular pathology, subacromial impingement
- Acromioclavicular joint pathology
- Medial epicondylitis
- Lateral epicondylitis
- Cubital tunnel syndrome
- Radial tunnel syndrome
- Pronator syndrome
- Elbow pathology instability or contracture
- Forearm or wrist tenosynovitis
- Wrist tenosynovitis, extensor, flexor, or De Quervain tenosynovitis
- Digital tenosynovitis (trigger finger)
- Guyon canal syndrome
- Hypothenar hammer syndrome
- Wrist or carpal fracture
- Intra-articular wrist pathology

NONOPERATIVE MANAGEMENT
- Mild CTS can often be modulated through conservative means.5,16
- Any systemic conditions should be identified and treated.5,16
- Activity modification can be attempted, especially if the activity includes highly repetitive loading of the hand, wrist, and upper extremity.
- Wrist splints can be introduced.
- The physician can recommend or prescribe nonsteroidal anti-inflammatory drugs (NSAIDs).
- Corticosteroid injection into the carpal canal can be considered (FIG 2).
  - Temporary relief from such an injection indicates that surgical decompression is likely to be successful.
- Hand therapy can be considered.
- Some believe oral vitamin B12 treatment can be helpful in some cases.
SURGICAL MANAGEMENT

- The diagnosis of CTS is confirmed by either the presence of classic clinical symptoms and signs or positive NCS or EMG studies.
  - If the NCS or EMG findings are negative, at least one trial of corticosteroid injection should be given to evaluate the clinical response.
  - The surgeon should confirm that a trial of conservative treatment has been undertaken without a cure.
  - The surgeon should confirm that differential diagnoses have been considered.
  - The surgeon should understand that the presence of other diagnoses and conditions will affect the overall results of CTS treatment; this needs to be discussed with the patient before, not after, surgery. In fact, one should strongly consider delaying CTS treatment to control or improve other conditions that may be amenable to nonoperative treatment.
  - If the above conditions are met, CTR should have good to excellent results in more than 90% of cases.\(^\text{14}\)
  - In the case of recurrent CTS, the key to success is patient selection. Although there are scant data to correlate the preoperative evaluation with results, the patient’s clinical course, response to conservative treatment, and interpretation of electrodiagnostic studies and MRI should be carefully considered before revision surgery.

Positioning

- CTR surgery is performed with the arm outstretched on a hand table.
- Pneumatic tourniquet use facilitates accurate identification of critical anatomic structures.
- Loupe magnification is recommended.
- Anesthesia can be by general anesthesia or regional anesthesia such as an axillary block or Bier block.

- Experienced surgeons can perform CTS safely under wrist block or local infiltration.

Approach

- The goal of CTR surgery is to decompress the median nerve at the carpal canal by complete division of the TCL to allow the carpal tunnel to expand.
- A volar exposure is used, but incision position and length vary.
- The locations of critical deep structures are defined using superficial landmarks and a line drawn down the axis of the fourth ray and another drawn obliquely across the palm in line with the ulnar border of the abducted thumb (Kaplan cardinal line) (FIG 3).

OPEN CARPAL TUNNEL RELEASE

Exposure

- Mark the skin incision location, beginning at the intersection of the Kaplan cardinal line and a line drawn along the radial border of the fourth ray, and ending at the wrist flexion crease (TECH FIG 1A).
  - Use a longitudinal hypothenar crease if available.
  - The incision may be placed anywhere along this mark (TECH FIG 1B), depending on the surgeon’s preference. I prefer the midpoint of the proximal third of the palm.
- The incision should be long enough to allow full access to the proximal to distal extent of the TCL to ensure full TCL division. This generally can be achieved without having the incision extend proximal to the wrist flexion crease.
Dissect in line with the incision using a scalpel or scissors, through the subcutaneous fat and the palmar fascia down to the TCL (TECH FIG 1C).

Frequently, the palmaris brevis muscle is encountered directly superficial to the TCL. It is incised and “feathered” from the ligament for adequate visualization of the TCL.

Incise the TCL over a small segment, avoiding injury to deep structures (TECH FIG 1D).

Contents of the carpal canal will have a characteristic appearance due to the tenosynovium.

Place an instrument such as a mosquito clamp or Carroll elevator into the carpal canal, just deep to the TCL (TECH FIG 1E).

This defines the undersurface of the TCL, the location of the hamate hook, and the proposed direction for release.

Visualize the superficial surface of the TCL along its course and place a right-angle retractor to protect the critical structures located between the skin and the ligament (TECH FIG 1F,G).

**TECH FIG 1** • **A.** A longitudinal incision is marked for an open carpal tunnel release. **B.** Either all or a limited portion of this incision may be used, depending on the surgeon’s preference. **C.** The palmar fascia has been incised, the deep fat retracted ulnarily, and the palmaris brevis muscle fibers dissected revealing the transverse fibers of the TCL. **D.** The distal portion of the TCL is carefully incised with a no. 15 knife blade. **E.** A mosquito clamp is placed deep to the TCL in a distal to proximal direction. **F.** A right angle retractor is utilized to visualize the proximal TCL and the distal forearm fascia. **G.** The same retractor is then utilized to visualize the distal TCL to allow complete release. (B–G: Copyright Thomas R. Hunt, III, MD.)
Transverse Carpal Ligament Release

- Staying ulnar in the canal but still leaving a 2-mm cuff of TCL attached to the hamate hook, release the TCL under direct vision proximally and distally with a scalpel, scissors, or mini-meniscotome Beaver blade.
  - Keep a radially based TCL leaflet over the median nerve.
- Release the distal forearm fascia proximally (see Tech Fig 1F).
  - This tissue may be a secondary compression site, especially in patients with two wrist flexion creases.
- Completely divide the TCL and inspect the median nerve and canal contents (see Tech Fig 1G).
  - In rare instances a space-occupying lesion will require removal (ie, “billowing” synovium in a patient with rheumatoid arthritis).
- In primary CTR procedures without systemic disease, there is no role for internal neurolysis or tenosynovectomy (TECH FIG 2).3,8,10
- The wound is closed and sterile dressings are applied.
- Use of a splint is based on the surgeon’s preference.

SINGLE-INCISION ENDOSCOPIC CARPAL TUNNEL RELEASE (MODIFIED AGEE TECHNIQUE)14

Exposure

- Mark out the palmaris longus, the flexor carpi radialis, and the flexor carpi ulnaris.
- Make a transverse 1- to 2-cm incision in a wrist flexion crease centered over or just ulnar to the palmaris longus (TECH FIG 3A).
  - If the palmaris longus is not present, incise halfway between the flexor carpi radialis and the flexor carpi ulnaris.
- Expose the palmaris longus and retract it radially with a Ragnell retractor.
- Identify the flexor retinaculum deep to this structure (TECH FIG 3B).
- Incise the flexor retinaculum and create a distally based U-shaped flap 1 cm wide. Elevate and retract it with a mosquito clamp.
  - On the undersurface of the retinaculum adherent tenosynovium is frequently seen.
  - Visible deep to the opening should be the tenosynovium-covered digital flexor tendons and median nerve.
- Pass small and large hamate finders down the carpal canal in an antegrade manner to evaluate the space and the location of the hamate (TECH FIG 3).
- Palpate the tip of the instruments as they become subcutaneous distal to the distal edge of the TCL at the Kaplan cardinal line.
  - Make sure these instruments are not palpable subcutaneously in the proximal third of the palm, which would indicate incorrect placement superficial to the TCL and carpal canal and probably within the canal of Guyon.
- Use the tenosynovial elevator and pass it proximally and distally a dozen times along the axis of the fourth ray to dissect tenosynovium from the undersurface of the TCL.
  - A “washerboard effect” should be felt with this maneuver.

Device Insertion

- Introduce the assembled Agee endoscopic carpal tunnel release (ECTR) device into the carpal canal, with the scope directed palmarly.
- The undersurface of the TCL with its characteristic transverse striations is visible.
- While viewing the monitor, advance the instrument until the distal edge of the TCL is identified.
- The distal edge is noted by a transition from the white, transverse fibers of the TCL to the yellow amorphous midpalmar fat, which often contains visible vessels and nerves.
- Using your nondominant hand on the palm, perform a ballottement maneuver to help distinguish the transition between the midpalmar fat and the distal edge of the TCL while viewing the signal from the endoscope within the carpal canal on the monitor.
- In the palm, palpate the tip of the ECTR device as it emerges into the subcutaneous space just distal to the TCL. Drive the device with the other dominant hand (TECH FIG 4).
- The transillumination pattern from the ECTR device light source changes from underneath the TCL to the midpalmar fat.

### Transverse Carpal Ligament Release
- Elevate the blade and withdraw the device slowly, cutting the TCL from distal to proximal. Keep the device pressed up against the undersurface of the TCL so no structures come between the blade and the TCL; cut only the TCL (TECH FIG 5).
- Cut only when visualization is excellent. If needed, withdraw the device and redefine the undersurface of the TCL in the manner detailed above until visualization is ideal.
- Repeat the above step as needed until there is a full release of the TCL, with good separation of radial and ulnar leaflets from proximal to distal.
- With a full release, it should not be possible to visualize the radial and ulnar leaflets simultaneously.

**TECH FIG 4** The surgeon’s nondominant index and long digits palpate the tip of the endoscopic carpal tunnel release device as it emerges into the subcutaneous space just distal to the transverse carpal tunnel ligament. The transillumination pattern from the device light source changes from underneath the transverse carpal ligament to the midpalmar fat.

**TECH FIG 5** After careful identification of the distal edge of the transverse carpal ligament (A), the ligament is released from distal to proximal (B). (continued)
Chapter 67 CARPAL TUNNEL RELEASE: ENDOSCOPIC, OPEN, AND REVISION 2663

TECH FIG 5 • (continued) C. This is the start of the TCL division using the Agee device. The blade is elevated (center) and is shown starting to divide the TCL from distal to proximal. The median nerve is just seen radial to the blade. (Copyright Ekkehard Bonatz, MD.)

TWO-INCISION ENDOSCOPIC CARPAL TUNNEL RELEASE (CHOW TECHNIQUE)

- Make the proximal incision and create the distally based U-shaped flap of antebrachial fascia in the manner described for the single-incision ECTR technique.
- Introduce a clamp, elevator, or trocar under the TCL.
- Advance the instrument until it is palpable in the palm subcutaneously distal to the TCL.
- Make a second small incision to expose the tip of the instrument, usually at the junction of the middle and proximal thirds of the palm.
  - Take care to identify the superficial arch, common digital nerves, and fibers of the distal TCL in the area.
  - A variety of techniques (open or scope-assisted) can be used at this point, including slotted trocars for two-incision endoscopic release, or use of a mini-meniscotome blade or scissor or other cutting instrument with a retractor or elevator to protect the median nerve and flexor tendons from the TCL cutting instrument.
- The complete distal TCL division can be ascertained by direct visualization, also taking note that the vessels and nerves have not been injured.
- A pitfall of the two incision techniques, aside from the potential injury to the palmar arterial arch and/or the branches of median or ulnar nerve, is incomplete release of the TCL distally. Therefore, inspection of the operative site with magnifying loupes at the distal incision is important.

REVISION RELEASE FOR RECURRENT OR RESIDUAL CARPAL TUNNEL SYNDROME

- If the recurrent CTS is due to prior incomplete release, revision surgery can be attempted using an ECTR technique; otherwise, open release is indicated (TECH FIG. 6A,B).
- Use a generous skin incision, incorporating previous incisions as needed.
- Perform the release using a similar technique to that described for primary open CTR.
  - Scarring often requires scalpel dissection, and separation of superficial tissues from the TCL is difficult.
- Carefully separate the TCL (in the area of its previous division) from the underlying median nerve.
  - Dense scarring of the median nerve to the TCL is expected and will place the nerve in jeopardy during this exposure.
- Completely release the TCL and the scarred median nerve, taking great care to protect the median nerve motor branch.
- Use an operating microscope to inspect the median nerve for signs of damage or scarring.
Part 6  HAND, WRIST, AND FOREARM  •  Section VII  NERVE COMPRESSION AND INJURY

POSTOPERATIVE CARE

- Traditionally, CTR patients were managed in wrist splints for 1 to 3 weeks after surgery. However, multiple studies have shown that faster recovery occurs when the wrist is not splinted postoperatively.
- Temporary postoperative splints may still be indicated in specific clinical scenarios, such as open revision surgery.
- Hand therapy is helpful in the postoperative period, especially if the patient is having difficulty with full digital active and passive motion.
- Grip and pinch strength, subjective symptom measures, and functional evaluations are helpful to manage the postoperative course.
- Some patients have prolonged periods of tenderness under the TCL, or pillar pain on the thenar or hypothenar side of the proximal palm, and require extended hand therapy and periods of time to gradually increase hand strength and endurance for hand activities.

OUTCOMES

- There should be greater than 95% good or excellent results. This randomized, double-blinded multicenter study compared open and single portal endoscopic CTR and showed statistically significant improvements in the endoscopic group between 6 weeks and 3 months postoperatively in terms of pain and hand strength compared to that of the open group, and equivalent good results in both groups at 1 year.
- Stutz et al reported on a retrospective series of 200 patients who underwent a secondary exploration during a 26-month period at a single institution for persistent or recurrent CTS symptoms after CTR. There were 108 cases of incomplete release of the TCL. Twelve patients had evidence of median nerve laceration during the index procedure. Forty-six patients had scarring of the nerve to surrounding tissues. In 13 patients the cause of their problem could not be determined.
- Varitimidis et al reviewed 22 patients (24 wrists) who underwent revision open CTR after an initial ECTR and who had

TECH FIG 6 • (continued) C. Revision carpal tunnel release with NeuraGen tube around scarred branch of median nerve.

- Create a TCL flap through Z-lengthening and tissue rearrangement if flexor tendon prolapse or palmar migration of the median nerve seems likely.

Hypothenar Fat Pad

- When revision CTR reveals median nerve scarring, surgical tactics to improve the environment around the nerve after the neurolysis to reduce rescarring are attractive. Strickland has described this technique in several publications. The tissue is readily available and has been shown to be of benefit. In a 1996 article, 62 patients were reviewed. Results were good based on pre- and postoperative patient satisfaction scores, with only three transient minor complications.
- Dissect the fat pad to the level of the ulnar nerve and artery, and advance the radial edge to cover the median nerve.
- Sew this edge to the radial flap of the TCL.

Palmaris Brevis Flap

- Rose et al described this flap in 1991.
- Expose the thin palmaris brevis muscle on the ulnar side of the CTR incision.
- Divide it from its insertion in the subcutaneous space and transpose or rotate it into a position covering the median nerve.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Poor patient selection</th>
<th>Perform a full history and physical examination and contemplate the entire list of differential diagnoses.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Incomplete release of TCL</td>
<td>Whatever technique is used, make sure it is performed in a technically proficient manner. Confirm complete TCL division, especially distally.</td>
</tr>
<tr>
<td>Damage to median nerve</td>
<td>The surgeon must be able to identify the various anatomic structures and distinguish them. The median nerve must be protected during CTR. In techniques where the median nerve is visualized, inspection should be performed after TCL release and before skin closure.</td>
</tr>
</tbody>
</table>

An external epineurotomy to expose the bands of Fontana on the surface fascicles of the median nerve is recommended in the case of significant nerve scarring.

If there is minimal nerve scarring or damage, the wound can be closed in the usual manner.

If nerve injury is dramatic and rescarring seems likely, cover the damaged nerve with a hypothenar fat pad flap, palmaris brevis muscle flap, vein wrapping, or neural conduit (TECH FIG 6C).
persistent CTS. Twenty-two patients had incomplete TCL release. One patient had a partial and another a complete median nerve transection. One patient had a Guyon canal release instead of a CTR. Twenty patients returned to work, 15 at the previous level and 5 at lighter duty. The two patients with nerve injuries continued to do poorly, one requiring a vein-wrapping procedure.

**COMPLICATIONS**
- Incomplete TCL release
- Median nerve scarring or damage (especially the common digital nerve to the third web space and the thenar motor branch)
- Ulnar nerve or artery damage
- Sympathetically mediated pain syndrome
- Damage to palmar arterial arch

**REFERENCES**
2. Diao E, Shao F, Liebenberg E, et al. Carpal tunnel pressure alters median nerve function in a dose-dependent manner: a rabbit model for carpal tunnel syndrome. J Orthop Res 2005;23:218–223.
DEFINITION

- Pronator syndrome and anterior interosseous syndrome are compression neuropathies of the median nerve and its main branch, the anterior interosseous nerve (AIN), at the elbow and proximal forearm.

ANATOMY

- The median nerve passes in the distal upper arm between the brachialis and the medial intermuscular septum, with the brachial artery sitting lateral to it.
- A rare supracondylar process may arise from the distal aspect of the humerus, giving origin to a fibrous band extending to the medial epicondyle. This is the ligament of Struthers.
- If a ligament of Struthers is present, the median nerve passes underneath it.
- At the elbow, the median nerve sits underneath the lacertus fibrosus and then typically passes between the superficial (humeral) head and the deep (ulnar) head of the pronator teres.
- In 20% of individuals, the deep head is absent or consists of a small fibrous band.
- Motor branches to the palmaris longus, flexor carpi radialis, flexor digitorum superficialis, and flexor digitorum profundus typically branch from the median nerve in an ulnar direction proximal to the pronator teres.
- Under the pronator teres, the AIN branches in a radial direction from the median nerve, and both pass underneath the fibrous arcade of the flexor digitorum superficialis.
- The surgeon should be cognizant of the cutaneous nerves passing over the antecubital and proximal forearm region. Damage to these nerves can result in numbness and paresthesia, as well as symptomatic neuromas in the forearm.
- Anomalous muscles and nerve branches may be present, the most common of which is the so-called Martin-Gruber anastomosis.
- The surgeon should also be aware of more proximal or distal branching of the AIN from the median nerve.
- The Martin-Gruber anastomosis, which occurs in about 15% of the population, consists of branches from either the median nerve or AIN to the ulnar nerve.

PATHOGENESIS

- Compression of the median nerve in the proximal forearm is rare compared with carpal tunnel syndrome.
- Median nerve compression in the proximal forearm has been labeled as either pronator or anterior interosseous syndromes.
- The true incidence of median nerve compression in the proximal forearm is difficult to ascertain, as is the relative contribution of the various potential impinging structures.
- Numerous studies have shown that the most common causes of median nerve compression in the region of the elbow and proximal forearm seem to be fascial bands and muscular anomalies of the pronator teres and the fibrous arcade of the flexor digitorum superficialis.
- Less common sites of nerve compression include the lacertus fibrosus and the ligament of Struthers (in cases with an existing supracondylar process).
- A large number of additional structures have been identified as potential sources of compression of the median nerve. These include an accessory bicipital aponeurosis and a variety of anomalous muscles, the most frequently cited of which is the accessory head of the flexor pollicis longus muscle, or Gantzer’s muscle.
- A persistent median artery penetrating the median nerve also has been described.
- Space-occupying lesions such as lipomas or scarring from trauma can result in nerve compression.
- Anterior interosseous syndrome caused by nerve compression must be differentiated from Parsonage-Turner syndrome, or mononeuritis.

NATURAL HISTORY

- Compression of the median nerve in the forearm often is transient, due to excessive physical activity or swelling from injury.
- Recovery from Parsonage-Turner syndrome can be prolonged, but the prognosis usually is good without surgical decompression.
- The natural history and prognosis of pronator syndrome is not well understood.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Classically, pronator syndrome presents as paresthesia in the median nerve distribution with minimal or no weakness. The patient also may complain of pain localized to the proximal forearm that is increased with activities. There may be a focal area of increased pain localizing to the specific area of compression.
- In severe cases, weakness of the anterior interosseous innervated muscles—the flexor pollicis longus, the index and long flexor digitorum profundus, and the pronator quadratus—might be seen, as well as select thenar muscles.
- Theoretically, patients may have paresthesia in the distribution of the palmar cutaneous branch of the median nerve, in contrast to carpal tunnel syndrome.
- AIN syndrome presents as diminished motor function of the index (and long) flexor digitorum profundus, flexor pollicis longus, and pronator quadratus without injury or specific known cause.
- The patient typically complains of spontaneous loss of dexterity and voices specific complaints related to flexion of the thumb IP joint and/or index DIP joint.
- Decreased sensation is not a common presenting symptom.
  - In cases of space-occupying lesions or scarring from trauma compressing the nerve, one would expect to see sensory symptoms as well as motor abnormalities.
  - Patients suffering from Parsonage-Turner syndrome often will experience a prodromal viral-type illness together with significant pain for several days or weeks before the onset of weakness.

- Physical examinations to perform include:
  - **Pronator compression test.** Paresthesia in the median nerve distribution within 30 seconds is considered a positive test. The test is nonspecific and can be seen with carpal tunnel syndrome.
  - **Resisted PIP flexion of long finger.** Paresthesia in the median nerve distribution and pain in the forearm are considered a positive test. The test is thought to be consistent with compression of the median nerve at the fibrous arcade of the flexor digitorum superficialis.
  - **Resisted pronation test.** Paresthesia in the median nerve distribution and pain are considered a positive test. A positive finding is consistent with compression of the median nerve by the pronator teres.
  - **Elbow flexion test.** Paresthesia and pain are considered a positive test. A positive test is thought to be consistent with lacertus fibrosis compression of the median nerve.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Electrodiagnostic studies are often not helpful in pronator syndrome. Numerous studies have shown that symptoms and outcome of surgery do not correlate well with electrodiagnostic studies.
- In anterior interosseous syndrome, electrodiagnostic studies will confirm denervation of the anterior interosseous muscles.
- Electrodiagnostic studies are most valuable in the diagnosis of proximal median nerve compression for ruling out carpal tunnel syndrome.

- Ultrasonography and MRI are valuable tests for identifying space-occupying lesions such as lipomas or ganglions.
- Plain radiographs of the proximal forearm and elbow may reveal a supracondylar process or anatomic variation.

**DIFFERENTIAL DIAGNOSIS**

- **Carpal tunnel syndrome**
- **Mononeuritis, or Parsonage-Turner syndrome**
- **Other form of neuritis**

**NONOPERATIVE MANAGEMENT**

- In the acute phase, rest, immobilization, and avoidance of aggravating activities, such as repetitive pronation and heavy gripping, should be recommended.
- Forearm stretching exercises can be tried in chronic cases.
- Modalities such as ultrasound and electrostimulation have been advocated, although there is limited validation of their usefulness.
- Nerve gliding and nerve mobilization remain controversial.

**SURGICAL MANAGEMENT**

**Approach**

- The greatest variation in surgical technique concerns the skin incision.
- For decompression of both pronator and anterior interosseous syndromes, extensile exposures using a modification of Henry’s approach allows for safe and thorough exposure of the median nerve and decompression of all sites of potential compression.
  - This incision sometimes is associated with unsightly scarring and injuries to the cutaneous nerves.
  - Lesser incisions have been described, therefore; these include a lazy S-shape incision in the proximal volar forearm, as well as two longitudinal, oblique, and transverse incisions.
  - Limited incisions require significant retraction to ensure decompression both proximally and distally.
  - The surgeon’s experience and comfort level may be the determining factors in deciding on the type of incision.

**EXTENSILE EXPOSURE**

- The incision is made on the medial aspect of the distal arm proximal to the elbow flexion crease (TECH FIG 1A). It is brought across the elbow flexion crease and extended distally for approximately 10 cm.
- Cutaneous nerve branches, including branches of the lateral brachial and medial antebrachial cutaneous nerves, are identified and atraumatically mobilized.
- The median nerve is identified proximal to the elbow flexion crease and then is traced distally, releasing the lacertus fibrosus (TECH FIG 1B).
  - The existence of a ligament of Struthers and supracondylar process can then be ascertained.
- Motor branches of the median nerve to the muscles originating from the medial epicondyle must be protected throughout the operation. These include the palmaris longus; the flexor carpi radialis; and the flexor digitorum superficialis as well as the pronator teres (TECH FIG 1C).
  - It will be necessary to ligate some vessels, but it will be possible to retract most of them.
  - The radial artery lies radial to the nerve and must be protected throughout the procedure.
  - The median nerve will be adherent to the pronator teres. Retracting the proximal portion of the pronator muscle mass identifies the median nerve and the pronator teres tendon (TECH FIG 1D).
  - The larger, superficial pronator head is identified.
  - It sometimes is possible to retract the entire muscle mass and follow the median nerve into the superficialis arcade. Frequently, however, it is necessary to release the tendinous portion of the pronator teres (TECH FIG 1E).
  - Considerable variation exists within the pronator teres.
  - The median nerve can either pass between the superficial and deep pronator heads or, less commonly, pass underneath both heads.
Up to 20% of the time the deep head is absent.

In the most uncommon variation, the median nerve pierces the humeral head.

It is critical for all tendinous portions of the pronator teres potentially compressing the nerve to be released in the procedure.

If scarring of the pronator teres is present as a result of trauma, a Z-lengthening of the pronator teres tendon is advisable.

This will improve exposure by allowing the humeral head to be reflected in an ulnar direction, exposing the AIN, the median nerve, and the flexor digitorum superficialis arcade (see Tech Fig 1E).

The superficialis arcade can then be released, and the median nerve and AIN visualized distally by gentle retraction of the muscle fibers.

Anterior interosseous nerve branches to the flexor pollicis longus and flexor digitorum profundus must be protected.

Use of atraumatic technique with careful hemostasis is important to prevent postoperative scarring, with resultant pain and potential weakness.

If the pronator teres tendon has been released, it should be repaired in a lengthened fashion.

We prefer to use subcutaneous closure and subcuticular suturing.
LIMITED INCISION

■ An oblique or transverse incision can be made in the proximal forearm just distal to the elbow flexion crease (TECH FIG 2A).
■ Retractors are placed proximal and distal to identify the cutaneous nerve fibers.
■ The lacertus fibrosus is released first, and then the median nerve is identified, as previously described.
■ Retractors are placed to allow visualization and palpation of the median nerve proximally, to permit identification of proximal lesions such as a ligament of Struthers (TECH FIG 2B).
■ Distally, the pronator teres is identified and the muscle and tendon mobilized.
■ If required, the superficial or deep tendons (or both) are released.
■ Fascial impinging structures are identified and released as needed.
■ The superficialis arcade is identified and released, protecting the median nerve and AIN.

PEARLS AND PITFALLS

Anatomy

■ Tendinous portions of the pronator teres and the fibrous portions of the arcade of the flexor digitorum superficialis are the most common causes of compression.
■ Motor branches that go from the median nerve to the muscles originating from the medial epicondyle branch from the ulnar side of the nerve.
■ The AIN originates from the radial side of the median nerve and under the pronator teres.
■ Considerable variation occurs within the pronator teres. Tendinous portions of the pronator impinging on the median nerve should be released, with preservation of the muscle fibers when possible.
■ The humeral or superficial head of the pronator teres is the largest portion of the muscle. The ulnar head or deep head is far smaller, sometimes absent, and most commonly is deep to the median nerve. Both heads, however, have tendinous insertion sites, which may be sources of impingement. In addition, fascial connections between the heads may be present, impinging on the median nerve.

Surgical technique

■ The fibrous portion of the superficialis arcade can be released with preservation of the muscle.
■ Palpation and visualization proximally and distally can be obtained by appropriate retraction.
■ Extensile exposures result in easier surgery but at the expense of potential unsightly scarring and dysesthesia from cutaneous nerve injury.
■ Judicious release of the pronator teres limits the postoperative morbidity and decreases the recovery time.

Relation to carpal tunnel syndrome

■ Patients often may have both carpal tunnel syndrome and a more proximal compression, resulting in the so-called double crush phenomenon.
■ Some authors have implied that failed carpal tunnel syndrome is due to a misdiagnosis in which the more proximal compression of the median nerve in the forearm was not identified.
■ In cases, however, where electrodiagnostic studies clearly show carpal tunnel syndrome even when proximal forearm symptoms are present, it is wise to merely decompress the carpal canal, because the carpal tunnel procedure has a more predictable outcome with less morbidity than proximal forearm median nerve decompression.
POSTOPERATIVE CARE

- Splinting or casting is avoided.
- Early elbow range of motion is encouraged.
- If the pronator tendon has been released, lifting and forearm rotation are restricted for 4 weeks.

OUTCOMES

- Outcome following surgical treatment of proximal forearm median nerve compression has been inconsistent compared to the more uniformly good outcomes associated with carpal tunnel release.
- Many, if not most, patients continue to be at least somewhat symptomatic after surgical decompression.
  - This may reflect persistent compression due to inadequate release or scarring from the surgery itself.
  - It is more likely, however, that it reflects the difficulty in making the diagnosis due to the lack of objective criteria.
- Few studies have evaluated outcome following median nerve decompression in the forearm. Most such studies report results of decompression for pronator syndrome.
- Olehnik et al\(^4\) and Hartz et al\(^2\) both reported results for decompression of pronator syndrome.
- Olehnik et al\(^4\) showed surgery to be of benefit in 30 of 37 extremities, but 9 of 39 were unchanged and 20 had only partial relief.
  - Hartz et al\(^2\) showed 28 good or excellent results in 36 operations, but a majority of patients still had symptoms.

COMPLICATIONS

- Persistent symptoms due to incorrect diagnosis
- Damage to cutaneous nerve branches with subsequent dysesthesias
- Damage to or scarring of motor branches of median nerve or interosseous nerve
- Scarring of pronator teres and forearm musculature

REFERENCES

DEFINITION
- The site of compression must be identified to determine the appropriate treatment for symptoms of ulnar nerve dysfunction. Guyon’s canal at the wrist is the second most common site of ulnar nerve entrapment.
- Symptoms may be purely motor, purely sensory, or mixed, depending on the site and cause of compression.

ANATOMY
- In the distal half of the forearm, the ulnar nerve is joined on its lateral side by the ulnar artery. Proximal to the wrist, the nerve gives off a large dorsal sensory branch, which supplies sensation to the dorsum of the wrist and the ulnar side of the hand. The ulnar nerve continues into the hand through Guyon’s canal.
- Guyon’s canal is a triangular tunnel at the base of the ulnar side of the palm. It is 4 cm in length, extending from the proximal edge of the palmar carpal ligament to the fibrous edge of the hypothenar muscles. The space functions as a physiologic anastomosis with discrete anatomic landmarks (FIG 1A).
- Both the ulnar nerve and artery pass through the canal to enter the hand.
- The dorsal cutaneous branch of the ulnar nerve usually branches before the nerve enters Guyon’s canal.
- It is bordered laterally by the hook of the hamate and the transverse carpal ligament. The medial wall is formed by the pisiform and the attachments of the pisohamate ligament.
- Dividing the tunnel into three zones helps in correlating the clinical symptoms with the specific pathologic cause4,13 (FIG 1B).
- Zone 1, about 3 cm in length, is the area proximal to the bifurcation of the ulnar nerve into motor and sensory branches. Compression in zone 1 results in combined motor and sensory loss. It is most commonly caused by a fracture of the hook of the hamate or a ganglion cyst.
- Zones 2 and 3 are located next to each other, from the point where the ulnar nerve divides into a superficial or sensory branch and a deep motor branch, to the region just beyond the fibrous arch of the hypothenar muscles.
- Zone 2 encompasses the motor branch of the nerve, located in the dorsoradial portion of the tunnel. The deep motor branch, along with the deep branch of the ulnar artery, passes between the abductor digiti quinti and the flexor digiti quinti brevis, perforating the opponens digiti quinti. The motor branch then follows the deep volar arch across the palm to innervate the interossei.
- The nerve supplies the three intrinsic muscles of the small finger, the third and fourth lumbricales, the volar and dorsal interossei, the adductor pollicis, and the deep head of the flexor pollicis brevis.
- Compression in this area causes pure motor loss to all of the ulnar-innervated muscles in the hand. Ganglions from the pisotriquetral joint and fractures of the hook of the hamate are the most common etiologic factors (FIG 1C). Due to the nerve’s proximity to the hamate, it is unfortunately easy to damage the nerve while excising the hook of the hamate.
- Zone 3, located ulnar to zone 2, encompasses the superficial or sensory branch of the bifurcated ulnar nerve. Compression here causes sensory loss to the hypothenar eminence, the small finger, and part of the ring finger, but does not usually cause motor deficits. Common causes are aneurysm of the ulnar artery, thrombosis, and synovial inflammation.
- The superficial branch of the ulnar nerve in Guyon’s canal supplies the palmaris brevis and the skin of the hypothenar eminence and forms the digital nerves to the small and ulnar side of the ring finger.
- Two specific nerve anomalies can confuse the diagnosis.
- Martin-Gruber anastomosis in the forearm: fibers that supply the intrinsic muscles are carried in the median nerve to the middle of the forearm, where they leave the median nerve to join the ulnar nerve. Functioning intrinsic muscles can be observed when the ulnar nerve is injured proximal to this anastomosis.
- Riche-Cannieu anastomosis: the median and ulnar nerves are connected in the palm. Even with an injury at the wrist, some intrinsic function remains.

PATHOGENESIS
- Causative factors of compression or injury of the ulnar nerve in Guyon’s canal include repeated blunt trauma from power tools and gripping or hammering with the palm of the hand, which may result in thrombosis or aneurysm of the ulnar artery compressing the nerve (hypothenar hammer syndrome)2,6,10 (FIG 2A,B, Table 1). Direct pressure on the ulnar nerve may occur during activities such as cycling.
- Fractures of the hook of the hamate can impinge on the nerve.
- Idiopathic compression may occur secondary to thickening of the proximal fibrous ligament at the entrance to the canal.
- Compression also may occur as a result of swelling after distal radius fracture.
- Compression of the ulnar nerve at Guyon’s canal also has been shown to occur in conjunction with carpal tunnel syndrome. It typically resolves after surgical decompression of the carpal canal.5,16
- Other etiologies include tumors, such as ganglia or lipomas (FIG 2C,D), anomalous muscle bellies,8,15 or hypertrophy of the palmaris brevis.
- Ganglia and other soft-tissue masses are responsible for 32% to 48% of cases of ulnar tunnel syndrome. Another 16% of cases are due to muscle anomalies.12
- Synovitis secondary to rheumatoid arthritis may encroach upon the canal and the nerve.
FIG 1 • A. Anatomic landmarks of the distal ulnar tunnel (Guyon’s canal). **Zone 1**: Ulnar nerve in the region proximal to the bifurcation. **Zone 2**: Ulnar nerve motor segment, following bifurcation. **Zone 3**: Ulnar nerve sensory segment, distal to the bifurcation. B. Location of the three zones. **Zone 1** is proximal to the bifurcation; **zone 2** encompasses the motor branch; **zone 3** is the region surrounding the sensory branch. C. The proximity of the motor branch of the ulnar nerve to the hook of the hamate as seen during excision of the hook.

FIG 2 • A. Ulnar artery thrombosis. B. Resected thrombosed segment. C. Hypothenar mass as a cause of compression of the ulnar nerve at the wrist. D. Lipoma causing compression of the nerve.
A careful clinical history is imperative, noting the time of occurrence of symptoms. Determine whether symptoms are transient or continuous. Determine whether symptoms are related to work, sleep, or recreation. Elicit duration of symptoms and possible relation to trauma.

</table>

Metabolic or infectious diseases such as diabetes, thyroid disease, or leprosy may also mimic the symptoms of nerve compression.

Iatrogenic causes must also be recognized, such as compression by tendon or muscle transfer (Huber opponensplasty).11

NATURAL HISTORY

Untreated compression may result in permanent dysfunction, weakness, and numbness.

PATIENT HISTORY AND PHYSICAL FINDINGS

Clinical History

Presenting symptoms can vary from mild, transient paresthesias in the ring and small fingers to clawing of these digits and severe intrinsic muscle atrophy.

The patient may report severe pain at the elbow or wrist with radiation into the hand or up into the shoulder and neck.

Patients may report difficulty or clumsiness when opening jars or turning doorknobs.

Early fatigue or weakness may be noticed if work requires repetitive hand motions.

Depending on the climate and work conditions, cold intolerance in the ring and small fingers may be present.7

A careful clinical history is imperative, noting the time of occurrence of symptoms. Determine whether symptoms are transient or continuous. Determine whether symptoms are related to work, sleep, or recreation. Elicit duration of symptoms and possible relation to trauma.

Physical Examination7,17

It is important to determine the level of pathology of the ulnar nerve, because compression commonly occurs at four points: the cervical spine, the thoracic outlet, the elbow (cubital tunnel syndrome), or the wrist (Guyon’s canal).

Begin the clinical examination at the neck and shoulder and move down the affected extremity to the elbow.

Pain on neck movement mimicking the patient’s symptoms could indicate cervical disc disease.

Pain on palpation of the plexus or with shoulder motion could indicate a pathologic condition in the brachial plexus or lung. Results of provocative maneuvers for thoracic outlet syndrome should be assessed.

Masses on the medial side of the arm could indicate a soft tissue tumor or hemorrhage compressing the nerve.

At the elbow, note any deformity, palpate the nerve, and determine whether abnormal mobility is present.

The course of the nerve is palpated in the forearm all the way to the wrist.

A positive Tinel or Phalen’s sign is often found at the wrist over the ulnar nerve.

Tenderness over the hook of the hamate is particularly important.

Sensory function is assessed.

Semmes-Weinstein monofilament testing may be abnormal, but often is normal early in the course of the compression.

Two-point discrimination of the ring and small fingers usually becomes abnormal only late in the course of the disease.

To help differentiate cubital tunnel syndrome from compression of the ulnar nerve at the wrist, assess flexor carpi ulnaris and flexor digitorum profundus strength.

Intrinsic muscle function is tested by asking the patient to cross the long finger over the index finger (ie, crossed finger test).

Only two muscles can be tested accurately in the hand—the abductor digiti quinti and the first dorsal interosseous. The tendons or bellies of these muscles can be palpated or visualized.

Weakness of thumb pinch may be elicited by the Froment sign. Froment’s sign is ruled positive if the person must flex the thumb interphalangeal joint to maintain grasp.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Radiographs of the elbow and wrist are mandatory in ulnar nerve compression, because entrapment of the ulnar nerve may occur at more than one level.

Radiographs of the hand and wrist should include carpal tunnel views as well as standard anteroposterior (AP), lateral, and oblique views. Radiographs of the wrist may reveal fractures of the hook of the hamate, dislocations of the carpal bones, or, less commonly, soft tissue masses and calcifications.

Radiographs of the elbow may reveal abnormal anatomy, such as a valgus deformity, bone spurs or bone fragments, a shallow olecranon groove, osteochondromas, or destructive lesions (eg, tumors, infections, abnormal calcifications).

Radiographs of the neck should be obtained if cervical disc disease is suspected and to rule out cervical ribs.

Obtain radiographs of the chest if a Pancoast tumor or tuberculosis is suspected.
MRI is not usually necessary unless further delineation of soft tissue masses such as lipomas or ganglions or visualization of fractures, aneurysms, congenital abnormality, or other abnormalities in the nerve is required. MRI also may detect structural abnormalities along the course of the ulnar nerve accounting for compression (eg, fibrous bands).

Ultrasonography may be used to detect cysts or masses in Guyon’s canal and to assess ulnar nerve diameter at the elbow.

Electromyography (EMG) and nerve conduction studies are helpful to confirm the specific area(s) of entrapment as well as document the extent of the pathology.

Motor and sensory conduction velocities are more useful in a recent entrapment, whereas conduction velocities and EMG are useful in chronic neuropathies (EMG shows axonal degeneration).

Conduction velocity short-segment stimulation (also known as the inching technique) can increase the sensitivity of this method and can improve localization by helping the examiner determine exactly where a blockage is occurring.

EMG evaluation of motor unit morphology and recruitment patterns ascertain ongoing loss of muscle fibers via detection of abnormal spontaneous activity (eg, fibrillation potentials and fasciculations). It also checks the integrity of the muscle membrane to expand differential diagnosis (eg, myotonia, paramyotonia, periodic paralysis) as manifested by increased insertional activity such as complex repetitive discharges, myokymia, and (para)myotonic discharges.

DIFFERENTIAL DIAGNOSIS
- Cervical disc disease
- Brachial plexus abnormalities, thoracic outlet syndrome, Pancoast tumor
- Elbow abnormalities, epicondylitis
- Infections, tumors, diabetes mellitus, hypothyroidism, rheumatoid diseases, alcoholism
- Wrist fractures
- Ulnar artery aneurysms or thrombosis at the wrist

NONOPERATIVE MANAGEMENT
- Conservative treatment of ulnar nerve compression is most successful when paresthesias are transient. Patient education and insight are important.

SURGICAL MANAGEMENT
- Surgical intervention is indicated if paresthesia increases despite adequate conservative treatment combined with abnormal nerve conduction studies or EMGs, and at the first sign of motor changes.

Prospective Planning
- The diagnosis should be confirmed with EMG and nerve conduction velocity or imaging studies (eg, MRI) before planned surgery.

Positioning
- Patients are operated on in the supine position with the arm extended on an armboard.
- A tourniquet is placed above the elbow and inflated to 250 to 265 mm Hg before the incision is made.

Approach
- Operative treatment is aimed at exploring and decompressing the nerve from the distal forearm into the hand throughout all three zones.

ULNAR NERVE EXPLORATION AND DECOMPRESSION OF GUYON’S CANAL

- Palpate and mark the pisiform.
  - The hook of the hamate can be found 1 cm distal and lateral to the pisiform.
  - Make a curvilinear incision beginning distally in the interval between the pisiform and the hook of the hamate. Cross the wrist, extending proximal to the distal wrist flexion crease, along the radial border of the flexor carpi ulnaris (TECH FIG 1A).
  - The wrist should be crossed in a zigzag fashion to prevent longitudinal contracture of the scar.
  - Perform the dissection proximal to distal. Identify the ulnar nerve proximal to the distal wrist flexor retinaculum and follow it distally through Guyon’s canal by reflecting the flexor carpi ulnaris and the pisohamate ligament.
  - The neurovascular bundle is traced distally to the point at which it enters Guyon’s canal beneath the palmar carpal ligament.

- Incise the ligament, palmaris brevis muscle, and fibrous tissue, decompressing the nerve along its entire course through the canal.
  - The branches of the ulnar nerve to the hypothenar muscles and palmaris brevis, as well as the deep branch of the nerve, can be identified and protected with this approach.
  - The incision should not be carried ulnarly over the hypothenar eminence, to avoid injury to the palmar cutaneous branch of the ulnar nerve.
  - The ulnar artery should be examined for areas of thickening or thrombosis, and the ulnar nerve should be examined along its course for intra- or extraneural tumors (eg, schwannoma, neurolemmoma).
  - Further exploration of the floor of the canal should be done to identify masses, ganglions, anomalous muscles,
fibrous bands, osteophytes, or fracture fragments. The motor branch is followed into the interval between the flexor digiti minimi and abductor digiti minimi muscles and through the origin of the opponens digiti minimi (TECH FIG 1B).

PEARLS AND PITFALLS

**Pearls**
- Differentiation between proximal and distal nerve compression:
  - Weakness of the small finger profundus points to ulnar nerve compression at the elbow.
  - Involvement of the dorsal sensory branch indicates compression proximal to Guyon’s canal.
  - Clawing is seen more commonly in distal (wrist) than proximal (elbow) lesions.

**Pitfalls**
- Inadequate preoperative evaluation, resulting in:
  - Inaccurate or incomplete diagnosis
  - Inadequate decompression

POSTOPERATIVE CARE
- Postoperatively, patients are placed into a protective splint for about 2 weeks to prevent excessive wrist flexion and extension.
- Sutures are removed at 10 to 14 days after surgery, at which time gentle active range of motion is started, as well as scar care.
- The wrist splint should be continued for 2 to 3 more weeks to prevent scar thickening, which is common in this area.
  - Silicone or otoform is helpful to prevent hard, firm scars.

OUTCOMES
- Symptoms can be expected to improve in all cases, with fewer than 20% of patients complaining of slight persistent numbness after the surgery.
  - The most common cause of failure of surgery is failure in diagnosis, followed by inadequate decompression of all of the branches of the ulnar nerve.

COMPlications
- Laceration of the ulnar nerve or artery (or both)
- Inadequate decompression
- Injury to the ulnar artery

REFERENCES
DEFINITION
- Cubital tunnel syndrome is a compression neuropathy of the ulnar nerve that occurs at or around the level of the elbow (cubis is Latin for “elbow”).
- Cubital tunnel syndrome is the second most common compression neuropathy of the upper limb requiring treatment, after carpal tunnel syndrome.

ANATOMY
- The ulnar nerve is the terminal branch of the medial cord of the brachial plexus, with contributions from C8 and T1 nerve roots.
- The ulnar nerve traverses the cubital tunnel, a fibro-osseous tunnel at the elbow. The medial epicondyle, the olecranon, the medial collateral ligament of the elbow (which forms the floor), and the fibrous retinaculum extending from the medial epicondyle to the olecranon make up the anatomic landmarks (FIG 1).
- Any of several possible sites of compression of the ulnar nerve around the elbow can result in cubital tunnel syndrome. All of these sites should be considered when selecting the type of surgical decompression.
  - The arcade of Struthers is a controversial site of compression, because it is found in only a minority of patients. If present, it is found approximately 8 cm proximal to the medial epicondyle and consists of a fascial band running from the medial head of the triceps to the intermuscular septum.
  - The medial intermuscular septum is a fascial band from the coracobrachialis to the medial humeral epicondyle, especially thick at its attachment to the epicondyle. The ulnar nerve may rest or scissor over the septum as it crosses from the anterior to the posterior compartment, as it approaches the medial epicondyle, or after an anterior transposition if it is not adequately excised.
- The arcuate ligament of Osborne at the cubital tunnel, which is the fibrous band extending from the medial epicondyle to the olecranon, can cause stenosis of the cubital tunnel and, thus, ulnar nerve compression.
- Distally, the nerve can be compressed as it passes between the two heads of the flexor carpi ulnaris, especially if each muscle head from the medial epicondyle and the olecranon converge close to the elbow joint.
- The presence of an anconeus epitrochlearis (FIG 2), an anomalous thin muscle extending from the triceps or olecranon to the medial epicondyle, also can cause ulnar nerve compression.
- The medial antebrachial cutaneous nerve and the medial brachial cutaneous nerve both emanate directly from the medial cord and are thus not ulnar nerve branches, but they importantly may lie in the surgical field. They are usually found deeper than expected, along the fascia of the triceps, brachialis, and flexor carpi ulnaris.

PATHOGENESIS
- Cubital tunnel syndrome is a compressive neuropathy. Several anatomic factors make the ulnar nerve susceptible to compression at the elbow.
  - The nerve is superficial at the level of the elbow, making it susceptible to minor and major trauma, ranging from mild repetitive contusion to high-energy injury.
  - The bony tunnel and its soft tissue support between the olecranon and medial epicondyle may be shallow, either inherently or traumatically, promoting subluxation, “perching” on the epicondyle, and microtrauma.
  - Elbow flexion increases pressure on the nerve and decreases the volume of the cubital tunnel, resulting in compression of the nerve.
NATURAL HISTORY

- Without operative intervention, about half of mild cases can resolve with activity modification.\(^{10}\)
- No long-term studies have been done of the natural history for severe disease.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Subjective complaints include numbness in the small and ring fingers, often with accompanying burning pain around the medial epicondyle. Symptoms may be worse at night.
- As the disease progresses, patients may complain of weakness or clumsiness of their hands. More advanced disease will demonstrate wasting of the intrinsics and clawing of the ring and small fingers.
- Systemic diseases such as diabetes, amyloidosis, or alcoholism may cause peripheral neuropathy, which can mimic the symptoms of a compressive neuropathy.
- A smoking history is important, not only for impaired vascularity, but because it may point to the rare Pancoast tumor, an apical lung tumor, which causes plexus compression, mimicking the symptoms of cubital tunnel syndrome.
- Elbow trauma can create deformity, causing ulnar nerve compression. Deformities include a cubitus valgus, cubitus varus, or malunion. The elbow trauma can be remote and result in tardy ulnar nerve palsy.
- Look for atrophy of the intrinsic muscles of the hand or a clawed posture of the ring and small fingers. Check for masses around the elbow.
- Palpate the elbow and hand to evaluate for tender masses or other anomalous elbow anatomy.
- Put the elbow through its range of motion and assess whether the ulnar nerve subluxates or perches at the medial epicondyle with elbow flexion (FIG 3A).
- Visible atrophy of the first dorsal interosseous nerve correlates with significant ulnar nerve compression and can indicate significant motor impairment (FIG 3B).
- Perform a sensory examination of the hand, using Semmes-Weinstein monofilaments to obtain threshold measurements. Evaluate sensation on the ulnar dorsum of the hand. If sensation is normal, it suggests the problem may be distal, at the level of Guyon’s canal.
- Clinical tests that can help with diagnosis include the following:
  - Tinel’s test. This test may not be specific, because many normal individuals will have a positive Tinel’s response to percussion.
  - Elbow flexion test. This test is sensitive for cubital tunnel syndrome.
  - Crossed finger test. This test demonstrates weakness of dorsal and palmar interossei.
  - Froment’s sign. A positive Froment’s sign indicates weakness of the adductor pollicis.
  - Wartenberg’s sign (in which the small finger assumes an abducted posture with finger extension). This sign is the result of weakness in the palmar interossei, resulting in unopposed ulnar pull of the extensor digiti quinti.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographs of the elbow define the bony architecture and its alterations: masses, erosions, arthritis, and previous trauma. An axial view is helpful to evaluate the cubital canal (FIG 4).
- Normal results on electrodiagnostic studies (eg, nerve conduction and electromyography) do not exclude the diagnosis of cubital tunnel syndrome; the syndrome may be present but not severe.
- These tests localize the area of compression if the nerve conduction is measured at short segment intervals.
- Several positive electrodiagnostic findings suggest ulnar compression:
  - Motor conduction across the elbow less than 50 m/sec.\(^{13}\)
  - Focal slowing of nerve velocity across the elbow
Fibrillation potentials or positive waves suggest axonal degeneration, representing a poorer prognosis for complete recovery.

MRI and CT may occasionally be helpful as ancillary imaging studies to define soft tissue aberrancies and localize bone abnormalities such as osteophytes in the cubital tunnel.

DIFFERENTIAL DIAGNOSIS
- Cervical spine disease affecting C8 and T1
- Compression of the inferior aspect of the brachial plexus from shoulder trauma
- Apical lung tumor (Pancoast tumor)
- Thoracic outlet syndrome
- Entrapment of the ulnar nerve at the wrist (Guyon’s canal)

NONOPERATIVE MANAGEMENT
- Activity modification
  - Ulnar nerve protection limiting microtrauma to the nerve through elbow padding and limiting direct pressure on the nerve
  - Minimize prolonged elbow flexion, especially at night, through sleep modifications or splints.
- Splinting
  - Splints to prevent elbow flexion; rigid splints are more effective but are less tolerated by patients. If persistent paresthesias exist, a trial of temporary full-time use is recommended. For milder cases, the splint is worn only at night.
  - Nonoperative treatment requires a trial of several months before determining its success.

SURGICAL MANAGEMENT
- Surgical intervention should be considered for patients presenting with motor involvement or permanent sensory changes, or for those who have failed nonoperative treatment.

Preoperative Planning
- Review the history and physical examination.
- Review plain radiographs for evidence of old trauma, valgus or varus deformity, or loose bodies.
- Electrodagnostic testing and examination may correlate with postoperative results.
- Body habitus, especially the presence of abundant adipose tissue around the elbow, may help the surgeon select a subcutaneous transposition—a procedure with less dissection—rather than a more extensive but protective procedure such as an intramuscular transposition.
- A patient with a visible and symptomatic subluxating nerve may be considered for a medial epicondylectomy.
- Patients with severe disease with muscle wasting are less likely to have complete recovery.

Positioning
- The patient usually is placed in the supine position.
- If a sterile tourniquet is preferred, drape out the forequarter. A standard tourniquet may be used, but position it high in the axilla, with good padding. A proximally placed tourniquet can be challenging to position in the obese arm in either circumstance, because the tourniquet tends to gap distally. It is worth the extra time to position it properly, because adequate hemostasis and visualized proximal dissection are important aspects of ulnar nerve surgery.
- The patient’s shoulder is externally rotated and abducted on an arm table.
- The tourniquet is inflated after exsanguination of the arm.
- Folded towels stabilize and elevate the elbow (FIG 5).
- An obese patient with sleep apnea under peripheral nerve block (most commonly supra- or infraclavicular block) may require slight truncal elevation, which may be vexing for the surgeon.

Approach
- The choice of technique depends on the severity of symptoms, the patient’s body habitus, the presence of elbow anatomic pathology, and the surgeon’s preference.
- The three general types of release are in situ release, in situ release with medial epicondylectomy, and anterior transposition (subcutaneous, intramuscular, and submuscular).
- Table 1 summarizes the surgical options for treating cubital tunnel syndrome.
### Table 1  Techniques for Cubital Tunnel Release

### IN SITU RELEASE

- Center the longitudinal incision just anterior to the medial epicondyle, making an incision about 8 cm long (TECH FIG 1A).
- Dissect through the fat, down to the level of the medial epicondyle.
- Preserve the branches of the medial brachial and antebrachial cutaneous nerves. Although the course is variable, branches can be found from 6 cm proximal to 6 cm distal to the medial epicondyle and often are at the level of the fascia (TECH FIG 1B,C).
- Identify the ulnar nerve and dissect it free proximally until it pierces the medial intermuscular septum. Release any areas of constriction.
- Take the dissection distal to the level of the medial epicondyle and release the band spanning from the medial epicondyle to the olecranon.
- Preserve the branches of the ulnar nerve: the first is the articular sensory branch, followed by the motor branches to the flexor carpi ulnaris (FCU) and flexor digitorum profundus (FDP). The FCU branches are found proximally with appearance of the muscle.

**TECH FIG 1** A. The standard incision, centered just anterior or posterior to the medial epicondyle. B,C. Preservation of crossing medial brachial and antebrachial nerves. The cutaneous nerves lie deep in the fat, typically on the fascia. Here two branches are encountered before and after fasciotomies to expose the nerve. (Copyright Amy Ladd, MD.)
IN SITU RELEASE WITH MEDIAL EPICONDYLECTOMY

- The incision and dissection are the same as the in situ release.
- Excise a strip of the tough fascial intermuscular septum as it attaches to the medial epicondyle to minimize the nerve “scissoring” over the firm edge.
- Once the nerve is free of all areas of entrapment, a longitudinal incision is made slightly anterior to the medial epicondyle with a knife or electrocautery, reflecting the periosteum to reveal the bony prominence of the epicondyle. Carefully protect the ulnar nerve; gentle retraction with a saline-lubricated ¼-inch Penrose drain on a short hemostat is sufficient.
- Expose the medial epicondyle subperiosteally.
- Remove the prominence of the epicondyle, which is most acute in its posterior position, removing 2 to 3 mm of prominence and 6 to 8 mm in length. Use a small, sharp osteotome and smooth with a file while protecting the nerve (TECH FIG 2A).
- Place bone wax over the raw bone. This minimizes postoperative hematoma.
- The periosteum is closed with buried sutures, either braided absorbable or nonabsorbable, minimizing contact with the nerve.
- Check that the nerve glides, rather than perches, when the elbow is flexed and extended before closure of the skin (TECH FIG 2B).
- Because of potential bony bleeding, a drain is recommended.
- Apply a posterior plaster splint for 10 to 14 days, with protected mobilization thereafter.

ANTERIOR SUBCUTANEOUS TRANSFER

- The incision and dissection are the same as for the in situ release, except that the incision may have to be slightly longer.
- Release the nerve at every potential level of entrapment.
- Range the elbow and check for smooth ulnar nerve excursion. If perching (snapping) over the medial epicondyle occurs, consider medial epicondylectomy. This is often a preclinical determination.
- Close the soft tissues using the surgeon’s preferred technique.
- Typically, no drain is placed.
- Place the arm in a bulky supportive dressing or a posterior plaster elbow splint with flexion of about 60 degrees. Remove the splint according to wound care and the surgeon’s mobilization preference.

TECH FIG 2 • Medial epicondylectomy. A. The medial epicondyle is exposed, and the most prominent aspect is removed. We recommend removal of the most prominent and inferior portion, 2 to 3 mm in depth, to avoid disruption of the medial collateral ligament. B. Once the epicondylectomy is performed and the fascia closed, the elbow is flexed to visualize smooth movement of the nerve. The nerve no longer perches on the medial epicondyle. (Copyright Amy Ladd, MD.)

Circumferentially dissect the nerve to allow it to be moved anterior to the medial epicondyle. Free all posterior attachments to allow for maximal anterior excursion.
- Excise the intermuscular septum from the crossover of the ulnar nerve, anterior to posterior in the proximal dissection, all the way to its tough attachment at the medial epicondyle.
- Preserve the longitudinal vasculature accompanying the nerve to prevent devascularization of the nerve. Use caution around the medial epicondyle and the most fibrous part of the intermuscular septum, where lies an external but vulnerable large venous leash.
- Develop the interval between the skin and the fascia overlying the flexor pronator muscle mass anterior to the medial epicondyle, about 4 cm.
- Transpose the nerve to lie anterior to the medial epicondyle (TECH FIG 3A).
- The nerve should lie in its new position without any tension or areas of compression. An intraneural dissection to release the motor branches to the FCU may be required proximally.
- To prevent the nerve from subluxating, a 1-cm fasciodelmal sling is constructed from the fascia overlying the flexor pronator mass (ie, the FCU, FCR, and the pronator teres) (TECH FIG 3B). This flap is sutured to the skin. This flap prevents the nerve from sliding back to its old position.
- Care must be taken to ensure that this flap does not become a new area of compression.
- No drain is required.
- Apply a posterior plaster splint for 10 to 14 days, with protected mobilization.
- The nerve is fully released, as described for the subcutaneous transposition.
- The interval between the skin and the fascia is developed anterior to the medial epicondyle, to about 4 cm.
- Transpose the nerve so that its rests along the flexor pronator mass (ie, FCU, FCR, and the pronator teres).
- A trough slightly bigger than the nerve is carved out of the muscles along this anterior course (TECH FIG 4). Release any fascial bands found within the muscle substance.
  - Flex the elbow and place the nerve in the trough.
  - Suture fascia over the nerve, creating a tunnel.
  - Range the elbow to ensure that there is no kinking or tethering of the transposed nerve.
  - The arm is immobilized with a pronated forearm in an elbow splint for 2 to 3 weeks at 45 to 60 degrees of flexion with progressive protected mobilization.
- The nerve is fully released as described with the preceding procedures, and the skin flap is developed similarly to the intramuscular procedure.
- Divide the flexor pronator mass about 1 cm distal to its insertion on the medial epicondyle, either as a straight incision or in a V-Y fashion (TECH FIG 5A).
Chapter 70  SURGICAL TREATMENT OF CUBITAL TUNNEL SYNDROME

TECHNIQUES

TECH FIG 5  • Submuscular transposition. The flexor pronator mass is incised (A), and the nerve is passed deep to the flexor pronator muscle mass (B). Sutures are in place to repair the muscle origin following use of a simple straight incision. (A: Copyright Amy Ladd, MD. B: Courtesy of Thomas R. Hunt, III, MD.)

PEARLS AND PITFALLS

Dissection

- Avoid cutting the medial brachial and antebrachial nerve. Damage to this nerve is the most common cause of pain after cubital tunnel release.8,14
- Make an adequate proximal dissection: follow the nerve to the crossover of the anterior-to-posterior compartment, where a thin or thick fascial band is present at the septum, or rarely, the arcade of Struthers. Make certain the tourniquet is high enough to reach this spot, usually 5 to 8 cm above the epicondyle.
- Make an adequate distal dissection: follow the nerve several centimeters into the muscle bellies to ensure a full release, including the fascia of the FCU encasing its branches.

Transposition

- Preserve the longitudinal blood supply to the nerve.
- If transposing the nerve, ensure that a new point of compression is not created. Compression may be created at the following sites: proximally at the crossover from anterior to posterior; the intermuscular septum just proximal to the medial epicondyle; the flexor pronator mass if submuscular or intramuscular transposition is performed; and the entrance to the FCU muscle bellies.

POSTOPERATIVE CARE

- Postoperative care instructions are given individually with the discussion of each technique. In general, the more extensive the dissection, the more protected postoperative splinting and mobilization is required. Strengthening may begin a few weeks after an in situ decompression, for example, and 6 to 8 weeks following a submuscular transposition.

OUTCOMES

- Overall, all procedures have a success rate of about 90% for mild cases. The rate of total relief decreases as severity of disease increases.5
- Postoperative outcomes are proportional to disease severity: ic, severe disease is less likely to achieve full recovery.3
- Recent studies suggest that outcomes are similar for the different procedure types.1,4,10

COMPLICATIONS

- Pain at the elbow
- Decreased sensation around the scar
- Incomplete symptom relief
- Painful neuroma of cutaneous nerves
- Symptomatic subluxating nerve
- Injury to motor branches to the FCU

REFERENCES

DEFINITION
- Radial tunnel syndrome was first described by Michele and Krueger in 1956 as radial pronator syndrome.
- It was described as a compression neuropathy involving primarily the posterior interosseous nerve (PIN), associated with a predominant symptom of pain.

ANATOMY
- The radial nerve pierces the lateral intermuscular septum 10 to 12 cm above the lateral epicondyle. It travels along the lateral border of the brachialis muscle and is covered laterally and anteriorly by the brachioradialis (BR), extensor carpi radialis longus (ECRL), and extensor carpi radialis brevis (ECRB) muscles (see Fig. 1B, Chap. 76).
- It divides into the PIN and the superficial radial sensory nerve 3 to 5 cm distal to the lateral epicondyle.
- The PIN then enters the “radial tunnel.”
  - The floor of the tunnel begins at the anterior capsule of the radiocapitellar joint and continues as the deep head of the supinator.
  - The roof begins as inconstant fibrous bands between the brachialis and BR, and then continues as the medial border of the ECRB. Distally, the roof of the tunnel consists of the superficial or oblique head of the supinator.
  - The radial tunnel ends with the distal edge of the supinator.
- Proximal to the supinator, the nerve is crossed superficially by branches of the radial recurrent artery known as the vascular leash of Henry.

PATHOGENESIS
- Roles and Maudsley described the concept of radial nerve compression in 1972, suggesting that it could result in a wide spectrum of symptoms. Radial tunnel syndrome, defined as localized pain over the mobile wad, is thought to be a result of compression of the PIN.
- If the primary complaint is weakness, the symptom complex is referred to as posterior interosseous syndrome, even though the pathogenesis in both conditions is thought to be due to a compression neuropathy.
- The compression may rarely be due to space-occupying lesions such as ganglion, neoplasm, or florid synovitis of the proximal radioulnar, radiocapitellar, or ulnotrochlear joints.
- The sites of compression of the PIN most often cited are the fibrous proximal border of the supinator (arcade of Frohse), the medial border of the ECRB, fibrous bands passing volar to the radial head, and the vascular leash of Henry.
- The arcade of Frohse and the medial border of the ECRB are thought to be the most common sites of compression.
- Werner recorded pressures from 40–50 mm Hg exerted on the nerve with passive stretch of the supinator muscle. Pressures exceeding 250 mm of Hg have been recorded on the nerve with stimulated tetanic contraction of the supinator muscle. Ischemia of the nerve has been demonstrated at 60–80 mm of Hg, and blockade of axonal transport at 50 mm of Hg.
- The documented changes in pressure due to positioning of the forearm in conjunction with the observation that symptoms often are associated with repetitive pronation and supination have led to the theory that the clinical syndrome may be provoked by dynamic and intermittent compression on the radial nerve.
- Although the PIN is considered a motor nerve, it has been well documented that afferent sensory fibers run within the nerve. The muscles innervated by the PIN contain nerve endings corresponding to group IIA fibers. These fibers are commonly thought to be responsible for the pain from muscle cramps, and, therefore, could likely be mediators of pain in radial tunnel syndrome.
- Because of the common association with (or difficulty in distinguishing it from) lateral epicondylitis, some authors have suggested that referred pain from lateral epicondylitis or intra-articular pathology may contribute to radial tunnel syndrome.
- In 1984, Heyse-Moore suggested that radial tunnel syndrome may be an analogue of a musculotendinous lesion of the common extensor tendon, causing lateral epicondylitis in the supinator.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The diagnosis of radial tunnel syndrome is based on clinical findings. Historically, it was described as a cause of treatment-resistant lateral epicondylitis. The two disorders may have similar and overlapping symptoms.
- Symptoms can be variable, but the classic history described by the patient with radial tunnel syndrome is of pain over the lateral forearm musculature distal to the lateral epicondyle (along the course of the radial nerve) that is exacerbated by activity.
- The pain is often described as a constant “aching” that is aggravated by or prevents activities.
- Pain is most pronounced with active supination, and less severe with activities involving extension of the fingers.
- Lesser symptoms of weakness of the finger and wrist extensors also may be present, as may dysesthesias over the distal lateral forearm and wrist.
- Other symptoms include writer’s cramp, paresthesias, night cramps, and radiation of pain proximally and distally in the arm and forearm. Some patients complain of a “popping” sensation over the elbow during pronation.
- The most specific finding on physical examination is pain with digital pressure placed over the course of the radial nerve at the radial neck, or the proximal edge of the supinator.
- Two other pathognomonic signs (described by Lister et al) are pain in the lateral forearm with resisted extension of the middle finger, and pain with resisted supination.
Posterior interosseous nerve palsy

Differential Diagnosis

- Electromyographic or nerve conduction studies. Symptoms of radial tunnel syndrome and the findings of either conduction velocity have shown no consistent relation between the EMG and causing increased pressure on the PIN.
- Injection of lidocaine into the radial tunnel has been described as a diagnostic tool for radial tunnel syndrome.
- MRI can be helpful in identifying possible cervical degenerative disc disease of the cervical spine.
- Multiple studies using electromyography (EMG) and nerve conduction velocity have shown no consistent relation between symptoms of radial tunnel syndrome and the findings of either electromyographic or nerve conduction studies.
- In 1980, Rosen and Werner demonstrated that static motor nerve conduction at rest was not significantly different between symptomatic patients and a nonsymptomatic control group. They did find, however, that active supination of the forearm produced an increase in the conduction time of the PIN across the supinator muscle more often in patients with radial tunnel than in control subjects.
- Verhaar and Spaans tested patients while holding the forearm in active supination and found that 14 of 16 patients with radial tunnel syndrome had no abnormal latency on nerve conduction studies or abnormality of the EMG.
- Kupfer et al found that differential latency (ie, different latency measurements recorded in the same nerve in different positions) may be more significant in identifying “pathologic” latency than comparing a measured latency to a standard “normal “ latency measurement. Differential latencies were higher in patients with radial tunnel syndrome than in the control group and improved after surgical decompression, correlating with clinical results.

Imaging and Other Diagnostic Studies

- If the patient’s clinical examination is suggestive of elbow arthritis or cervical radiculopathy, radiographs of the elbow and a cervical spine series may be helpful in elucidating associated pathology that may contribute to a neuropathy of the radial nerve caused by an anterior osteophyte of the elbow or degenerative disc disease of the cervical spine.
- MRI can be helpful in identifying possible cervical degenerative disc disease or elbow ganglia.
- Injection of lidocaine into the radial tunnel has been described as a diagnostic tool for radial tunnel syndrome.
- Because it is difficult to reliably contain the anesthetic within the radial tunnel, the main criticism of this technique is the lack of specificity in differentiating pathology of the radial nerve from other sources of pain.
- Multiple studies using electromyography (EMG) and nerve conduction velocity have shown no consistent relation between symptoms of radial tunnel syndrome and the findings of either electromyographic or nerve conduction studies.
- In 1980, Rosen and Werner demonstrated that static motor nerve conduction at rest was not significantly different between symptomatic patients and a nonsymptomatic control group. They did find, however, that active supination of the forearm produced an increase in the conduction time of the PIN across the supinator muscle more often in patients with radial tunnel than in control subjects.
- Verhaar and Spaans tested patients while holding the forearm in active supination and found that 14 of 16 patients with radial tunnel syndrome had no abnormal latency on nerve conduction studies or abnormality of the EMG.
- Kupfer et al found that differential latency (ie, different latency measurements recorded in the same nerve in different positions) may be more significant in identifying “pathologic” latency than comparing a measured latency to a standard “normal “ latency measurement. Differential latencies were higher in patients with radial tunnel syndrome than in the control group and improved after surgical decompression, correlating with clinical results.

Differential Diagnosis

- Lateral epicondilitis
- Posterior interosseous nerve palsy
- Cervical radiculopathy C5–6
- Neuritis of the lateral antebrachial cutaneous nerve
- Waardenburg syndrome
- Myofascial pain syndrome

Nonoperative Management

- A course of nonoperative treatment should always be attempted.
- Activity modification may be helpful, particularly in patients whose vocation or avocation involves frequent repetitive supination and pronation of the forearm.
- The patient should attempt stretching exercises of the supinator and the ECRB, with pronation of the forearm and wrist flexion with the elbow in extension. Gentle strengthening exercise also may be helpful in improving symptoms.
- An injection of local anesthetic and corticosteroid in the radial tunnel may provide relief in some patients.

Surgical Management

- Surgical management should be considered in the patient who has failed nonoperative treatment. A 4- to 6-week trial of nonoperative treatment should be sufficient to determine whether there is any improvement.
- There is no consensus as to which anatomic structures should be released at the time of surgery. It is agreed, however, that this is typically a clinical decision. Electrodiagnostic studies have not been shown to locate the area of pathology reliably.
- Most authors recommend releasing the PIN as it passes under the superficial head of the supinator by dividing the fibrous arcade of Frohse and the tendinous border of the ECRB, as needed.
- Lister and others emphasize release of the fibrous bands of the radial tunnel anterior to the radial head.
- Sponseller has reported cases where the PIN is compressed by the distal aspect of the supinator muscle.
- Some surgeons advocate the release of the common extensors as well as structures compressing the PIN to address all potential causes of pain. Ritts et al stated that the pathology of radial tunnel syndrome and that of lateral epicondylitis appear to be interrelated.
- Little literature has been published supporting release of the superficial sensory branch of the radial nerve. It has been associated with neurapraxia and complex regional pain syndrome.
- The surgeon should remain mindful of less common causes of pain over the radial tunnel, including radial nerve compression proximal to the supinator.
- When the diagnosis is not clear on physical examination, and the patient has symptoms and examination findings suggestive of lateral epicondylitis, surgical treatment of lateral epicondylitis can be done concomitantly.

Preoperative Planning

- A tourniquet should be placed on the arm to facilitate visualization. If it is thought that more proximal release or exploration of the radial nerve into the arm may be necessary, a sterile tourniquet is used.

Positioning

- The patient is placed in the supine position, with the arm and forearm rotated as needed to facilitate the preferred approach.
Approach

- The most direct dissection path to the radial nerve may be established by palpating the radial nerve through the mobile wad and rolling the PIN under a thumb with enough force to cause an extension flicker of the digits.
- Multiple surgical approaches are possible. Determination of which structures require decompression may influence the approach chosen.
- Anterior approach
  - Advantages: it can easily be extended proximally to decompress the radial nerve in the arm if indicated. This exposure may be of benefit in cases of compression on the nerve by rarer causes such as elbow synovitis or ganglia.
  - Disadvantages: in muscular patients it can be difficult to retract the BR radially well enough to obtain adequate visualization of the radial tunnel. Distal compression sites often are difficult to release.

- Transbrachioradialis approach
  - Advantage: provides a more direct approach to the radial tunnel, improving exposure
  - Disadvantage: some surgeons find the intramuscular dissection unappealing given the relative paucity of definable landmarks.
- Posterior and posterolateral approaches (the author’s favored approaches)
  - Advantage: dissection between the ECRB and the extensor digitorum communis (EDC), or between the BR and ECRL, allows direct exposure to the entire radial tunnel with relatively less dissection and a bloodless field.
  - Disadvantage: the ECRB–EDC interval is limited in that it does not allow easy extension of the incision to expose the radial nerve more proximally.

POSTERIOR APPROACH AND NERVE DECOMPRESSION (EDC–ERCB INTERVAL)

Exposure

- The forearm is held in pronation. The radial nerve is palpated just posterior to the mobile wad (TECH FIG 1A).
- A 5-cm longitudinal incision is made over the proximal lateral forearm along Thompson’s cardinal line from Lister’s tubercle to the lateral epicondyle (TECH FIG 1B).
- The posterior cutaneous nerve of the forearm is identified and protected (TECH FIG 1C).
- The interval between the EDC and ECRB is located. The overlying fascia is first incised, beginning distally where the structures are better identified. The incision is extended proximally to the lateral epicondyle.
- The EDC and ECRB muscles are separated bluntly, using finger dissection, or with scissors, as required (TECH FIG 1D).
- Opening of this interval will reveal the superficial fascia of the ERCB, to which the fibers of the EDC often are securely attached and from which they must be carefully released.

TECH FIG 1 • A. The points of maximal tenderness help delineate the course of the nerve and isolate areas of compression. B. Standard positioning, use of a sterile tourniquet, and placement of the 5-cm posterior proximal forearm incision. C. The posterior cutaneous nerve of the forearm is consistently seen crossing the proximal incision, superficial to the fascia. It must be protected. D. The fascia between the EDC and ECRB has been divided, and the supinator is exposed.
Releasing the Compression

- The leading edge of the ECRB often is thickened and taut (TECH FIG 2A). This potential site of nerve compression is incised.
  - Release of the origin of the ECRB simultaneously treats coexisting lateral epicondylitis.
  - Further blunt dissection in the EDC–ECRB interval reveals fibers of the superficial head of the supinator distally and fat more proximally over the radial neck (TECH FIG 2B).
  - The PIN will be found within this fat.
  - Gentle dissection of the nerve is performed through this proximal fat as necessary for complete visualization of the nerve.
  - Proximally, the leash of Henry usually is seen running transversely, superficial to the nerve.
    - Typically the vessels are not large or obviously constricting.
    - If any of the vessels of the leash are substantial enough to appear to cause compression, or if they impede full decompression of the supinator, they are separated and coagulated with bipolar cautery.
    - Once the nerve is well visualized proximally, the superficial fascia of the supinator is released in a proximal-to-distal direction to the most distal border of the supinator.
  - A white crescent-shaped band of fibers represents the proximal border of the superficial head of the supinator; this is termed the arcade of Frohse (TECH FIG 2C).
  - This arcade can be observed to tighten over the PIN as the forearm is pronated.
  - These fibers of the superficial head of the supinator are then carefully released. Protect the small motor branches to the ECRB (TECH FIG 2D).
  - This release generally results in significant stretching of the remaining underlying supinator muscle fibers and appears to reduce tension over the nerve.
  - The nerve is inspected and palpated along its entire course for any other sites of compression.
    - During palpation, special attention is paid to the proximal nerve in the interval between the brachialis and BR.
    - A thin fascial layer occasionally is present. This layer is confluent with the fascia of the superficial supinator that extends proximally, causing compression of the nerve. If this is present, it is carefully released.
    - Before completion, visualize and palpate the nerve over its entire course to make sure there are no further sites of compression, especially proximally (TECH FIG 2E).
    - The fascial layer between the ECRB and the EDC is closed with absorbable suture, the skin is closed in the usual manner, and an above-elbow splint is applied with the elbow at 90 degrees and the wrist extended 20 to 30 degrees.
Chapter 71 RADIAL NERVE DECOMPRESSION

POSTEROLATERAL APPROACH AND NERVE DECOMPRESSION (ERCL–BR INTERVAL)

- A 5- to 7-cm incision is made starting at the lateral epicondyle and heading distally along the posterior border of the BR with protection of the sensory nerve branches.
- The fascial interval between the BR and the ECRL is defined.
  - The BR is a deeper red compared with the ECRL due to its thinner overlying fascia.
- The interval is further developed using blunt finger dissection.
  - Difficulty in dissection usually indicates that the muscular interval is not correct.
  - The remainder of the procedure mirrors that detailed for the EDC–ERCB interval.

BRACHIORADIALIS MUSCLE-SPLITTING APPROACH AND NERVE DECOMPRESSION

- A 4- to 6-cm longitudinal incision is made over the proximal, anterolateral surface of the forearm, starting distal to the elbow flexion crease and 3 cm radial to the biceps tendon and extending over the radial head.
  - A 4-cm transverse incision just distal to the radial head also may be used.
- The deep fascia is divided in the line of the skin incision, and the BR is exposed. Its fibers are parted by blunt dissection.
- Immediately deep to this muscle, the vivid white of the superficial branch of the radial nerve is seen. Inspection at the level of the radial head reveals the fat overlying the PIN.
- The transverse branches of the radial recurrent artery and accompanying veins are divided as they pass between the PIN and radial sensory nerve.
- The radial nerve and its branches are now more fully exposed by dividing adhesions and fibrous bands overlying the nerve as well as the proximal fibrous edge of the ECRB.
  - The superficial branch is followed distally anterior to the extensor carpi radialis brevis.
  - The PIN is traced as it disappears beneath the fibrous edge of the superficial proximal border of the supinator, easily distinguished by its prominent oblique striations.
  - This fibrous edge and the muscle are divided longitudinally.
  - The nerve is carefully inspected for untreated sites of compression before closure and splinting.

MODIFIED ANTERIOR APPROACH OF HENRY AND NERVE DECOMPRESSION

- A 5-cm longitudinal incision is made beginning at the antecubital flexion crease and proceeding distally along the medial border of the BR.
  - More proximal and extensile exposure may be obtained by extending the incision obliquely across the elbow flexion crease in the interval between the brachialis and the BR.
- The deep fascia is incised, and the BR is retracted radially. The proximal radial tunnel can be visualized over the capitellum.
  - Any constricting vessels are ligated and divided.
  - The superficial sensory branch of the radial nerve and the PIN are identified.
- The PIN is traced distally.
  - Significant retraction of the BR is required for adequate exposure.
  - The medial border of the ERCB is released to aid in exposure and to eliminate a potential site of compression.
  - The arcade of Frohse is visualized, and the supinator muscle is divided to its distal border.
  - The arm is supinated and pronated to identify constricting structures, and the course of the PIN is carefully inspected.
  - Despite closure and splinting, as detailed previously, the scar often is conspicuous.

PEARLS AND PITFALLS

POSTOPERATIVE CARE
- Patients are splinted for 7 to 10 days.
- Gentle active range of motion exercises are initiated and progressively advanced. Nerve gliding exercises are emphasized.
- Patients are allowed to resume normal activities in a progressive and graded fashion over the next few weeks.

OUTCOMES
- The efficacy of surgical treatment for radial tunnel syndrome is widely variable.
  - This variability in results may be due to heterogeneous patient populations and varying diagnostic criteria.
  - Lister et al, Roles and Maudsley, and Ritts et al all reported high cure rates after release of the PIN.
  - Sotereanos et al reported more modest results (11 of 38 good or excellent), although their population did have a high proportion of worker’s compensation patients.
  - Verhaar and Spaans reported even more modest results (1 of 10 patients had good results; 3 of 10 had fair results). Their diagnostic criterion was limited to tenderness over the radial nerve where it passes under the arcade of Frohse.

COMPLICATIONS
- The incidence of PIN palsy following the procedure is reported to be low.
- Sotereanos et al reported a 31% incidence of paresthesias of the superficial radial nerve.
- Paresthesias of the lateral cutaneous nerve of the arm have also been reported.

REFERENCES
DEFINITION

- **Complete transection** of a peripheral nerve is defined as interruption of all of the axons within the nerve.
- **Primary nerve repair** is the tension-free reapproximation of severed nerve ends performed within a week of injury.
- **Delayed primary repair** is performed up to 3 weeks from injury when local soft tissue injuries do not permit primary wound closure.
- The healing of an injured peripheral nerve is different from the healing of other tissue types.
- Injury is followed by an immediate degeneration, followed by incomplete recovery.
- Irreversible changes in the motor and sensory end-organs make timing of repair critical to achieve useful recovery.

ANATOMY

- The anatomy of the peripheral nerve can be simplified by examining its component parts (FIG 1).
- **Axon.** The basic unit of a nerve is composed of a cell body, dendrites, and longer axons.
  - All axons are surrounded by Schwann cells, which produce the myelin sheath surrounding the axon.
  - Interruptions in the myelin sheath are referred to as **nodes of Ranvier.** Impulse propagation is faster in myelinated axons, because the depolarization potential “jumps” between nodes.
  - Myelinated fibers are between 2 and 22 μm in diameter. The larger the fiber, the faster the conduction speeds.
  - Axonal transport of cytoskeletal elements and neuronal factors is oxygen-dependent. Antegrade transport along the axon occurs at roughly 1 to 4 mm per day. The transport is the rate-limiting step in nerve regeneration.
- **Endoneurium.** Delicate connective tissue that supports and surrounds each axonal fiber and associated Schwann cells
  - Consists of longitudinally arranged collagen fibrils and intrinsic blood vessels
- **Perineurium.** The connective tissue that surrounds groups of axons, creating bundles referred to as **fascicles.** The fascicle is the smallest visible unit of the nerve at surgery.
  - The fascicle is several layers thick and acts as a protective membrane and a barrier to diffusion.
- **Epineurium.** Surrounds groups of fascicles to form the superstructure of a peripheral nerve
  - Forms a sheath about the entire nerve and also supports the fascicular structure by passing between all the fascicles
  - Forms 60% to 85% of the cross-sectional area of a peripheral nerve
  - Composed of longitudinally oriented collagen fibers, fibroblasts, and intrinsic vessels
- **Paraneurium or mesoneurium.** Loose areolar tissue surrounding the epineurium
  - Limited to the outer surface of the nerve
  - Location for the extrinsic vascular supply of the nerve
  - Makes up the gliding apparatus of a peripheral nerve
  - Fascicles have a definite topographic arrangement within a peripheral nerve.
  - Fascicular segregation into motor and sensory components is important when aligning a sectioned nerve before repair.
  - This concept of functional segregation allows for use of part of a donor healthy nerve for nerve transfer with minimal functional deficit.

PATHOGENESIS

- Injuries involving peripheral nerves can be simply classified as tidy or untidy.
- **Tidy wounds** involve sharp transections with minimal to no tissue loss:
  - Sharp lacerations from glass or knife wounds
  - Most iatrogenic nerve injuries
- **Untidy wounds** involve maceration of all tissues in the area:
  - Bony injury may be present.
  - Surrounding soft tissue may have been lost or rendered nonviable and is expected to heal with significant scarring.

NATURAL HISTORY

- Complete transection of a nerve results in retraction of the nerve ends. The nerve will not heal without surgical intervention to approximate the nerve ends.
- Wallerian degeneration occurs in the nerve segment distal to the level of transection.
  - The axon distal to the injury degenerates and does not directly contribute to repair. The axonal and myelin debris are
cleared by macrophages. Schwann cells proliferate, releasing nerve growth factors or neurotrophic factors. The distal stump does produce a complex protein, neurotropic factor, that attracts regenerating axons from the proximal stump. The cell body swells, Nissl granules in the cytoplasm diminish, and its dendritic processes retract. Several cells rupture and die, especially with more proximal nerve injuries (FIG 2).

Regenerating axons sprout from the surviving axons and migrate toward the empty tubules in the degenerate distal stump at a rate of 1 to 3 mm/day.

Proliferating Schwann cells myelinate the newly regenerated axons.

In an unrepaird nerve, the random proliferation of axons from the proximal stump forms a tender mass or neuroma.

PATIENT HISTORY AND PHYSICAL FINDINGS

- History of trauma
  - Penetrating, ballistic, burn, stretch, blunt, fracture, or previous surgery
  - Timing of onset of symptoms: at initial presentation; after procedure, eg, manipulation and casting or internal fixation of a fracture
  - Depth and location of the injury
  - Severity of bleeding-associated blood vessel injury

- Patient reports
  - Paresthesias (pins and needles) or absent sensation (numbness) in fingers
  - Weakness
  - Paralysis due to nerve or associated tendon injury
  - Pain: neurogenic type; can be constant and severe
  - Rarely, a sensation of warmth or anhydrosis

- Physical examination
  - Note the distribution of sensory loss. The area of sensory loss varies with the nerve that is injured (FIG 3).
  - Examine the skin for trophic changes or dry skin. Dry, warm skin implies sympathetic interruption.
  - Perform thumb abduction test to check for paralysis of the abductor pollicis brevis from median nerve injury.
  - Perform the Froment’s sign test. The test is positive if paper is held by flexing the thumb interphalangeal joint (IP), indicating recruitment of the flexor pollicis longus, which implies paralysis of the adductor pollicis from ulnar nerve injury.
  - The thumb IP hyperextension test may indicate paralysis of the extensor pollicis longus due to posterior interosseous palsy.
  - Perform the Tinel sign test. The test is positive if the patient notes a tingling sensation in the sensory distribution of the nerve. Serial progression of Tinel sign distally is useful to monitor axon progression after repair.
  - When performing physical examinations, it is helpful to use motor function grading according to the Medical Research Council system. This grading allows for quantitative measurement of function and allows the physician to chart recovery objectively:
    - M0: no contraction
    - M1: palpable contraction with only a flicker of motion
    - M2: movement of the part with gravity eliminated
    - M3: muscle contraction against gravity
    - M4: ability to contract against moderate resistance
    - M5: normal function

- Sensory grading is also useful in evaluation. Sensory function is evaluated within the anatomic distribution of the nerve in question. Sensation is quantified using two complementary tests—(1) Semmes-Weinstein monofilaments, which measure innervation threshold, and (2) two-point discrimination, which measures innervation density. Vibratory, pain, and temperature sensation should also be evaluated. Semmes-Weinstein filaments demonstrate subtle and early sensory loss and are more useful in evaluation of compressive neuropathy. Two-point discrimination measurements help gauge the severity of nerve injury, with two-point discrimination of less than 12 mm indicating neurapraxic injury and readings greater than 15 mm suggesting complete disruption. Used together, the various sensory tests allow for quantitative measurement of function and allow for the physician to objectively chart recovery:
  - S0: lack of sensation
  - S1: recovery of deep cutaneous pain sensibility within the autonomous area of the nerve
  - S2: return of some degree of superficial cutaneous pain and tactile sensibility
  - S3: Return of function (S2) without evidence of hyper-sensibility
  - S3 plus: return of function (S3) with some return of two-point discrimination
  - S4: normal function

Sensory recovery classification on two-point discrimination alone:

- Normal: < 6 mm
- Fair: 6–10 mm
- Poor: 11–15 mm

FIG 2 • Comparison of a normal neuron cell body (A) with that of a nerve after transection (B). Note cellular swelling, dissolution of Nissl granules in the cytoplasm, and retraction of the dendritic processes.

FIG 3 • Distribution of sensory loss with nerve injury. Yellow, median nerve; blue, ulnar nerve; pink, radial nerve.
IMAGING AND OTHER DIAGNOSTIC STUDIES

- Diagnosis in acute injuries is usually based on history and clinical examination alone without need for additional investigations.
- Plain radiographs are of little use in evaluation of the nerves themselves, but may be helpful in cases of injury from fracture or projectiles.
- CT myelography is useful for evaluation of injuries to the brachial plexus. The formation of a pseudomeningocele is indicative of root avulsion.
- MRI is useful for evaluation of peripheral injury but is not routinely indicated for peripheral nerve injuries.
  - Short tau inversion recovery (STIR) MRI may show enhancement of the nerve near the site of injury or interruption of the nerve trunk on T1- and T2-weighted images.
  - MRI provides visualization of pseudomeningoceles at the spinal cord levels in root avulsion injuries.
- Electrodiagnostic testing
  - Nerve conduction velocity (NCV) and electromyography (EMG) are useful in evaluation of closed nerve injuries, eg, after fracture or multiple nerve injuries such as brachial plexus injury.
  - If stimulation distal to the suspected injury elicits a motor response about 3 days after injury, then the lesion is likely a conduction block. However, muscle action may be present in the case of complete transection for up to 9 days.
  - Fibrillation potentials on EMG appear after 2 to 3 weeks and indicate muscle denervation and a severe grade nerve injury.
  - Recovery is best evaluated with serial examination of compound muscle action potentials. Early recovery of only a few motor units may indicate reinnervation from adjacent intact nerves and should not be used as an indicator of recovery of the repaired nerve.

DIFFERENTIAL DIAGNOSIS

- Muscle or tendon injury in open lacerations
- Parsonage-Turner syndrome (brachial plexus neuritis)
- Peripheral nerve entrapment

NONOPERATIVE MANAGEMENT

- Nonoperative management of a completely transected nerve after an open injury is doomed to failure, because cut ends retract and scar tissue forms in the gap.
- Pending recovery of the nerve, splinting of the paralyzed joint maintains functional position and prevents contractures.

SURGICAL MANAGEMENT

- Nerves that have been completely interrupted require surgical measures to restore continuity.
- All open injuries with neurologic impairment must be explored expeditiously.
- With closed injuries or delayed presentation, consider the overall functional capacity of the injured limb.
- In a largely motor nerve, eg, the radial nerve, tendon transfers may restore function more reliably than nerve repair.

Preoperative Planning

- The cause of the peripheral nerve injury must be identified. The repaired nerve must have a favorable local environment if the repair is to be successful.
- Underlying fractures must be stabilized.
- Adequate soft tissue coverage of the nerve repair must be planned.
- Repair should be delayed when multiple debridements are necessary until the bed for the repaired nerve is optimal and wound can be primarily closed.
- If segmental loss is suspected, as with a crushing injury, the patient must give informed consent for additional options such as conduit repair or nerve grafting.
- Injuries that present late should be evaluated with electrophysiologic studies to look for signs of recovery.
- If intraoperative nerve stimulation is to be used, muscle relaxants should be avoided at induction of general anesthesia.
- If associated muscle or tendon lacerations are present, muscle relaxation facilitates their repair.
- Regional anesthetics such as supraclavicular block provide excellent muscle relaxation, and a supraclavicular catheter will help in administering postoperative analgesia.

Positioning

- The patient is positioned supine, with the arm positioned on a hand table.
- Use of a tourniquet facilitates dissection but will interfere with intraoperative nerve stimulation, because it results in ischemic conduction blocks after 15 minutes.
- Use of intraoperative magnification (eg, loupes) for the dissection and a surgical microscope during nerve repair is essential.
- Microinstrumentation is needed for nerve handling and repair.
- Alcoholic solutions should be avoided for the preparation of open wounds to avoid chemical damage to nerve tissue.

APPROACH

- The area of injury should be exposed both proximally and distally to allow for visualization of the proximal and distal nerve stumps using extensile approaches.
- After all injured structures have been assessed, repair fractures and tendons first to take tension off the nerve repair.
- Mobilize nerve ends for about 1 to 2 cm at either end, avoiding unnecessary stripping of the mesoneurium over long distances.
- Preserve the common sheath of neurovascular bundles to maintain nerve vascularity and minimize tension on nerve repair.
- Nerve end preparation is critical. Crushing is present even after sharp lacerations.
- Under an operating microscope, the nerve end is stabilized over a sterile wooden spatula and a fresh no. 11 blade is used to progressively cut back 2-mm segments of the nerve end until sprouting fascicles are seen (TECH FIG 1).
End-to-end repair should be attempted as long as this can be accomplished with minimal tension on the repair and with minimal mobilization of the nerve.

If a single epineurial stitch of 8-0 suture fails to maintain nerve approximation, tension is excessive. Additional mobilization or alternative options such as conduit repair or nerve grafting must be considered.

Posterior wall repair is completed with three or four simple epineurial sutures, as needed. The long tails are then cut short, and the nerve is examined carefully to ensure that a complete epineurial seal is achieved (TECH FIG 2B).

The distal and proximal joints are placed in minimal flexion. Excessive flexion is to be avoided, because it will result in flexion contractures or tension on healing nerve.

Additional length can be gained by transposition of the proximal nerve, eg, ulnar nerve at the elbow, or bone shortening, eg, during replantation surgery.

The distal and proximal joints are placed in minimal flexion. Excessive flexion is to be avoided, because it will result in flexion contractures or tension on healing nerve.

Additional length can be gained by transposition of the proximal nerve, eg, ulnar nerve at the elbow, or bone shortening, eg, during replantation surgery.

Epineurial repair, the most common type of nerve repair, consists of alignment and approximation of the nerve ends using sutures placed in the epineurium.

After clean, pouting bundles of fascicles are exposed, the epineurium is identified circumferentially by resection or pushing back of the mesoneurium.

Correct alignment of the nerve ends is critical. Line up blood vessels and other external markings in the epineurium, and match fascicular bundles in the two ends.

Suture must be monofilament (eg, nylon) on an atraumatic needle to minimize trauma to the nerve ends. Suture size varies with the size of the nerve. Usually an 8-0 suture is used in the arm and 9-0 in the fingers. Repair with larger suture dimensions does not add strength to the repair: sutures fail by pull-out of the neural tissue.

Two simple sutures are placed 180 degrees from one another. Care must be taken to avoid penetrating fascicles with the needle (TECH FIG 2A).

One tail of each suture is left long to stabilize the nerve during repair.

Three or four additional sutures are placed on the anterior face of the repair as necessary to approximate the epineurium and prevent fascicular extrusion.

By flexing the limb further to relax the nerve, the nerve is turned over, using the suture tails, to expose the posterior wall. Each suture tail can be weighted down with a small vascular clip.

Posterior wall repair is completed with three or four simple epineurial sutures, as needed. The long tails are then cut short, and the nerve is examined carefully to ensure that a complete epineurial seal is achieved (TECH FIG 2B).
GROUP FASCICULAR REPAIR

- Groups of nerve fascicles are approximated by perineurial sutures (TECH FIG 3).
- Group fascicular repair is indicated for partial nerve injury involving a few groups of fascicles or in a mixed nerve with distinct motor and sensory components, such as the median nerve proximal to the wrist.
- The advantage of improved fascicular alignment may be counteracted by increased intraneural scarring from the increased surgical dissection and manipulation of the group fascicular repair.
- After exposing clean, pouting bundles of fascicles, the epineurium is resected back for 5 mm to clearly expose groups of fascicles surrounded by perineurium.
- The internal arrangement of the fascicles is noted, and similarly sized fascicular groups are aligned.
- For partial nerve injury with a few injured fascicles, repair individual fascicles with 10-0 nylon simple sutures placed in the perineurium. Usually, two sutures per fascicle are adequate.
- In the case of a complete nerve injury involving a larger nerve, a group fascicular repair that approximates groups of fascicles is faster and less traumatic.
- When approximating larger groups of fascicles, four to six sutures are placed per group in a circumferential pattern. For additional stability, sutures at the external surface of the fascicular group should be passed through both the epineurium and perineurium. (These sutures are known as epi-perineurial sutures.)
- After completion of fascicular repair, four additional sutures of 9-0 nylon are placed in the epineurium to take tension off the repair.

CABLE GRAFT REPAIR

- Nerve grafting is indicated when end-to-end approximation is not possible, eg, after crushing of the nerve ends, retraction of nerve ends after delay in surgical intervention, or after neuroma resection.
- After the nerve ends are prepared back to pouting bundles of fascicles, the epineurium is identified circumferentially.
- The internal arrangement of the fascicles is noted, and a quick sketch of the fascicular arrangement helps to plan graft alignment (TECH FIG 4).
- Epineurium is resected to expose the perineurium of the fascicles.
- The gap between the prepared nerve ends is measured.
- When grafting a larger-diameter nerve such as the median nerve using a smaller diameter nerve such as the sural nerve, several strands of donor nerve are interposed in the gap as a cable graft.
- The length of nerve graft needed is calculated as follows: gap $\div 15\% \times$ estimated number of strands.
- Donor nerves include the sural (located midway between the lateral border of the tendo achilles and the lateral malleolus), posterior interosseous (located in the floor of the fourth extensor compartment), and the medial antebrachial cutaneous nerve (located in the anteromedial forearm along branches of the basilic vein).
- Each segment of graft is reversed and attached to a similar-sized group of fascicles at the proximal stump using two sutures of 9-0 nylon, 180 degrees from one another.
- Although the donor nerve allows growth of regenerating axons in either direction, reversing the nerve graft helps to minimize the possibility of regenerating axons growing out along branches of the donor nerve.
- Place the limb in a neutral position; then lay the graft in the defect and align it with a similar fascicular group in the distal stump. The graft is cut and sutured to the distal stump fascicles.
- Follow the same sequence, laying segments of graft across the gap until the gap is filled.
- The repair can be reinforced with fibrin glue placed at the anastomosis and between segments of the graft.

TECH FIG 3 • Technique of group fascicular repair. The epineurium is pulled back, and sutures are placed in the perineurium after fascicular groups have been aligned.

TECH FIG 4 • Nerve grafting using “cables” of nerve graft. After aligning the nerve ends, similar fascicular groups are bridged with segments of nerve graft.
VASCULARIZED NERVE GRAFT REPAIR

- Vascularized nerve graft repair may be indicated in cases when the gap is 6 cm or more, or in a scarred tissue bed in large proximal nerve reconstruction after brachial plexus injuries.
- The most common vascularized nerve graft donor is the ulnar nerve (following C8 and T1 root avulsion), along with its mesoneurium, containing the superior ulnar collateral vessels.
- For local nerve defects, the ulnar nerve segment is divided, preserving the vascular pedicle. The segment is transposed with its intact pedicle, and epineurial repair is performed.
- If a more remote defect is to be grafted, the vascular pedicle and nerve segment are divided. The nerve is reversed and placed in the defect. Following epineurial repair, microvascular anastomosis is performed between the artery and vein in the vascular leash to a local arterial and venous recipient vessel.

CONDUIT REPAIR

- Conduit repair is indicated for clinical use in nerve gaps up to 2 cm.
- Advantages over conventional repair are that it is tension free, less traumatic, permits no axonal escape, and allows spontaneous axonal orientation.
- Two types are in clinical use: reversed autogenous vein or artificial conduits.
  - Artificial conduits may be either manufactured using absorbable materials such as polyglycolic acid or made of collagen engineered from natural xenograft sources such as bovine tendon. Artificial conduits have obvious advantages over a vein conduit in regard to shelf availability, size variation, no additional dissection for harvesting, and resilience and elasticity. Collagen tubes degrade over time with natural processes and without any inflammatory reaction.
  - After nerve end preparation, the nerve diameter is measured. A conduit that is oversized by 1 mm is chosen to avoid constriction of the regenerating nerve.
  - The conduit is rehydrated in saline for 5 minutes.

- The aim of repair is to invaginate each end of the nerve into the tube for a distance of 5 to 8 mm using a mattress suture followed by a single anchoring suture for stability (TECH FIG 5).
- The suture is first passed through the tube from the outside in and about 5 mm from the tube edge. The suture is then passed transversely across the epineurium 3 mm from the edge of the nerve stump and then back through the tube in an inside-to-outside direction.
- Gently ease the nerve into the tube as the knot is tightened.
- Place a simple suture between the epineurium and the edge of the tube at a diametrically opposite point to anchor the tube and prevent rotation.
- Repeat the same steps for the distal stump, and fill the tube with saline using a fine cannula.

**TECH FIG 5** • Technique of conduit repair. A. A horizontal mattress suture is placed between the conduit and the epineurium of the nerve. B. As the suture is tightened, the nerve is drawn into the conduit. A simple stitch is placed anchoring the epineurium to the tube opposite the location of the mattress suture.
PEARLS AND PITFALLS

Intraoperative precautions
- If contemplating intraoperative nerve stimulation, avoid muscle relaxants and tourniquets.
- Repair bones and tendons before undertaking fragile nerve repair.
- Proceed with nerve repair only if the wound bed is clean and healthy and primary closure is possible.
- If delayed repair is planned, place a marking suture in the epineurium to facilitate later identification.

Nerve precautions
- Limit handling of nerve and use microsurgical instruments.
- Use operating microscope to prepare nerve ends and for fascicular alignment.
- Always be prepared to use graft or conduit rather than suture nerve under tension or with joints excessively flexed.
- Keep nerves (including grafts) moist.
- Repair should be tension-free.
- Soft tissue coverage is a must.

Instrumentation
- Make certain microinstrumentation is in good repair.
- Forceps should be free of spurs and should approximate correctly.
- Use 8-0 or 9-0 suture with atraumatic taper-point needles.

POSTOPERATIVE CARE
- Consider use of a local anesthesia infusion pump for postoperative pain control.
- Immobilization is very important to prevent tension across the repair:
  - The elbow should be held at 90 degrees of flexion.
  - Wrist flexion greater than 20 degrees should be avoided.
  - The metacarpophalangeal joints should be held at 70 degrees of flexion.
- Mobilization varies with associated tendon repair. After isolated nerve repair, gentle finger flexion and shoulder range of motion are started soon after surgery to promote nerve gliding and prevent finger stiffness.
- Remove skin sutures after 2 weeks and replace the splint.
- For nerve repairs around the elbow, allow motion in an extension blocking splint. Full extension is permitted after 6 weeks.
- For repairs in the distal forearm and wrist level, immobilize the wrist at 20 degrees flexion and block metacarpophalangeal hyperextension for 4 weeks. Allow active finger motion within the splint. Bring the wrist to neutral at 4 weeks, and then allow mobilization out of the splint at 6 weeks.
- Nerve regeneration is followed at regular intervals with clinical examination of motor and sensory recovery and Tinel sign.
  - The distal-most point at which the Tinel sign is observed is recorded at each visit and its distance from the suture line noted.
  - Expect distal progression of Tinel sign at the rate of about 1 mm per day, with a delay of 1 month after the date of repair.
  - Failure of Tinel progression over serial visits may indicate repair failure; consider re-exploration and grafting.
  - Sensory re-education is initiated early in the postoperative phase with the goal of teaching recognition of new input in a useful manner.
- Three stages to this process are introduced sequentially in the recovery period:
  - Desensitization: the patient is presented with graded stimuli to decrease unpleasant sensations.
  - Early-phase discrimination and localization: the patient works with static and moving touch, using visual reinforcement.
  - Late-phase discrimination and tactile gnosis: the patient works with varying shaped objects.

OUTCOMES
- The outcome after nerve repair is generally less favorable than that of repair of other tissues, such as bone or tendon injury.
- It is difficult to predict the outcome because of several variables, including type of nerve (pure sensory versus mixed), age of patient, type of injury—clean or crushed, associated soft tissue injuries.
- The single most important factor that correlates with outcome is patient age. The best results are seen in children younger than 10 years of age.
- Pure motor or pure sensory nerves fare better than mixed nerves.
- The outcome also correlates with level of injury. Injuries closer to the end organs fare better, because there is less distance for the regenerating axons to cover.
- Peripheral factors that are determined by the injury and cannot be modified by the treating surgeon include axonal cell death, end-organ atrophy, and extensive scarring from surrounding crush injury.
- The surgeon can control, to a limited extent, the scarring in and around the nerve repair.
- Central factors that account for poor results include cortical remapping and reorganization, with reduced and disorganized cortical representation of denervated areas.
- Children recover greater function than their adult counterparts with primarily repaired lesions at similar levels due to a combination of better axonal regeneration and cortical plasticity.
- Delayed repairs fare worse than those repaired acutely, with an estimated 1% decrease in performance for every 6 days of delay in the repair.
- The nature of the injury often determines the likelihood of recovery. Massive soft tissue injury or burns involving a peripheral nerve are less likely to regain function than injuries involving sharp or limited transection of a nerve.
- Median nerve outcome after high injuries usually is poor because of hand intrinsic atrophy. After low injuries, useful
motor function is regained in 40% to 90% of repairs, and useful sensation is restored in 53% to 100% of patients.

- Ulnar nerve injuries show similarly poor results for motor recovery, with functional restoration in 35% of cases and functional sensory recovery in 30% to 68% of cases.
- Because the ulnar nerve is largely a motor nerve, better results can be expected after acute radial nerve repairs, with functional return in 60% to 75% of patients. Poor results are noted with high injuries, however.
- After repair of digital nerves, about 50% of patients regain static two-point discrimination of less than 10 mm. Younger children demonstrate near-normal sensory recovery due to their cortical adaptability.
- Lingering symptoms of hypersensitivity and cold intolerance are common with sensory nerve injury in the upper extremity, resolving in most patients after 2 to 3 years. The cause is unclear.
- Complex regional pain syndrome is more likely to be present after untreated nerve injuries. If it does occur, significant joint contractures and atrophic changes can result, and the patient generally has a prolonged recovery period and a poor outcome.

**COMPlications**

- Causes for failure of repair include:
  - Tension on the initial repair
  - An unfavorable local tissue environment with excessive scarring
  - Noncompliance with protective measures or therapy and consequent joint contractures
  - Painful neuromas usually form in unrepaired or poorly repaired nerves close to the surface. These usually are treated with desensitization, local padding, etc. because surgical results are often disappointing.
  - Altered sensation is a result of axonal misdirection and cortical misrepresentation and can present as loss of temperature sensation or cold intolerance, hyperesthesia, or neuropathic pain.
  - Some amount of altered function is inevitable after all complete nerve injuries in the upper extremity except in young children. It is due to a combination of altered sensation and proprioception along with loss of motor strength.
  - Complex regional pain syndrome type II can occur after nerve injury especially in untreated cases or after delayed treatment or failure to control pain. Typical features include dramatic changes in the color and temperature of the skin accompanied by intense burning pain, skin sensitivity, sweating, and swelling. Early recognition is the key with referral to a pain management specialist for stellate blocks along with steroids, antiepileptic drugs, and therapy.

**SUGGESTED READING**

de Medinaceli L, Prayon M, Merle M. Percentage of nerve injuries in which primary repair can be achieved by end-to-end approximation: Review of 2,181 nerve lesions. Microsurgery 1993;14:244–246.

DEFINITION

■ A nerve injury in continuity occurs when there is loss of axonal function with preserved structure of the supportive connective tissue.
  □ By definition, the epineurium is preserved in a nerve injury in continuity.
  □ Because varying degrees of axonal interruption may occur, the extent of functional loss in terms of numbness and paralysis is variable.
  □ The severity of injury varies with degree of preservation of the endoneurium and the perineurium.

ANATOMY

■ The cross-sectional anatomy of the peripheral nerve is discussed in detail in Chapter HA-72.
  □ Endoneurial tubes form the basic conduit for the Schwann cell–encased axon.

PATHOGENESIS

■ Several mechanisms may cause a nerve injury in continuity, but the most common is nerve stretch.
  □ When a nerve is subject to blunt injury or stretch, axonal disruption can occur without externally visible injury to the nerve.
  □ Stromal elements are more resilient to stretch and remain preserved to a variable extent (FIG 1).
  □ The type of recovery seen after an injury depends on preservation of the endoneurial tube.

■ In the mildest forms of injury, with preserved endoneurial tubes, regenerating axons follow their original path. The destination is reached with good outcome. There is no axonal mismatch, and the recovery is termed uncomplicated regeneration.
  □ When the endoneurial tube is disrupted, axonal regeneration is disorganized. Axons sprout and grow in a different direction, and mismatch occurs. This form of repair, termed complex regeneration, is associated with a clinically less satisfactory outcome.
  □ With more severe forms of stretch injury, additional disruption of the perineurium occurs, resulting in a greater fibrotic response and resultant scarring of the nerve.
  □ The nerve trunk, which externally appears uninterrupted due to the intact epineurium, demonstrates an injured segment that is enlarged due to intraneural fibrosis surrounding a mass of disorganized axons. This is referred to as a neuroma in continuity (FIG 2).

NATURAL HISTORY

■ Pathoanatomy associated with the injury, pathologic changes resulting from this altered anatomy, and functional recovery are closely related.
  □ More anatomic disruption results in a stronger pathologic response and worse outcome.
  □ Sunderland’s classification of injury severity is useful to categorize injury and plan treatment.

□ Type I
  □ The mildest form of injury involves loss of axonal function without actual structural interruption: neurapraxia (FIG 3A).
  □ Type I injury is seen after mild stretch injuries, tourniquet palsy, and external compression of a nerve, as in radial nerve compression in “Saturday night palsy.”
  □ Although structurally intact, axons fail to conduct impulses, secondary to malfunction of ion channels along the injured segment.
  □ No visible change in the microscopic or macroscopic appearance of the nerve is present, and there is no wallerian degeneration of the distal segment.
  □ Electrophysiologic testing does not reveal a conduction block or denervation potentials.

FIG 1 • Pathogenesis of a nerve injury in continuity. The effect of increasing stretch is seen, from normal nerve at the top to complete rupture at the bottom. Neural elements fail first in response to stretch; epineurium fails last.

FIG 2 • Neuroma in continuity. The enlarged part of the nerve consists of a mixture of intact and damaged axons surrounded by scar tissue and regenerating axons.
Recovery starts within a few weeks and can be expected to be complete.
Because axons recover conductivity in a variable pattern, clinical recovery follows a random pattern.

Type II
There is structural disruption of the axon, but the endoneurium is preserved (FIG 3B).
Type II injury is seen after more severe stretch injuries, such as radial nerve palsy resulting from a closed humerus fracture.
Wallerian degeneration results and electrophysiologic tests reveal distal conduction block and denervation.
As regenerating axons progress distally, proximal muscles are reinnervated first. Clinically, recovery occurs in a proximal-to-distal direction.
Because there is no axonal mismatch, recovery usually is complete but takes longer, usually several months.

Type III
The axon, myelin sheath, and endoneurium are interrupted (FIG 3C).
Recovery is less predictable, because regenerating axons may not follow previous pathways (complicated regeneration).
With the perineurium preserved, recovery can take place without surgical intervention but usually is incomplete due to axonal misdirection.
Injury to small vessels within the endoneurium leads to an inflammatory response. Fibroblast activation results in a variable degree of interfascicular scarring that may impede nerve regeneration.

Type IV
In more severe stretch injuries, the internal nerve structure is completely disrupted, leaving only an intact epineurium (FIG 3D).
Retraction of fascicles and scarring within the nerve are present. Even though the nerve is in continuity, no clinically significant recovery can be expected without surgical intervention.

Type V
Complete rupture or laceration of the nerve with retraction of the nerve ends (see Chap. HA-93) (FIG 3E)

PATIENT HISTORY AND PHYSICAL FINDINGS
Stretch injuries that result in nerve injury in continuity usually are proximal. These injuries often take place as the nerve root exits the spinal cord or involve the brachial plexus in the neck or upper arm.
At more distal levels, nerve stretch injuries usually are the result of displaced fractures or dislocations.
There usually is a history of significant trauma, and patients complain of pain and paresthesias with a variable amount of functional loss distal to the site of injury.
Incomplete loss of function often indicates an incomplete nerve injury.
Severe pain or paresthesias after any closed fracture should alert the clinician to the possibility of an associated nerve injury.
Complete loss of function does not necessarily imply complete disruption of the nerve.
Documented lack of recovery on serial clinical examinations is essential to determine the severity of the injury and the need for surgical intervention.
Muscle strength is charted against a timeline at every visit. Progressive muscle recovery in a proximal-to-distal direction indicates spontaneous axonal regeneration.
Tinel sign and its gradual progression is also a useful measure of nerve recovery.
Recovery within a few weeks of injury and with a random pattern usually suggests a Type I injury or neurapraxia.

After incomplete injury to a peripheral nerve, function is lost in a predictable order: motor, proprioception, touch, temperature, pain, and sympathetic function.

Recovery usually occurs in the reverse order.

In a closed injury without any obvious fractures, the site of nerve injury is not always obvious.

Careful mapping of the motor and sensory deficit will help to distinguish the level of injury.

The pattern of sensory loss is a reliable way to determine the level of injury. A more proximal injury usually follows a dermatomal pattern, whereas a distal injury follows the distribution of the nerve.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- MRI done several weeks after injury may reveal an enlarged nerve segment, suggesting a neuroma in continuity.
- Neuropathologic studies are useful in evaluating and monitoring an injured nerve when there is no external injury.
- Conduction blocks usually reverse within 10 to 14 days; therefore, tests should be delayed until this time.
- Complete loss of muscle action potentials does not necessarily indicate a complete interruption of all axons.
- Electromyograms (EMGs) will show variable denervation of muscle groups innervated by the nerve in question.
- Fibrillation potentials on EMG usually appear within 10 to 40 days, indicating complete denervation of a muscle group.
- Electromyographic evidence of reinnervation may precede voluntary muscle contraction by several weeks and may be of use in tracking the progress of nerve regeneration.
- Return of a muscle action potential requires not only regeneration of the nerve to the level of the end organ but also re-establishment of a physiologic connection between the nerve and the target tissue. Re-establishment of the motor endplate is required before EMG provides evidence of functional return.
- Nerve conduction studies (NCSs) also are useful in the evaluation of a closed nerve injury.
  - In a closed injury, lesions may be localized using NCSs.
  - Continuity of the nerve also may be assessed, but should be undertaken at about 10 days after the injury to prevent erroneous results, because the axons distal to a complete transection may continue to conduct during this initial period after injury.
- Parameters evaluated include amplitude and latency.

**DIFFERENTIAL DIAGNOSIS**

- Complete transection
- Conduction block
- Partial axonal injury
- Compressive injury

**NONOPERATIVE MANAGEMENT**

- Lesions in continuity may improve spontaneously, especially in types I and II, in which recovery is complete without any surgical intervention.
- Type I through III injuries can be watched closely with serial mapping of the sensory and motor recovery.
- Type IV and V injuries usually require surgical repair of the nerve to restore axonal continuity.
- Preservation of some function distal to the suspected level of the injury within the distribution of the injured nerve suggests a partial injury, and observation is appropriate.
- If there is a complete palsy of a nerve after a closed injury, an initial period of observation may be best until signs of denervation appear in end organs.
- If signs of reinnervation appear, such as a Tinel sign distal to the level of injury, continued observation is prudent.
- If no signs of reinnervation appear, one should strongly consider electrophysiologic studies to evaluate the continuity of the axonal fibers.
- Physical therapy is very important to maintain mobility during the period of observation.

**SURGICAL MANAGEMENT**

- If no signs of recovery are present at 2 to 4 months, then surgical exploration may be indicated.
- Electrophysiologic testing should be used in this instance to define the level of injury.
- Longer delays may compromise the efficacy of surgical repair, secondary to end organ degenerative changes.
- Focal injuries are usually observed for shorter periods, because the extent of the injured nerve segment usually is smaller.
- Blunt or blast injuries may be observed for up to 6 months after the initial large segments of injured nerve undergoing repair.

**Preoperative Planning**

- Intraoperative nerve action potentials (NAPs) may provide information about lesions in continuity, including the degree and extent of interruption.
- If NAPs are not recordable across a lesion, then resection and direct repair rather than grafting will likely be required.
- Resection is performed from the point at which NAPs are lost to the point where they return.
- If NAPs are present, external neurolysis or nerve decompression may be adequate treatment.

**Positioning**

- The patient is positioned supine, with a hand table.
- If nerve grafts may be required, the opposite leg is prepared to allow access to the sural nerve. Rarely, if bilateral sural nerves are to be harvested, the patient initially is placed prone.
- Use of a tourniquet may result in ischemic conduction block, which will render intraoperative nerve stimulation ineffective.
- It generally is preferable to use a tourniquet for only the first 20 minutes of surgery, to facilitate initial dissection.
- The use of an operating microscope and fine soft tissue sets or microinstrumentation is necessary for nerve handling and repair.

**Approach**

- Surgical exposure should provide adequate access to the section of damaged nerve as well as proximal and distal to this site.
- Mobilization should be minimized to prevent additional vascular insult to the nerve.
- Sources of external compression should be identified and alleviated.
- The bed for repair should be free of scar tissue. Nerve transposition may be required.
EXTERNAL NEUROLYSIS

- External neurolysis is defined as the circumferential freeing of a peripheral nerve from surrounding scar tissue (TECH FIG 1A).
- Dissection proceeds from normal nerve (both proximal and distal) to the area of scarring (TECH FIG 1B).
- The nerve should be mobilized away from the scar tissue bed to prevent recurrence.

- Use of a xenograft nerve wrap or fat graft may be considered to prevent recurrence of scarring (TECH FIG 1C).
- External neurolysis may relieve neuropathic pain associated with compression, but results for sensory and motor recovery are variable.

EXTERNAL NEUROLYSIS

- Use of a xenograft nerve wrap or fat graft may be considered to prevent recurrence of scarring (TECH FIG 1C).
- External neurolysis may relieve neuropathic pain associated with compression, but results for sensory and motor recovery are variable.

INTERNAL NEUROLYSIS

- Internal neurolysis is defined as the resection of fibrotic tissue from within the structure of the nerve itself.
- This procedure is indicated for late management of incomplete injuries such as stretch injuries when the nerve has regained partial function that is clinically inadequate.

- Intraoperative recording of NAPs will indicate functioning fascicular groups and help guide the surgeon during this procedure.
- Internal neurolysis is performed along the fascicular segment that has lost NAPs (TECH FIG 2).

TECH FIG 1 • External neurolysis and xenograft nerve wrap. A. The median nerve at the wrist developed painful scarring after carpal tunnel release. B. External neurolysis has been performed by excision of all scar tissue and thickened epineurium. C. A xenograft collagen nerve wrap has been placed around the nerve to minimize scar tissue formation around the nerve.

TECH FIG 2 • A–C. Intraoperative microscope images of internal neurolysis of the ulnar nerve at the wrist. A. The ulnar nerve is surrounded by dense scar tissue. B. After external neurolysis, there is a persistent area of narrowing of the nerve (arrows) requiring internal neurolysis. (continued)
SPLIT REPAIR

- **Split repair** is defined as a procedure in which intraoperative NAP recordings are used to guide the resection of individual nonconducting fascicles.
- First, external neurolysis is performed to expose the injured segment of the nerve.
- The epineurium is excised circumferentially to expose the injured fascicles (TECH FIG 3A).
- Intraoperative NAP recordings are made to identify the injured fascicular segments (TECH FIG 3B).
- Resection of the nonconducting segments is performed using either a blade or sharp microvascular scissors (TECH FIG 3C).
- Repair is performed either directly or with autogenous grafting.

This procedure is performed in cases of incomplete functional loss distal to the site of injury.

Some loss of intact axons can be expected as a result of the dissection, so the patient should be advised that additional loss of function could be possible with this procedure.

TECH FIG 2 • (continued) C. Appearance after internal neurolysis—the constricting epineurium and scar between fascicles has been excised. D. Illustration of a neuroma in continuity treated by internal neurolysis. The segment of scarred epineurium is excised, and all scar tissue between fascicles also is excised.

TECH FIG 3 • Exploration and split repair of a partial injury of the posterior interosseous nerve 4 weeks after palsy following a dog bite at the elbow. A. The posterior interosseous nerve demonstrates a neuroma in continuity (white arrow). B. Internal neurolysis has been performed, isolating intact peripheral fascicles with a central neuroma (white arrow). C. A gap remains in the injured fascicular group after neuroma resection. Mobilization of the intact fascicles is limited because of their proximity to the motor branches, making end-end repair of the injured fascicles difficult. (continued)
If no conduction of NAPs is noted across a lesion after internal neurolysis is performed, then the entire lesion should be resected.

The proximal and distal portions of the nerve flanking the lesion should be mobilized to prevent undue tension on the repair. During mobilization, longitudinal blood vessels within the epineurium must be preserved.

The lesion is sharply excised using a fresh, sharp blade against a block (usually a moistened tongue depressor).

**Epineurial Repair**

- If the extent of the lesion is short, then direct end-to-end epineurial repair without tension often is possible.
- Direct epineurial repair is then performed as described in Chapter HA 93.

**Cable Graft Repair**

- Cable graft repair is useful when the extent of the lesion precludes direct repair because of either tension or a large gap (TECH FIG 4A).
- Cable graft repair is then performed as described in Chapter HA-93.
- Sural nerve graft can be harvested through a single longitudinal or multiple transverse incisions (TECH FIG 4B).

**Cable Grafting**

- Cable grafting is the more common technique, using donor nerve from either the sural or antebrachial cutaneous nerve.
- Grouped fascicular repair is then performed (TECH FIG 3D–F).
  - The internal arrangement of the fascicles is noted, and a quick sketch of the fascicular arrangement is made to allow alignment of the nerve ends.
  - Nerve grafts will not match the exact fascicular pattern—the aim is to place graft “cables” between groups of fascicles.
  - The gap between nerve ends is measured, and the length of graft needed is calculated.

- Length = gap + 15% × estimated number of grafts
- Grafts are attached to a group of fascicles using two sutures of 9-0 or 10-0 nylon, 180 degrees from one another.
- Each graft is sutured to the proximal and distal stumps before moving on to the next graft, thus allowing for more accurate fascicular matching.
- Check the repair to ensure that no stitches have pulled out. The repair may be reinforced with fibrin glue.
- Handling of the grafts should be minimized.
- Grafts should be kept moist from harvest to repair.

**RESECTION OF THE NERVE LESION IN CONTINUITY**

- If no conduction of NAPs is noted across a lesion after internal neurolysis is performed, then the entire lesion should be resected.
- The proximal and distal portions of the nerve flanking the lesion should be mobilized to prevent undue tension on the repair. During mobilization, longitudinal blood vessels within the epineurium must be preserved.
- The lesion is sharply excised using a fresh, sharp blade against a block (usually a moistened tongue depressor).

- The nerve is easily identified by careful spreading dissection in the subcutaneous tissue midway between the lateral malleolus and the tendo-achilles (TECH FIG 4C).
- Use of a tendon stripper to harvest the nerve is not recommended.
- This technique can result in stretch or laceration of the sural nerve.
- Additionally, the posterior tibial nerve may be inadvertently injured.
POSTOPERATIVE CARE

- General guidelines for splinting and postoperative care are detailed in Chapter HA-72.
- Serial examination is important to follow the progress after surgical repair.

OUTCOMES

- Neurolysis
  - If NAPs are recorded through a nerve segment, recovery is thought to be about 90%.
  - NAP recording and subsequent neurolysis without resection have been found to consistently result in better outcomes than direct or graft repair.
- Split repair
  - Outcomes are superior to complete repair when NAPs are recorded through some portion of the nerve.
  - Direct and graft repair of the injured fascicles yield similar results.
- Complete resection with direct repair or graft repair
  - The outcome of direct repairs appears to be superior to those requiring the use of a graft; however, injuries requiring a nerve graft often are more substantial and require regeneration along a greater distance.
  - In general, radial nerve repairs are more successful than median nerve repairs, and both are better than ulnar nerve repairs.
- Children generally have better overall outcomes than adults.
- Internal neurolysis or resection of any lesion in continuity may be related to a decrease in preoperative function as some intact axons may be transected.

COMPLICATIONS

- Infection
- Scarring
- Loss of function
- Increased neuropathic pain
  - Either distal to the lesion or in the form of a painful neuroma
- Failure of recovery of function

SUGGESTED READINGS

DEFINITION
- The median nerve can be compromised by any number of causes, including trauma, tumor, chronic compression, or synovitis.
- Palsy of the median nerve can result in motor or sensory deficits, or both, within the distribution of this nerve.

ANATOMY
- The median nerve enters the forearm between the two heads of the pronator teres muscle.
- The median nerve travels down the forearm between the flexor digitorum superficialis and profundus muscles to enter the carpal tunnel.
- Along its course, the anterior interosseous nerve branches from the median nerve to provide innervation to the flexor pollicis longus, flexor digitorum profundus (FDP) to the index, and the pronator quadratus muscles.
- The median nerve proper provides innervation to the flexor carpi radialis, pronator teres, flexor digitorum superficialis (FDS), palmaris longus, and FDP to the long finger.
- The palmar cutaneous branch arises from the median nerve 5 cm proximal to the wrist joint, crosses the wrist volar to the transverse carpal ligament, and supplies sensibility to the thenar eminence.
- Just proximal to the wrist, the median nerve becomes superficial and travels within the carpal tunnel.
- The recurrent motor branch originates from the central or radial portion of the median nerve during its passage through the carpal tunnel. The recurrent branch usually passes distal to the transverse carpal ligament to innervate the thenar muscles. The nerve can also pass through the transverse carpal ligament (occurs in 5% to 7% of individuals).6
- The thenar muscles are the opponens pollicis, flexor pollicis brevis, and abductor pollicis brevis. The flexor pollicis brevis muscle receives dual innervation from both the recurrent branch and the deep motor branch of the ulnar nerve.
- The median nerve terminates into multiple sensory branches, which supply sensibility to the thumb, index, long, and ring (radial side) fingers. The sensory branches to the radial side of the index and radial side of the long fingers possess a minor motor component that sends a small branch that innervates the adjacent lumbrical muscle.

PATHOGENESIS
- Most injuries to the median nerve occur at the wrist and affect the thenar muscles. The resultant functional loss is lack of thumb opposition.
- Compression injuries are most common and are usually attributed to prolonged carpal tunnel syndrome.
- Carpal tunnel compression may also be secondary to tumor, adjacent synovitis, or fracture-dislocation.
- Penetrating or perforating injuries may directly damage the median nerve.
- Pediatric causes include lipofibrohamartoma of the median nerve or Charcot-Marie-Tooth disease, a demyelinating process that has a preference for the median and ulnar nerves (FIG 1).6
- High median nerve injuries are rare. Similar causes exist, including trauma and nerve compression.

NATURAL HISTORY
- With a median nerve compression neuropathy (ie, carpal tunnel syndrome), palsy of the median nerve is insidious in onset and manifestation. Over a period of months to years, patients can progress to decreased median nerve function as well as sensory changes in the dermatome of this nerve.
- Acute injuries to the median nerve at the wrist or elbow have a traumatic onset followed by sensory or motor changes, or both.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Compressive neuropathy of the median nerve
- Patients report pain, numbness, and tingling in the thumb, index, middle, and sometimes ring ringer of the affected hand. They frequently describe problems with fine coordination of the hand, notably problems with pinch. Patients often report pain and numbness that awakens them at night.
- Physical examination findings include thenar muscle wasting and diminished thumb opposition (defined as the

FIG 1 • Left hand of 16-year-old boy with Charcot-Marie-Tooth disorder resulting in median nerve palsy. Note inability to oppose thumb with attempt to touch small fingertip. (Courtesy of Shriners Hospital for Children, Philadelphia.)
combination of palmar abduction, metacarpophalangeal [MCP] joint flexion, and thumb pronation).
- Additional signs include the Tinel sign, the Phalen sign, the carpal tunnel compression sign, and increased two-point discrimination in the thumb, index, and long fingers.
- High median nerve neuropathies have similar findings, in addition to loss of forearm pronation and flexion of the thumb, index, and long fingers.
- Acute median nerve injury
  - There is nearly always a wound on the upper extremity, usually on the volar wrist.
  - Physical findings include diminished sensibility in the thumb, index, and long fingers; increased two-point discrimination in those fingers; and an inability to touch the thumb tip to the small finger (ie, loss of opposition).
  - Depending on the level of injury, patients may display diminished sensibility of the thenar eminence of the thumb, signifying an injury proximal to the palmar cutaneous branch of the median nerve, or a concomitant injury to the palmar cutaneous branch.
  - Higher median nerve neuropathies have similar findings, in addition to loss of forearm pronation and flexion of the thumb, index, and long fingers.
  - Patients with median nerve palsy will not be able to oppose thumb to small finger. There may be some palmar abduction due to function of the abductor pollicis longus or extensor pollicis brevis muscles, but this will be minor. The ulnar-innervated deep head of the flexor pollicis brevis muscle will still function, creating MCP joint flexion but not true opposition.
  - Inability to make an “OK” sign indicates anterior interosseous nerve injury and high median nerve pathology.
  - The clinician should ask the patient to try to touch thumb to small finger with the wrist flexed. Due to median nerve palsy, the patient will likely not be able to fully touch the thumb to the small finger. However, if the palmaris longus is present, it will be visible as it tents up the skin over the volar wrist.
  - The patient is asked to spread his or her fingers apart and hold them against adduction pressure on the small finger. The examiner feels for resistance and palpates the hypothenar eminence at the same time. There should be resistance to adduction force on the small finger, and firmness of the hypothenar eminence should be appreciated.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographs
  - Plain radiographs are helpful in determining the nature of fractures or dislocations after acute trauma to the upper extremity.
  - Specific carpal tunnel radiographic views may demonstrate osteophytes within the carpal tunnel, but they are not routinely performed.
- Electrodiagnostic studies
  - In the setting of compressive neuropathy of the median nerve, nerve conduction studies typically show increased motor and sensory latencies in the median distribution.
  - In advanced stages of compressive neuropathy, electromyography demonstrates fibrillation potentials in various muscles tested, most commonly the abductor pollicis brevis. These fibrillation potentials signify denervation of the tested muscle.
  - Advanced high median nerve neuropathy reveals fibrillation potentials in more proximal muscles, such as the flexor carpi radialis and the pronator teres.

**DIFFERENTIAL DIAGNOSIS**
- Carpal tunnel syndrome
- Anterior interosseous syndrome
- Pronator syndrome
- Wrist synovitis
- Direct injury to the median nerve
- Tumor compression of the median nerve
- Charcot-Marie-Tooth disease
- Brachial plexus injury
- Stroke or other brain injury

**NONOPERATIVE MANAGEMENT**
- Patients with demonstrable carpal tunnel syndrome can undergo a trial of splinting, wrist corticosteroid injection, or both.
- Work modification is indicated in patients with compressive neuropathy as a result of overuse for both carpal tunnel and pronator syndromes.
- Anti-inflammatory and immunomodulatory medications are indicated in patients with wrist synovitis secondary to inflammatory arthropathy.

**SURGICAL MANAGEMENT**
- The chief surgical modality for a low or high median nerve palsy that has not responded to surgery or other interventions is tendon transfer.\(^5\,^6\)
  - Typically, in a low median nerve palsy, the only function that requires restoration via tendon transfer is thumb opposition, which is a combination of palmar abduction, MCP joint flexion, and thumb pronation.
  - In a high median nerve palsy, the additional loss of flexion of the thumb, index, and long fingers requires tendon transfer. In addition, lack of pronation may require tendon transfer.

**Preoperative Planning**
- The surgeon must ensure that there is good passive range of motion of the joints to be mobilized.
  - In longstanding median nerve palsy, the thumb MCP and carpometacarpal joints can become quite stiff.
  - Physical therapy must be employed to loosen these joints and increase their range of motion.\(^5\) This can usually be accomplished in 3 to 6 weeks.
  - A thorough assessment of muscle function and strength is made before selecting a transfer, especially in the setting of combined nerve deficits.
- When performing an opponensplasty, the donor tendon and attachment site are individualized to the particular patient, his or her injury, his or her needs, and the donor muscle–tendon availability. As the attachment site moves more dorsal, the amount of pronation and thumb extension is increased.
- Donor options for opponensplasty include:
  - FDS
  - Abductor digiti minimi (Huber)
  - Extensor indicis proprius (EIP)
Palmaris longus (Camitz). The palmaris transfer is associated with more abduction and less opposition compared to other opposition transfers.3

Other less common donors include the extensor pollicis longus, extensor carpi ulnaris, extensor carpi radialis brevis, and extensor digitorum quinti.4

Opponensplasty attachment site options include the following:3

- Abductor pollicis brevis tendon. This yields a lot of thumb abduction and some opposition.
- Extensor pollicis brevis or longus tendons. This yields thumb abduction, pronation, and MCP joint extension.

Single attachment options

- Riordan’s technique involves interweaving the transferred tendon into the abductor pollicis brevis tendon, with continuation onto the extensor pollicis longus tendon distal to the MCP joint.
- Littler’s technique attaches the transferred tendon into the abductor pollicis brevis tendon.
- Bunnell’s method involves passing the tendon through a small drill hole made at the proximal phalanx base from the dorso-ulnar to palmar-radial direction to provide pronation of the thumb.

Dual attachment options

- These are designed to rotate (pronate) the thumb and either passively stabilize the MCP joint or minimize interphalangeal joint flexion.
- There is a theoretical benefit in patients with combined median and ulnar nerve deficits who lack all thumb intrinsic function.
- Some authors question the utility of dual insertion techniques since the transfer will only function predominantly on the tighter of the two insertions.

In Brand’s technique, one half is woven through the abductor pollicis brevis tendon and then passed distal to the MCP joint and attached to the extensor pollicis longus tendon.

In the Royle-Thompson method, a slip is passed through a drill hole made in the metacarpal neck, from radial to ulnar, with the metacarpal pulled into as much opposition as possible. This slip is tied to the other half that is initially passed dorsally over the extensor hood at the MCP joint and through a small tunnel in the fascia and periosteum at the base of the proximal phalanx.

High median nerve palsy requires additional restoration of thumb, index, and long finger flexion. On occasion, re-establishment of pronation is required.

Flexion of the index and long fingers can be accomplished by side-to-side transfers of the FDP tendons of the index and long to the ring and small. We transect the recipient tendons proximal to the wrist and weave them into the donor tendons.

Thumb flexion can be restored by transfer of the brachioradialis to the flexor pollicis longus.

Loss of pronation can be overcome by rerouting the biceps around the radius, which converts the biceps from a supinator into a pronator.

Positioning

- The patient is positioned supine on the operating table.
- The affected limb is abducted at the shoulder and placed on an attached hand table or armboard.

Approach

- The approach to opponensplasty for median nerve palsy depends on two factors: the donor tendon and the site of attachment.

TECHNIQUES

**Flexor Digitorum Superficialis Transfer (Authors’ Preferred Technique)**

- Make a palmar transverse skin incision over the first annular pulley of the ring finger.
- Identify the A1 pulley and incise it longitudinally. Isolate the FDS tendon.
- Apply traction to the FDS tendon to flex the proximal interphalangeal joint (TECH FIG 1A), and divide the FDS tendon transversely just proximal to its bifurcation while protecting the FDP tendon.
- Make a second zigzag incision at the volar ulnar distal forearm in the region of the flexor carpi ulnaris (FCU) tendon insertion.
- Isolate the FCU and the ring finger FDS tendons and protect the ulnar neurovascular bundle.
- Divide the radial half of the FCU tendon transversely about 4 cm proximal to its insertion onto the pisiform.

**LOW MEDIAN NERVE TRANSFERS**

TECH FIG 1 • A. Isolation of ring finger flexor digitorum superficialis (FDS) to be transferred for thumb opposition. (continued)
Pull the cut ring finger FDS tendon into the volar ulnar forearm incision and pass it through the constructed pulley (TECH FIG 1B).

- Make a third incision on the radial aspect of the thumb MCP joint.
- Create a subcutaneous tunnel between this incision and the wrist incision (TECH FIG 1C).
- Pass the ring FDS tendon through this tunnel to the thumb incision (TECH FIG 1D).
- Place the thumb into opposition with the small finger.
- Secure the FDS tendon to the thumb with a 3-0 or 4-0 braided polyester suture (TECH FIG 1E).
- The attachment sites usually include the abductor tendon plus or minus the dorsal capsule and extensor pollicis brevis tendon.
- Protect the ulnar sensory nerve to the small finger.
- Divide the ADM insertion sites, including a portion of the lateral band to increase its overall length.
- Dissect the muscle proximally to the pisiform (TECH FIG 2A).
- Release the origin from the pisiform; identify and protect the neurovascular bundle (on the dorsoradial side).
- Make a longitudinal incision on the radial aspect of the thumb MCP joint.
- Use blunt dissection to create a subcutaneous tunnel in the palm.
- Pass the ADM through the tunnel to the thumb MCP joint (TECH FIG 2B).
- Secure the ADM tendon to the thumb using 3-0 or 4-0 braided polyester suture (TECH FIG 2C).

**Abductor Digiti Minimi Transfer (Huber)**

- Make an oblique or zigzag incision beginning distally on the ulnar border of the small finger proximal phalanx, curving radially along the radial border of the hypothenar eminence.
- Separate the abductor digiti minimi (ADM) muscle from the flexor digiti minimi. Dissect the ADM distally to its insertion into the proximal phalanx and lateral band.

**TECH FIG 1 • (continued)**

B. Ring finger FDS passed through the flexor carpi ulnaris, which now serves as the pulley for the transferred tendon. C. Creation of the subcutaneous tunnel between the ulnar wrist and thumb incisions, through which the FDS tendon will be passed. D. Ring finger FDS tendon shown passing through both the flexor carpi ulnaris tendon and the subcutaneous tunnel. E. Suture fixation of the FDS tendon to the abductor tendon and extensor hood of the thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

**TECH FIG 2 • A.** Isolated and dissected abductor digiti minimi (ADM) muscle-tendon unit, to be used for transfer for thumb opposition (Huber transfer). (continued)
Extensor Indicis Proprius Transfer\(^4\)

- Make a longitudinal incision on the dorsum of the index finger MCP joint.
- Locate the EIP tendon deep and ulnar to the extensor digitorum communis tendon to the index finger (TECH FIG 3A).
- Identify the EIP tendon along with the extensor hood.
- Divide the EIP tendon on the proximal edge of the extensor hood. The EIP tendon can be elongated by taking a 3- to 4-mm slip of extensor mechanism along the proximal phalanx. Repair the rent in the extensor hood with interrupted 4-0 braided polyester suture.
- Make a longitudinal incision on the dorso-ulnar aspect of the wrist, just proximal to the point where the dorsal sensory branch of the ulnar nerve crosses the ulnar styloid.
- Carry dissection from this incision radially until the proximal EIP tendon can be identified (just distal to the extensor retinaculum) (TECH FIG 3B).
- Divide the distal extensor retinaculum over the fourth compartment to release the EIP tendon.
- Bring the EIP tendon out through the ulnar wrist incision (TECH FIG 3C).
- Make another small longitudinal incision on the radial edge of the pisiform.
- Make a fourth incision over the thumb MCP joint.
- Create a subcutaneous tunnel from the ulnar wrist incision to the pisiform incision, then on to the thumb MCP joint incision, using blunt dissection.
- Pass the EIP tendon first through the pisiform incision, then on to the thumb incision (TECH FIG 3D).
- Suture the EIP tendon to the thumb using a 3-0 or 4-0 braided polyester suture.

**TECH FIG 2** (continued) B. Passage of the ADM muscle–tendon unit through the previously created subcutaneous tunnel to the thumb. C. Final position of thumb after suture fixation of the ADM to the thumb. Note opposition and palmar abduction. (Courtesy of Shriners Hospital for Children, Philadelphia.)

A. Isolation of extensor indicis proprius (EIP) tendon ulnar and deep to the extensor digitorum communis tendon to the index finger. B. Wrist incision through which the proximal aspect of the EIP is found and isolated. C. The EIP tendon is brought out through the previously created ulnar wrist incision. D. Passage of EIP tendon through the subcutaneous tunnel between ulnar wrist incision and thumb incision.
Chapter 74 TENDON TRANSFERS FOR MEDIAN NERVE PALSY

HIGH MEDIAN NERVE TRANSFERS

Palmaris Longus Transfer (Camitz10)

- Confirm the presence of a palmaris longus (PL) tendon by having the patient attempt to oppose the thumb to the small fingertip with the wrist flexed.
- Make a longitudinal incision beginning at the distal wrist crease and continuing distally to the proximal palmar crease. This incision may be “zigzagged” at the wrist to prevent scar contracture.
- Dissect the PL tendon proximally to distally.

Brachioradialis Transfer

- Make a long radial incision from the radial styloid to the brachioradialis muscle belly.
- Release the brachioradialis tendon from the radial styloid and mobilize it along the forearm to optimize available excursion (TECH FIG 4).7
- Identify the flexor pollicis longus tendon deep to the flexor carpi radialis tendon.
- Weave the harvested brachioradialis tendon into the flexor pollicis longus using a tendon braider and multiple weaves.
- Determine proper tension of the transfer by placing the wrist in flexion and extension and judging tenodesis lateral pinch position and thumb release, respectively.

- Take a small (about 1 cm square) patch of palmar aponeurosis along with the PL tendon.
- Make an incision over the dorsum of the thumb MCP joint.
- Create the subcutaneous tunnel between the PL tendon and the MCP joint with blunt dissection.
- Pass the PL tendon through the tunnel to the thumb incision.
- Finally, secure the PL tendon to the thumb with 3-0 or 4-0 braided polyester suture.

Biceps Rerouting

- Biceps rerouting is our preferred technique for supple supination deformities of the forearm to correct the forearm position and to apply a pronation moment.
- Surgery is performed under general anesthesia and an upper arm tourniquet is used. The upper extremity is prepared and draped in the usual sterile fashion. The limb is exsanguinated and the tourniquet inflated.
- Design a Z-incision with a horizontal limb across the antecubital fossa (TECH FIG 5A).
- Identify the lateral antebrachial cutaneous nerve lateral to the biceps tendon and protect it (TECH FIG 5B).
- Isolate the biceps tendon and incise the lacertus fibrosis while protecting the underlying median nerve and brachial artery.

TECH FIG 4 • Brachioradialis harvested as donor for transfer to the flexor pollicis longus tendon (red loop) to restore lateral pinch. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

TECH FIG 5 • A. Skin incision for biceps rerouting. B. Isolation of the biceps tendon and lacertus fibrosis. The lateral antebrachial cutaneous nerve is just lateral to the tendon. (continued)
Trace the biceps tendon to its insertion into the radial tuberosity by careful dissection and placement of the forearm into supination (TECH FIG 5C).

Plan a Z-plasty of the biceps tendon along its entire length to ensure sufficient tendon length for passage around the radius (TECH FIG 5D).

Leave the distal Z-plasty attached to the insertion site and leave the proximal Z-plasty attached to the muscle belly (TECH FIG 5E).

Carefully reroute the distal attachment around the radius through the interosseous space to create a pronation force. A curved clamp, such as a Deborah cast clamp or Castaneda pediatric clamp, facilitates tendon passage (TECH FIG 5F,G).

Protect the supinator muscle and posterior interosseous nerve to prevent injury.

Place the elbow in 90 degrees of flexion and the forearm in pronation. Repair the rerouted distal tendon back to the proximal tendon that is still attached to the biceps muscle using a tendon weave augmented by nonabsorbable suture (TECH FIG 5H).

Close the subcutaneous tissue and skin in routine fashion. Apply a long-arm cast with the elbow in 90 degrees of flexion and the forearm in pronation. The cast is worn for 5 weeks.
POSTOPERATIVE CARE

- A bulky hand dressing and short-arm plaster splint is placed with the wrist in flexion and the thumb in full opposition.
- Immediate hand therapy commences to maintain motion in the fingers, especially the ring finger after FDS harvest.
- If the ring finger tends to position into flexion, a proximal interphalangeal joint extension splint is fabricated for nighttime wear.
- In contrast, a ring finger that tends to swan-neck secondary to loss of the FDS tendon requires a silver ring splint to prevent deformity until the remaining FDS scars along the volar aspect of the proximal interphalangeal joint.
- After 2 to 3 weeks, the plaster splint is removed and therapy is initiated. Longer periods of immobilization may yield scarring of the FDS tendon within the reconstructed pulley.
- An Orthoplast splint is fabricated to maintain mild wrist flexion and thumb opposition. The splint is removed four to six times a day to encourage tendon gliding exercises and retraining of the transferred tendon.
- Similar occupational therapy principles are applied after other opposition transfers as described, including the palmaris longus, EIP, abductor digiti minimi, and other transfers.

OUTCOMES

- In general, opposition transfers are successful: most patients regain opposition adequate to perform normal daily activities such as writing, buttoning clothes, and other fine manipulation tasks (FIG 2).9
- Burkhalter et al2 reported excellent results in 57 of 65 cases of EIP opponensplasty; excellent results were defined as those with 75% function compared to the opposite normal thumb or those with less than a 20-degree difference between the plane of the opposite thumbnail and the plane of the palm with good power.
- Jacobs and Thompson,5 using a variety of donor tendons (mainly FDS IV and FDS III tendons), pulley designs, and insertion techniques, reported 77 good or excellent, 9 fair, and 17 poor results. Similar results were obtained with the FDS IV and FDS III tendons.
- In a comparison of FDS versus EIP opponensplasty, Anderson et al1 compared 50 EIP to 116 FDS ring finger opponensplasty cases. Their analysis demonstrated that the EIP opponensplasty was best in supple hands, while the FDS opponensplasty was more suitable in less pliable hands.

COMPLICATIONS

- Suboptimal transfer outcome due to stiff joints
- Selection of suboptimal or weak muscle–tendon unit for transfer
- Incorrect vector of pull due to lack of or poor selection of pulley
- Rupture of transferred tendon
- Tendon adhesions
- Loss of grip strength after FDS ring finger transfer
- Difficulty with muscle–tendon re-education, especially with tendon transfers that are not synergistic. For example, EIP transfer is more difficult to learn compared to FDS tendon transfer.

REFERENCES

DEFINITION
- Ulnar nerve palsy refers to loss of sensory and motor function after injury to the ulnar nerve above or below the wrist (high vs. low ulnar nerve palsy).

ANATOMY
- The ulnar nerve is the terminal branch of the medial cord (C8 and T1).
- The ulnar nerve consists of motor and sensory fibers. There are no muscles innervated by the ulnar nerve in the arm. In the forearm, the flexor carpi ulnaris receives its nerve branches after the ulnar nerve passes through the cubital tunnel. The other muscles innervated in the forearm are the flexor digitorum profundus of the ring and small fingers.
- The muscles innervated in the hand (by order of innervation) are:
  - Hypothenar muscles
    - Abductor digiti minimi
    - Flexor digiti minimi
    - Opponens digiti minimi
  - Ring and small lumbricals
  - Dorsal and palmar interosseous muscles
  - Adductor pollicis
  - Deep head of flexor pollicis brevis
  - First dorsal interosseous (last muscle innervated by the ulnar nerve)
- The sensory fibers of the ulnar nerve supply the small finger and the ulnar half of ring finger over the entire palmar surface and the dorsal surface distal to the proximal interphalangeal (PIP) joint. The dorsal surface proximal to the PIP joint of the small finger and the ulnar half of the ring finger and ulnar dorsal of the hand is innervated via the dorsal sensory branch of the ulnar nerve, which arises from the ulnar nerve 7 cm proximal to the wrist. The sensory branch crosses from volar to dorsal at the level of the ulnar styloid.

PATHOGENESIS
- Ulnar nerve palsy can arise from a laceration anywhere along its course. Proximal injuries to the medial cord may present with additional sensory loss in the distribution of the medial brachial or antebrachial cutaneous nerves. Nerve compression typically occurs either at the cubital tunnel at the elbow or the canal of Guyon at the wrist.
- A variety of systemic conditions may mimic ulnar neuropathy, including Charcot-Marie-Tooth disease, syringomyelia, and leprosy. In Charcot-Marie-Tooth disease and syringomyelia, there is weakness involving other nerves. In leprosy, there is a profound loss of sensation in the ulnar nerve distribution in addition to the claw deformity of the fingers.

NATURAL HISTORY
- The severity of the nerve palsy depends on the degree of the nerve lesion and the presence of anomalous innervation patterns (Martin-Gruber, Riche-Cannieu) in determining the number of muscles involved and the extent of palsy. Anomalous innervation patterns can confuse the examiner.
- Martin-Gruber anastomosis patterns are divided into four types:
  - Type I (60%): motor branches from the median nerve are sent to the ulnar nerve to innervated “median” muscles
  - Type II (35%): motor branches from the median nerve are sent to the ulnar nerve to innervated “ulnar” muscles
  - Type III (3%): motor branches from the ulnar nerve are sent to the median nerve to innervated “ulnar” muscles
  - Type IV (1%): motor branches from the ulnar nerve are sent to the median nerve to innervated “median” muscles
- With prolonged nerve palsy, secondary abnormalities of the hand occur, such as stretching of the central slip of the extensor mechanism at the PIP joint or fixed joint flexion contractures.

PATIENT HISTORY AND PHYSICAL FINDINGS
- An important point is to identify the cause and timing of palsy to determine whether the pathology can be reversed. Treatment is first addressed at improving nerve function by procedures such as decompression of a compressed nerve or acute repair of a lacerated nerve. Recovery can be gauged by progression of symptoms, such as advancing Tinel sign, return of muscle function, and return of sensation. Tendon transfers are indicated when nerve recovery is not expected or possible.
- Loss of sensation in the medial arm or forearm indicates a proximal lesion. Loss of sensation to the dorsal side of the ulnar hand indicates a lesion proximal to the wrist to affect the dorsal sensory branch.
- The following specific tests of motor dysfunction are used to determine the functional loss of the hand:
  - Froment sign: hyperflexion of thumb interphalangeal joint (FIG 1A); indicates substitution of flexor pollicis longus (median nerve) for adductor pollicis (ulnar nerve)
  - Jeanne sign: reciprocal hyperextension of thumb metacarpophalangeal (MCP) joint (Fig 1A); indicates substitution of flexor pollicis longus for adductor pollicis
  - Wartenberg sign: abduction of small finger at MCP joint; indicates paralyzed palmar intrinsic muscle (ulnar nerve) with abduction from extensor digiti minimi (radial nerve)
  - Duchenne sign: clawing of ring and small fingers, hyperextension of MCP joints, and flexion of PIP joints (FIG 1B); indicates paralysis of interosseous and lumbrical muscles of the ring and small fingers (low ulnar nerve), more pronounced in low rather than high ulnar nerve palsy secondary
to functioning flexor digitorum profundus of ring and small fingers (high ulnar nerve)
- Bouvier maneuver: inability to actively extend PIP joint when MCP joints are hyperextended and ability to actively extend PIP joint when MCP joints are blocked from hyperextension (FIG 1C,D). When active PIP joint extension is possible with the MCP joints blocked, this indicates competence of the central slip (positive test). When PIP joints cannot actively extend (negative test), this implies central slip attenuation. In this case, tendon transfers will need to block MCP joint hyperextension and provide PIP joint extension.
- Andre-Thomas sign: clawing of ring and small fingers, hyperextension of MCP joints and flexion of PIP joints, flexion of wrist (Fig 1C). An increase in the claw deformity as the patient tries to extend the fingers by flexing the wrist indicates a poor prognosis for tendon transfer surgery.
- Masse sign: flattening of the metacarpal arch (Fig 1B); inability to oppose the small finger carpometacarpal joint
- Pollack sign: inability to flex the distal interphalangeal joint of the ring and small fingers; used to differentiate high from low ulnar nerve palsy
- In assessing for tendon transfers in ulnar nerve palsy, the primary functional concerns are:
  - Lack of thumb adduction and lateral pinch
  - Claw deformity of fingers that impairs object acquisition and grip
  - Loss of ring and small finger flexion (high palsy)

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Electromyographic and nerve conduction velocity studies are used to isolate the ulnar nerve pathology and rule out other diagnoses. Serial studies may demonstrate the potential for recovery.

**DIFFERENTIAL DIAGNOSIS**
- Cervical radiculopathy
- Lower brachial plexopathy
- Charcot-Marie-Tooth disease

**NONOPERATIVE MANAGEMENT**
- When the Bouvier test is positive (active PIP joint extension is possible when MCP joint hyperextension is prevented), a dorsal MCP blocking splint for the ring and small fingers is fabricated to preserve the integrity of the PIP joint central slips.
- If a fixed flexion contracture of more than 45 degrees occurs at the PIP joint, a supervised hand therapy program consisting of serial casting is required.
- If the fixed flexion contracture does not respond to therapy, preliminary surgical joint release is necessary before tendon transfers.

**SURGICAL MANAGEMENT**
- Tendon transfers address the primary functional concerns listed above:
  - Lack of thumb adduction and lateral pinch
  - Claw deformity of the fingers that impairs object acquisition and grip
  - Loss of ring and small finger flexion (high palsy)

**Considerations**

**Restoring Thumb Adduction**
- The first factor to consider in performing a transfer to restore thumb adduction is what donor muscle to use.
  - The extensor carpi radialis brevis (ECRB) and the flexor digitorum superficialis (FDS) are the most commonly used.
  - The FDS of the ring finger can be used in low ulnar nerve palsy when the flexor digitorum profundus of the ring finger is functioning.
  - In high ulnar nerve palsy, the FDS of the middle finger can be used instead of the FDS of the ring finger.
  - The brachioradialis can be used if the ECRB is required for an intrinsic reconstruction of the fingers.
  - Alternatively, the extensor indicis proprius or abductor pollicis longus can be used.
The second factor to consider is placement of the pulley.
- For transfers coming from the dorsum of the hand, the pulley is either the index or middle finger metacarpal. Passing the transfer through the third web space, using the middle metacarpal as the pulley, allows the transferred tendon to lie palmar to the adductor pollicis but dorsal to the flexor tendons and neurovascular bundles.
- For transfers originating from the palm of the hand (FDS), the vertical septum of the palmar fascia attached to the third metacarpal forms the pulley.
- The third factor is attachment of the transfer to the thumb.
  - The transfer can be inserted directly into the thumb metacarpal, into the adductor pollicis tendon, or into the abductor pollicis brevis tendon.
  - This last technique, favored by Omer, allows the tendon to be sewn to the strong fascia abductor pollicis longus tendon and improves pronation of the thumb to aid in pinch.
- The last factor to address is stability of the MCP and interphalangeal joints.
  - For patients with a persistent Froment sign and mild hyperextension of the MCP joint, the split flexor pollicis longus to extensor pollicis longus tenodesis will stabilize the interphalangeal joint without fusion.
  - When the MCP joint shows substantial instability or arthritic changes, it should be fused.

**Correcting Claw Deformity of Fingers**
- Procedures to correct MCP hyperextension may be either static or dynamic.
  - A static procedure prevents hyperextension of the MCP joint, improving extension of the fingers. The Bouvier maneuver must be positive. The disadvantage of static procedures, either the MCP volar capsulodesis or tenodesis procedure, is that they tend to stretch with time.
  - A dynamic transfer uses the FDS, extensor carpi radialis longus, ECRB, or flexor carpi radialis as a donor muscle.
  - If the Bouvier maneuver is positive, there is no need to restore PIP joint extension.
  - If the Bouvier maneuver is negative, the procedure must address both MCP joint flexion and PIP joint extension. The insertion site of the tendon transfer determines which joints are affected by the transfer.
- FDS transfers for finger clawing
  - Advantages
    - No need for tendon graft
    - Not passing tendon through interosseous spaces or through carpal tunnel
  - Disadvantages
    - Does not increase grip strength
    - High incidence of swan-neck deformities
    - Cannot use FDS of ring and small fingers in high ulnar nerve palsy
    - Wrist motors for transfers for finger clawing
      - Advantage: increases grip strength
      - Disadvantages
        - Requires tendon graft, either palmaris longus, plantaris, fascia lata, or toe extensor
        - Passes tendon through interosseous spaces or through carpal tunnel

**Restoring Ring and Small Finger Extrinsic Muscle Function**
- In patients with high ulnar nerve palsy, it is important to restore extrinsic flexion power before performing intrinsic transfers.
- Claw deformity of the ring and small fingers will worsen after these transfers.

**Preoperative Planning**
- Tendon transfers are indicated when no further nerve recovery is anticipated.
- In evaluating a patient for tendon transfer procedures, the examiner assesses the number of functions lost, determines the number of muscles available for transfer, and assesses the strength and excursion of each of the donor and recipient muscles.
- When there are insufficient donor muscles to substitute for all functions that are lost, tenodesis and arthrodesis procedures may partially substitute for the lost function.
- There should be no fixed flexion contractures of the joints affected by the transfers.
- The transferred tendons need to be placed in a smooth, scar-free bed to glide.
- The principle of “one muscle and one function” should apply to each tendon transfer.

**Positioning**
- The patient is supine with the arm abducted on an arm table.

**Approach**
- All transfers for thumb adduction must pass distal to the pisiform.
- All transfers for intrinsic reconstruction must pass palmar to the axis of rotation of the MCP joint and dorsal to the axis of the PIP joint.

### TRANSFERS TO RESTORE THUMB ADDUCTION

**Brachioradialis Extended With Tendon Graft, Through Third Web Space, Inserted into Abductor Pollicis Brevis Tendon**
- Make an incision between the flexor carpi radialis tendon and the radial artery beginning at the wrist crease and extending to the proximal third of the forearm.
- Dissect free of fascia the brachioradialis tendon and its muscle 7 to 10 cm proximal to the musculotendinous junction.
- Extend the tendon with a palmaris longus graft. Use a three-pass Pulvertaft weave to secure the palmaris longus graft to the brachioradialis tendon (TECH FIG 1A).
- Make incisions over the radial thumb MCP joint and in the third web space, both palmar and dorsal.
- Sew a tendon graft, using one slip of the abductor pollicis longus tendon, in a three-pass Pulvertaft fashion into the abductor pollicis brevis tendon.
Pass the tendon palmar to the adductor pollicis but dorsal to the flexor tendons and neurovascular bundles, as identified through the palmar incision over the third web space (TECH FIG 1B).

Use the tendon passer to bring the graft from palmar to dorsal, using the proximal metaphysis of the third metacarpal as the pulley (TECH FIG 1C).

Bring the tendon graft from the brachioradialis to the dorsum of the hand and perform the final Pulvertaft weave (TECH FIG 1D).

Set tension to allow the thumb to rest palmar to the index finger when the wrist is in neutral.

Take care to weave the tendons proximally enough on the hand such that the weave does not enter the third web space.

Tension on the graft will pull the thumb into adduction (TECH FIG 1E,F).

**Split Flexor Pollicis Longus to Extensor Pollicis Longus Tenodesis**

Make an incision along the radial proximal phalanx of the thumb. Identify the flexor pollicis longus (FPL) and extensor pollicis longus tendons. Take care to preserve the oblique pulley.
Identify the natural cleft between the radial and ulnar fibers of the FPL and split the tendon (TECH FIG 2A).

Weave the radial half of the FPL tendon into the extensor pollicis longus tendon (TECH FIG 2B, C).

Pin the interphalangeal joint in extension with a 0.045-inch smooth pin.

**TENDON TRANSFERS FOR CLAW DEFORMITY OF FINGERS**

**Zancolli Lasso**
- This operation is indicated when there is a positive Bouvier maneuver.
- Make a midpalm Bruner zigzag incision.
- Incise the tendon sheath between the A-1 and A-2 pulleys. Identify the FDS tendon and transect it just proximal to the bifurcation. Leaving the bifurcation intact will decrease the incidence of PIP hyperextension.
- Zancolli recommends using the FDS of each finger, but Anderson recommends using the FDS of the middle finger, split into four tails, to control MCP flexion of all four fingers.
- Pull the FDS tendon out of the tendon sheath distal to the A-1 pulley, bring it palmar to the A-1 pulley, and sew it to itself proximal to the A-1 pulley. If insufficient MCP flexion is attained, the tendon exits the pulley sheath in the middle of the A-2 pulley to improve the lever arm of the transfer.
- Set tension so the MCP joint is in 40 to 50 degrees of flexion with the wrist in neutral.
- When one FDS tendon is used for all four fingers, transect the FDS middle tendon distal to the A-2 pulley through an oblique incision on the finger.
- Make a transverse midpalm incision, retrieve the tendon, and split it into four tails.
- Pass each tail down the lumbrical canal, palmar to the deep transverse metacarpal ligament and into the flexor sheath proximal to the A-1 pulley. Pass the tendon around the pulley and sew the distal end of the tendon back to itself proximal to the A-1 pulley, tensioning it while the MCP joint is in 40 to 50 degrees of flexion with the wrist in neutral.
- For either the Zancolli or Anderson technique, the tendon may be sewn to the proximal metaphyseal-diaphyseal junction of the proximal phalanx via suture anchors or pullout drill holes.

**Stille Bunnel Transfer**
- This technique is indicated when the Bouvier maneuver is negative.
- One FDS tendon is used to motor two digits. Make radial midaxial incisions over the proximal phalanges of the digits. Make a midpalmar incision to retrieve the tendon. Cut the FDS ring tendon just proximal to its bifurcation between the A-1 and A-2 pulleys.
- Split the tendon and pass each half down the lumbrical canal. Pass the tendon passer from distally to proximally, going palmar to the deep transverse intermetacarpal ligament.
- Sew the tendon to the lateral band to restore PIP extension. Set tension with the MCP joint in 40 to 50 degrees of flexion and the PIP joints in full extension with the wrist in neutral. Excessive tension will cause PIP hyperextension.

**Dorsal Route Transfer of Extensor Carpi Radialis Brevis**
- Make radial midaxial incisions over the proximal phalanges of the digits.
- Pass the tendon passer from distally to proximally, going palmar to the deep transverse intermetacarpal ligament.
- For the ring and small fingers, make an incision in the dorsal fourth web space to retrieve the tendon grafts (TECH FIG 3A).
- Sew the distal end of the tendon graft to the proximal metaphyseal-diaphyseal junction of the proximal phalanx via suture anchors or pullout drill holes if the Bouvier maneuver is positive. Tension on the tendon graft will produce MCP flexion (TECH FIG 3B).
If the Bouvier maneuver is negative, attach the graft to the radial lateral band of the middle, ring, and small fingers and the ulnar lateral band of the index finger.

Retrieve the ECRB tendon through a dorsal incision. Bring the tendon grafts through the same wound. First sew the grafts to each other, synchronized to obtain even pull through the grafts. Then sew the grafts to the ECRB tendon with the wrist in 30 degrees of extension and the MCP joints in 60 degrees of flexion.

TRANSFER OF FLEXOR DIGITORUM PROFUNDUS RING AND SMALL TO FLEXOR DIGITORUM PROFUNDUS MIDDLE (HIGH ULNAR NERVE PALSY)

Make a longitudinal incision over the distal third of the forearm. After synchronizing the long, ring, and small tendons, place two rows of horizontal sutures between the three tendons.

PEARLS AND PITFALLS

**Evaluation**

- Differentiate high from low ulnar nerve palsy.
- Determine the potential for nerve and muscle recovery.
- Critically assess the strength of the donor muscles.
- Determine the integrity of the PIP central slip (Bouvier maneuver).
- Have the patient prioritize functional impairment.

**Adductorplasty**

- Assess both adduction and opposition.
- Dorsal transfers passed through the third web space allow for strong adduction using a wrist extensor or the brachioradialis muscle.
- Hyperextension of the MCP joint and hyperflexion of the interphalangeal joint must be addressed with either a capsulodesis and fusion of the MCP joint or a split FPL tenodesis. Both the MCP and interphalangeal joints should not be fused.

**Claw finger deformities**

- Determine the integrity of the PIP central slip (Bouvier maneuver).
- When the Bouvier maneuver shows that the PIP central slip is competent, the tendon transfer should be sewn to the proximal phalanx or the pulleys. If the central slip is not competent, the tendon transfer is sewn into the lateral band.
- Transfers need to pass palmar to the axis of rotation of the MCP joints.

POSTOPERATIVE CARE

- A knowledgeable hand therapist plays an important role in the postoperative care of tendon transfers for ulnar nerve palsy. Protecting the transfers with well-made splints while mobilizing uninvolved joints requires strict adherence to postoperative protocols.
- For most procedures, the hand is immobilized for 3 weeks, followed by a blocking splint to allow motion within the restraints of the splint for the next 3 weeks.
Passive exercises are begun at 6 weeks and strengthening at 8 weeks for the adductorplasty and at 10 to 12 weeks for the intrinsic tendon transfers.

OUTCOMES

- After tendon transfers for thumb adduction, pinch strength usually improves to 25% to 50% of normal.
- Tendon transfers to improve intrinsic function maintain good to excellent correction of the claw deformity in 80% to 90% of patients.
- Only the ECRB transfer improves grip strength.

COMPLICATIONS

- More complications occur after intrinsic muscle transfers than adductorplasty because of the delicate balance of the extensor hood mechanism.
- Transfer not strong enough
  - Problems include choice of a muscle with insufficient strength or excursion, use of a soft tissue pulley that stretched, or elongation at the tendon transfer site.
  - Elongation is a particular problem with sewing the transfer into the lateral bands of the extensor hood.
  - Patients with this transfer must be instructed on not hyperextending the MCP joints.
  - Transfers that are not strong enough can be treated with a therapy program to strengthen the muscle but often require surgical revision.
- Transfer too strong
  - Problems include choice of a muscle that is too strong or with too short of an excursion, or sewing the transfer in with too much tension.
  - When the transfer is sewn too tightly into the lateral band, it can produce a swan-neck deformity of the digit.

- Transfers that are too tight can be treated with passive range of motion in therapy, trying to stretch the transfer.

REFERENCES

DEFINITION
- Radial nerve palsy that is distal to the triceps innervation affects the forearm musculature. A lesion that does not recover results in predictable wrist, finger, and thumb extensor deficits.

ANATOMY
- The brachioradialis and forearm extensor musculature originate in the lateral humeral epicondyle and the interosseous membrane (FIG 1A).
  - Each of the extensor muscles has a relatively flat muscle belly before forming a flat, broad tendon.
  - The myotendinous junction for the wrist extensors is in the mid-forearm, whereas the myotendinous junction of the finger and wrist extensors is the distal forearm.
- The radial nerve arises from the posterior cord of the infraclavicular brachial plexus (FIG 1B). Multiple triceps motor branches are present as the nerve courses in the posterior compartment of the upper arm. The nerve traverses into the anterior compartment through the intramuscular septum. The nerve then lies between the brachialis and brachioradialis before it enters the forearm. The brachioradialis (BR), extensor carpi radialis longus (ECRL), and extensor carpi radialis brevis (ECRB) are innervated as the nerve divides into the deep radial nerve, the posterior interosseous nerve (PIN), and the superficial radial nerve. The PIN innervates the extrinsic extensors after exiting the supinator musculature.
  - The motor point for each nerve is fairly consistently located just proximal to the myotendinous junction. In most cases, there is one larger motor branch from the radial nerve or PIN to each muscle.
  - The sequence of muscle innervation is an important distinction when considering the anatomy of the radial nerve. Whereas some nerves distribute their nerve branches in a tree-like fashion, the radial nerve innervates the extensor compartment...
musculature in an orderly pattern, from proximal to distal. The proper radial nerve supplies the BR, the ECRL, and occasionally the ECRB. The PIN innervates the ECRB, the extensor digitorum communis (EDC), the extensor carpi ulnaris (ECU), the extensor indicis proprius (EIP), and the extensor pollicis longus (EPL).

- The order of innervation is important in differentiating a radial nerve injury from a mechanical myotendinous injury or muscle disruption after a forearm laceration.
- Understanding the innervation also is helpful while observing and assessing the clinical recovery after radial nerve injury or repair.

PATHOGENESIS
- Most radial nerve deficits result from traumatic injuries. Idiopathic and neoplastic etiologies are less common.
- Radial nerve injury is most commonly associated with mid-to-distal shaft humerus fractures.1,4,24,25,28

NATURAL HISTORY
- The type of traumatic injury is an important predictor of recovery after humerus trauma.
- Neurapraxic lesions typically result from low-energy injuries. Recovery can be expected over the course of 3 months. The clinical recovery can be followed by observing the advancing Tinel sign and the reinnervation sequence.
- Conditions that persist after 3 months can be further evaluated with electrodiagnostic studies. In the clinical setting of a nonadvancing Tinel sign and electromyographic findings of axonal loss, exploration with intraoperative electrophysiologic testing is warranted. Nerve grafting across the injury is indicated in lesions that do not demonstrate improvement after external neurolysis.18,24,25
- Exploration of open and penetrating injuries is recommended. The choice of primary repair or nerve grafting depends on the injury zone. Recent evidence warrants exploration of high-energy injuries, because these lesions have not demonstrated recovery. It is difficult to determine the injury at the acute setting. Interposition nerve graft is often necessary.18

PATIENT HISTORY AND PHYSICAL FINDINGS
- A deficit in radial nerve innervation of the extrinsic wrist and finger extensors results in no active wrist, finger, and thumb extension.
- The clinical presentation of radial and PIN palsies is differentiated by the fact that the brachioradialis and ECRL are preserved in PIN palsies.
- The brachioradialis can be palpated during resisted, neutral position elbow flexion, and the wrist assumes a radial deviated position during attempted active extension.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Electrodiagnostic studies (eg, nerve conduction studies and electromyography) are used initially for assessment and for determining subsequent treatment.
- Axonal loss injuries are evident about 4 weeks after the injury; therefore, the initial study is obtained 4 to 6 weeks after the injury.
- The electrodiagnostic study also can identify other nerve injuries that were not as evident on the initial evaluation.
- Recovery can be followed by clinical examination or with supplemental studies.
- A final study is obtained before tendon transfer at 12 to 18 months.

DIFFERENTIAL DIAGNOSIS
- Muscle or tendon laceration
- Closed myotendinous rupture
- Cervical spinal disease
- Joint or tendon subluxation (especially if there is lost digital extension)

NONOPERATIVE MANAGEMENT
- Splint
- Active and passive motion exercises to maintain motion and prevent contracture28

SURGICAL MANAGEMENT
- Tendon transfer is the mainstay of treatment. Microvascular repair and nerve graft are discussed in another chapter.
- The goal of treatment is independent wrist, finger, and thumb extension with thumb abduction. Donor muscles include the pronator teres (PT), flexor carpi ulnaris (FCU), flexor carpi radialis (FCR), flexor digitorum superficialis (FDS) 3 and 4, and palmaris longus (PL).
- Timing of surgical intervention is controversial. Conventional surgical recommendations are to proceed after the patient has reached a documented clinical and electromyographic plateau of useful radial nerve regeneration. This typically occurs 1 year after the nerve lesion.25
- Tendon transfer primarily for wrist extension may be performed early, at the same setting as nerve surgery, to improve function and minimize brace reliance as the nerve regenerates.

Preoperative Planning
- Prerequisites
  - MHC grade 4+ or 5 median or ulnar nerve–innervated donor musculature
  - Maintained passive motion in wrist and finger extension with no contracture
  - Controlled systemic disease processes

Positioning
- The patient is positioned supine with arm table support and a tourniquet.

Approach
- Three general exposures are used:
  - Radial incision with volar exposure for FCR and PT and dorsal exposure for the ECRB and ECRL
  - Distal, dorsal incision for EDC exposure
  - Individual approaches for harvest of the FCU, FCR, and FDS
- The ideal tendon transfer tension is based on the individual muscle properties. In general, the optimal tension is established at the peak of the length–tension curve for the donor muscle, while the wrist and fingers are maintained in the ideal position. Because this donor muscle position is difficult to determine intraoperatively without specialized equipment, this point reasonably corresponds to the midpoint of the passive muscle excursion. The ideal joint position for each transfer is discussed with the individual transfers.
WRIST EXTENSION RESTORATION THROUGH PT TO ECRL AND ECRB²,⁸,²⁷

- Make a longitudinal radial incision over the midshaft of the radius.
  - This allows exposure of the PT and the wrist extensors through a single incision.
- Identify and expose the PT volarly while protecting the radial artery and superficial radial nerve (TECH FIG 1A).
- Extend the pronator insertion by harvesting a strip of periosteum distally (TECH FIG 1B).
- Release the proximal muscle to improve its excursion (TECH FIG 1C).
- Develop the dorsal subcutaneous flap and identify the ECRB and ECRL.
- Deliver the PT dorsally, deep to the brachioradialis (TECH FIG 1D).
- Perform a Pulver-Taft weave into the ECRL and ECRB, and then secure the transfer with 2-0 or 3-0 nonabsorbable braided suture (TECH FIG 1E, F).

FINGER EXTENSION THROUGH FCU TO EDC TRANSFER⁷,¹⁶,¹⁹,²⁰

- Make a distal, volar longitudinal incision to expose the FCU insertion at the pisiform (TECH FIG 2A).
- Identify the ulnar neurovascular structures.
- Extend the exposure proximal to a point 8 cm from the humeral insertion and release the FCU periosteal attachments as necessary to improve excursion (TECH FIG 2B).
- Develop a broad subcutaneous dorsal flap to improve the ECU line of pull to the EDC (TECH FIG 2C). The ECU may be placed beneath the most superficial subcutaneous fascial layer.
Chapter 76 TENDON TRANSFERS FOR RADIAL NERVE PALSY

TECHNIQUES

■ Trim distal muscle and, if necessary, the tendon to enable passage of tendon into the EDC (TECH FIG 2D,E).
■ Make a dorsal longitudinal incision 5 to 7 cm long in the retinaculum of the distal forearm.
■ Release the proximal extensor retinaculum to permit excursion after transfer.
■ Perform a single or double weave into the EDC tendons. Locate the point of insertion into each slip that recreates the normal finger cascade (TECH FIG 2F).

■ The final transfer tension is set with the metacarpophalangeal joints in full extension while the wrist is in 30 degrees of extension.
■ Secure finger extensor transfers with 3-0 or 4-0 nonabsorbable braided sutures.

FINGER EXTENSION THROUGH FCR TO EDC TRANSFER7,9,12

■ Use volar radial exposure to identify the radial artery and the FCR (TECH FIG 3A).
■ Incise the FCR sheath and transect the tendon while maintaining the wrist in flexion.
■ Two different passage techniques may be chosen.
  ■ In the first, a subcutaneous tunnel to the dorsal incision (similar to the FCU transfer) is developed (TECH FIG 3B,C), and the FCR is passed beneath the superficial radial nerve to the EDC.
  ■ In the second, the FDS and median nerve are retracted ulnarly to identify the anterior interosseous nerve and the interosseous membrane proximal to the pronator quadratus (TECH FIG 3D–F), and the FCR tendon is passed volar-to-dorsal through an enlarged opening in the IOM (TECH FIG 3G,H). Be cautious of the anterior interosseous nerve.
  ■ Do not violate the central band.
■ Tension, weave, and suture into EDC, as with FCU transfer (TECH FIG 3I,J).
THUMB EXTENSION THROUGH PL TO EPL

- Identify the palmaris longus at the wrist crease through the same incision described for exposure of the FCR (TECH FIG 4A).
- Dissect and divide the proximal fascial bands to facilitate harvest (TECH FIG 4B).
- Develop a subcutaneous tunnel to the dorsal thumb below the cutaneous nerves.
- The EPL may be addressed in either of two ways:
  - Release the EPL from the third compartment to facilitate transfer location. This technique permits the muscle-tendon connection to remain intact if radial nerve recovery is possible (TECH FIG 4C).
  - Divide the EPL proximally (only if recovery is not possible) and perform the transfer in a more volar location. The thumb extension vector is improved with the transfer in this location.
- Set the tension at the level of the thumb metacarpal with the wrist in neutral and close to maximum tension on the PL and EPL (TECH FIG 4D,E).
- Secure the weave with 3-0 or 4-0 nonabsorbable braided suture.
Chapter 76  TENDON TRANSFERS FOR RADIAL NERVE PALSY

TECH FIG 4  •  A. This approach was combined with a FCR–EDC transfer with identification of the PL through the same exposure. B. Adhesions are released allowing tendon mobilization. C. The EPL is left intact, transposed volarly, and prepared for transfer at the level of the thumb metacarpal. D, E. The Pulvertaft weave is initiated and completed once proper tension is set.

MODICATION: FINGER EXTENSION AND THUMB ABDUCTION THROUGH LONG FINGER FDS TO EIP/EPL; RING FINGER FDS TO LONG, RING, AND SMALL EDC; AND PL TO ABDUCTOR POLLICIS LONGUS

- Perform oblique palmar incisions to harvest the FDS of the long and ring fingers.
- Include both slips for transfer.
- Suture the remaining distal tendon to the volar plate or soft tissue to prevent proximal interphalangeal hyperextension.
- Use the volar incision to retrieve the FDS tendons and to harvest the PL.
- Precisely expose the interosseous membrane (IOM) and make preparations for tendon transfer as discussed in the preceding section.
- Perform a dorsal incision and exposure similar to that detailed in the preceding section. Transfer the two FDS tendons dorsally through the IOM.
- The long finger FDS is transferred to the EIP and the EPL. The ring finger FDS is transferred to the long, ring, and small EDC tendons.
- Set tension at the wrist at 30 degrees and at the MP joint at full extension.
- Secure the transfer with 3-0 or 4-0 suture.
- The PL is harvested as detailed for the EPL transfer.
- The radial subcutaneous route also is used to transfer the PL to the abductor pollicis longus (APL), proximal to the retinaculum.
- The location of this transfer is slightly more proximal to the PL than the EPL transfer due to the length available for the APL.
- Set tension in near-full thumb abduction at wrist 30 degrees; secure with 3-0 or 4-0 suture.

FINGER EXTENSION AND THUMB ABDUCTION THROUGH FCU TO EDC AND EPL, AND PL TO APL

- Although one donor muscle is not typically transferred to two recipients,3 an FCU transfer to the EPL and EDC has been described. This may be combined with a wrist extension transfer.
- The technique is similar to that discussed for the FCU to EDC transfer along the ulnar subcutaneous route. The tension is such that the thumb and index metacarpal are parallel.

PEARLS AND PITFALLS

| Donor muscle properties | In setting tendon transfer tension, the donor muscle length–tension properties are important to consider. A good clinical approximation of a muscle at the peak of the length–tension curve is to place the muscle near the 50% excursion point. The distal recipient tendon is then pulled proximally until the ideal position of the joints has been achieved.11 |
| Pulvertaft weave | In performing a Pulvertaft weave, a curved tendon passer is very helpful. The weaves should be placed at 90 degrees to each other and secured with multiple mattress sutures. The sutures should have small purchase into the donor and recipient tendons to prevent necrosis. At least three weaves should be used. |
The choice between the most common extensor transfers—FCR or FCU—is difficult. Usually, the FCU

With finger extension transfers, it is important to determine the preoperative goals for the FCU/FCR

REFERENCES

POSTOPERATIVE CARE

- Postoperative splint with wrist at 30 to 40 degrees and MP joints in 0 to 10 degrees of hyperextension
- Proximal and distal interphalangeal active and passive motion at 3 to 5 days
- Static immobilization for 3 weeks, then tenodesis motions with activation of wrist extension transfer
- Integration of finger and thumb active extension as wrist motion improves
- The most difficult motion to obtain is independent finger extension with the wrist in the extended position.
- Passive wrist flexion exercises are determined by the recovery of wrist flexion after splint removal. The arc of flexion can be expected to be less than the preoperative level.
- A dynamic splint may be applied so that finger extension may begin at 1 week postoperative. An articulated splint may be used to permit dynamic wrist motion, but the patient must be very adept and have a clear understanding of the therapy regimen.23,28

OUTCOMES

- Wrist extension of 40 to 50 degrees (80% M4), wrist flexion 20 to 40 degrees
- Finger extension: at wrist neutral, 0 to 10 degrees flexion; at wrist in 30 degrees of extension, 0 to 30 degrees
- Functional scores: 80% excellent to good23; no reported disabilities of the arm, shoulder, or hand

COMPLICATIONS

- If transfer adhesions occur, the therapy can be modified according to postoperative course. Tenolysis should be delayed until at least 9 to 12 months after surgery.
- Transfer attenuation

REFERENCES

DEFINITION

- The finger metacarpophalangeal joint (MCP joint) is commonly and characteristically involved in inflammatory arthritis.
- The MCP joint is often involved early in inflammatory arthritis and usually presents with ulnar extensor tendon subluxation resulting in ulnar deviation of the fingers.
- Occasionally in systemic lupus erythematosus (SLE) radial subluxation of the extensor tendon is seen.

ANATOMY

- The normal MCP joint is a condylar joint that allows flexion and extension as well as radial and ulnar deviation and a combination of these movements. Normally there is 90 degrees of flexion, although hyperextension can vary.
- The stability of the MCP joint is provided by the radial and ulnar collateral ligaments, the accessory collateral ligaments, the volar plate, the dorsal capsule, and the extensor tendon (FIG 1).
- The metacarpal head diameter increases in both the transverse and sagittal planes and therefore has a cam effect, making the collateral ligaments tight in flexion and lax in extension. This allows more radial and ulnar deviation of the MCP joint in extension.
- The MCP joint collateral ligaments are asymmetric.
  - The ulnar collateral ligament is more parallel to the long axis of the fingers.
  - The radial collateral ligament is more oblique.
  - This causes supination of the MCP joint with MCP joint flexion.
  - The collateral ligament also resists volar-directed forces.
  - The volar plate is fibrocartilaginous distally and has a membranous portion proximally. It limits MCP joint extension.
  - The transverse intermetacarpal ligament connects the volar plates to each other.
  - The accessory collateral ligament connects the collateral ligament and volar plate and keeps the volar plate close to the volar aspect of the MCP joint throughout motion.
  - The A-1 pulley of the flexor tendon sheath is attached to the volar plate.
  - The extensor digitorum tendon is maintained centrally over the MCP joint by the transverse fibers of the sagittal band that attach volarly to the volar plate and the intermetacarpal ligament. This forms a sling mechanism. The ulnar sagittal band is felt to be stronger and denser than the radial sagittal band.
  - There is usually no direct extensor tendon insertion into the proximal phalanx. The proximal phalanx is extended through the sling mechanism.
  - The lumbrical muscle originates from the tendon of the flexor digitorum profundus and is volar to the intermetacarpal ligament. It inserts into the lateral band.
  - There are three volar (which adduct) and four dorsal (which abduct) interossei that have tendons that all pass dorsal to the
transverse intermetacarpal ligament. They have variable insertions into the proximal phalanx and extensor mechanism.

- The first dorsal interosseous almost always inserts completely into the radial side of the proximal phalanx of the index finger.

### PATHOGENESIS

- The pathology of inflammatory arthritis begins with proliferative synovitis.
- Selective changes in static and dynamic stabilizers of the MCP joint occur, resulting in alteration in the equilibrium of the joint. The most common deformity produced is ulnar deviation of the fingers (FIG 2A).
- Which comes first, the changes to the dynamic or static stabilizers, is unclear and may vary.
- The capsule, radial collateral ligament, and radial sagittal band are stretched by the synovitis and allow the equilibrium to move toward ulnar deviation.

---

![FIG 2 • A. Radiograph of a patient with extensor tendon subluxation and ulnar deviation of the metacarpophalangeal (MCP) joints. The joint spaces are maintained and the joints are not subluxated. B. Radiograph of a patient with extensor tendon subluxation and ulnar deviation of the MCP joints with reducible MCP joint subluxation involving the index and middle MCP joints.](image)

- The accessory collateral ligament and the membranous portion of the volar plate become lax.
- The joint capsule becomes thinned and a defect in the dorsal capsule may occur.
- With increasing ulnar deviation, the ulnar intrinsic muscle shortens.
- The intrinsic muscle contribution to the deformity is unclear. It may be a primary or secondary change. There is a cycle that is set up as the MCP joint ulnarily deviates and the extensor tendon acts as an ulnar deviator and may even act as a flexor of the MCP joint.
- The laxity of the volar plate and accessory collateral ligament causes the flexor tendons to develop a mechanical advantage and increased flexion force. This results in an increase in the deformity.
- The combination of changes to the capsule, radial collateral ligament, radial sagittal band, accessory collateral ligament, and the membranous portion of the volar plate and increases mechanical advantage of the flexor tendon is magnified by the normal ulnar and volar slope of the metacarpal condyles and allows ulnar deviation and volar displacement of the proximal phalanx (FIG 2B).
- The wrist may be a contributing factor to the development of the MCP joint deformity, and this must be considered in each case before correcting the MCP joint.
  - Radial deviation of the wrist can be a compensatory position to the ulnar deviation of the MCP joints to allow the fingers to line up with the forearm.
  - Ulnar deviation of the digit is more common in patients with radial deviation of the wrist.
- At first the deformity is correctable passively, but gradually this mobility is lost and the deformity becomes fixed.
- Articular cartilage changes progress from softening of the cartilage to erosion with significant loss of cartilage and bone. This contributes to the deformity.
  - Once there are significant cartilage and bone changes, extensor tendon realignment alone, without joint resurfacing, is not indicated.
- The changes seen in SLE are secondary not to synovitis but rather to alteration in the collagen that results in a change in the equilibrium of the MCP joint and subsequent deformity.
  - The finger deformity in SLE is often ulnar deviation, but radial deviation is not uncommon.
  - In SLE it is easy to change one deformity to another (ie, ulnar drift into a radial deviation deformity after surgery) because of the global changes to the supporting structures.
  - Despite the MCP deformity becoming fixed, the articular cartilage is usually preserved.

### NATURAL HISTORY

- The natural history of the MCP joint changes in inflammatory arthritis is not known and is probably highly variable and influenced by the new disease-modifying medications.
- Mild ulnar deviation of the fingers is normal and increases with MCP joint flexion.
- In inflammatory arthritis, such as rheumatoid arthritis, deformity is initially passively correctable.
- Mild ulnar deviation of the fingers is seen in less than 10% of the patients in the first 5 years of having rheumatoid arthritis.
PATIENT HISTORY AND PHYSICAL FINDINGS

In a patient with inflammatory arthritis who is being considered for MCP joint surgery, the entire upper extremity is evaluated. Involvement of the lower extremities must also be considered, given that the upper extremities may need to assist in ambulation.

- The need to use the upper extremities for weight bearing can significantly affect the durability of the correction obtained after MCP joint surgery.
- Ideally MCP joint surgery is performed when the upper extremity is not needed for such support.
- The wrist is evaluated for the presence of a static deformity at the time of MCP joint surgery. Presence of a static radial deviation deformity will negatively affect the results of MP joint surgery.
- The skin over the MCP joint is evaluated; it should be in good condition.
- Motion of the MCP joint is assessed. The surgeon should specifically ensure that ulnar deviation and flexion deformities can be easily corrected passively.
- Proximal interphalangeal (PIP) joint motion and alignment must be critically evaluated.
  - If there is a significant boutonnière deformity, this should be corrected before the MCP joint surgery since the PIP flexion will influence the amount of MCP joint flexion obtained postoperatively.
  - If there is a swan-neck deformity, this can be treated at the same time or after the MCP joint. A stiff PIP joint in extension will cause the patient to flex the finger at the MCP joint and can help obtain better flexion postoperatively.
  - Any radial or ulnar deformity at the PIP joint must be corrected before the MCP joint surgery.
- The flexor and extensor tendons must be intact before any MCP joint surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographs of the hand and wrist are essential before MCP joint surgery to evaluate alignment, congruence, and joint integrity.

DIFFERENTIAL DIAGNOSIS

- The most common cause of inflammatory arthritis that affects the MCP joint is rheumatoid arthritis.
- SLE is more common in black women, and the deformity is secondary to a collagen abnormality causing ligament and tendon imbalance. Articular cartilage loss is a much less common problem in SLE. Soft tissue realignment can be performed even after the condition has been present for a long time.
- Psoriatic arthritis is more common in men and has a characteristic skin rash, although patients may have joint involvement before a clinically obvious skin rash. The patient with psoriatic arthritis often has an asymmetric deformity and more stiffness. The cartilage and bone are also affected.

NONOPERATIVE TREATMENT

- A team approach to patients with inflammatory arthritis is important.
- Splinting in a corrected position (FIG 3) and joint protection may decrease the forces that contribute to the deformity.
- This may be helpful, but the effect in the long term is unknown, and we have not noticed significant long-term benefit.

SURGICAL MANAGEMENT

- One of the most difficult operations to decide to perform is MCP joint synovectomy and realignment.
  - This is usually best performed early when there is minimal deformity.
  - However, at this time the patient often has minimal pain and only slight loss of function.
  - With the use of disease-modifying medications, if the anatomy can be restored and the mechanical problems corrected, salvage procedures may be prevented or significantly delayed.
- The ideal patient for surgery is one with increasing deformity and good medical management with control of his or her synovitis.
  - The deformity should be passively correctable with good active MCP joint motion.
  - Ideally the MCP joint is not volarly subluxated, since correction and maintenance of correction is more unreliable.
  - There should be a well-aligned wrist with good PIP joint function without deformity.
  - If the deformity is passively correctable but cannot be actively corrected, obtaining active ulnar deviation such as by an extensor carpi ulnaris tendon relocation or transfer should be considered.
  - The radiographs should reveal good preservation of the joint space without volar subluxation.
  - If all of these criteria are met and the joints are not passively correctable or there is volar subluxation of the MCP joint, surgery can be performed, although the results may not be as reliable.
  - A firm diagnosis can help with establishing a prognosis for the maintenance of correction obtained at surgery.
  - The effect of the new disease-modifying medication is not known.
It is possible that the soft tissue correction obtained at surgery may now last longer and therefore the procedure should be entertained earlier and more often.

Ideally, earlier surgery will solve the correctable mechanical problem and will end the cycle of deformity.

**Positioning**

- The procedure is performed using tourniquet control. The hand is supported by a hand table.

**Approach**

- The procedure usually is performed on all four fingers through a transverse dorsal incision over the MCP joint (FIG 4).
  - If a single digit is involved, a longitudinal incision should be used.
  - If not all of the fingers are going to be corrected, the fingers on the side of the deformity (ie, if there is ulnar deviation deformity, the radial involved digits) must be corrected first to limit recurrent deformity.

**EXPOSURE**

- Expose the extensor mechanism at each joint (TECH FIG 1A).
- Release the juncture tendineae as needed (TECH FIG 1B).
- Develop the interval between the extensor hood and capsule.
- Try to relocate the extensor tendon to the midline.
- Sometimes this can be done without releasing the ulnar sagittal band.

- If the extensor tendon can be relocated to the midline, expose the joint by incising the radial sagittal band.
- The radial sagittal band will be reefed at the end of the procedure.
- If the extensor tendon cannot be relocated to the midline, release the ulnar sagittal band to expose the capsule.
- A central defect in the joint capsule is often present. Open the capsule through this defect using a distally based dorsal capsular flap (TECH FIG 1C).
SYNOVECTOMY AND TENDON REALIGNMENT

- Perform a synovectomy using small rongeurs, curettes, and elevators (TECH FIG 2A).
- Evaluate the intrinsics after the extensor tendon is relocated and the joint is in neutral position. Perform an intrinsic tightness test. If positive and intrinsic tightness persists, release the ulnar intrinsics.
  - Incise the sagittal band and expose the intrinsic tendon on the ulnar side of the joint.
    - It is superficial to the collateral ligament and capsule.
  - Pass a curved hemostat beneath the ulnar intrinsic tendon as it inserts into the lateral band (see Fig 1) and divide the tendon.
    - A section of the oblique fibers may be excised.
- If intrinsic tightness continues, release the proximal phalanx insertion by grasping the proximal portion of the tendon with a clamp and sectioning (TECH FIG 2B).
  - A step-cut lengthening of the ulnar intrinsics may be preferred to complete intrinsic release in patients with SLE to avoid late radial deviation.
- If the joint still cannot be corrected, release the ulnar collateral ligament.
- If the ulnar intrinsic has been released, an intrinsic transfer can be performed, usually attaching it to the radial collateral ligament (TECH FIG 2C).
  - The advantage of using the radial collateral ligament as the attachment site is that it does not increase the extensor force at the PIP joint, which could result in a swan-neck deformity.
- If the joint was subluxated volarly preoperatively, pin the MCP joint in extension with a Kirschner wire.
- After the proximal phalanx is reduced, reef or advance the radial collateral ligament as needed (TECH FIG 2D).
- Close the capsule in a pants-over-vest manner so that the MCP joint is in extension (TECH FIG 2E).
- The extensor tendon is relocated onto the dorsal midline of the joint.
- Strip the periosteum from the dorsum of the proximal phalanx base and tenodese the central tendon to the proximal phalanx using a suture anchor (TECH FIG 2F,G).
  - Alternatively, place two drill holes in the proximal phalanx to suture the tendon directly to the bone.
  - 2-0 PDS suture is used. Nonabsorbable suture may result in prominent knots in this patient population with thin skin.
- Reef the radial sagittal band fibers with a 4-0 nonabsorbable suture to rebalance and support the extensor tendon directly over the joint.
- Repair the juncture tendineae.
- Traction on the central tendon should result in full MCP joint extension.
- A bulky dressing with fluffs between the fingers is applied, followed by a volar splint supporting the MCP joints in extension and in a slightly overcorrected position.

TECH FIG 2 • A. A metacarpophalangeal joint synovectomy is performed. B. The ulnar intrinsic tendon is sectioned and the ulnar collateral ligament is released. The central tendon is centralized and sutured to the proximal phalanx. (continued)
TECH FIG 2  * (continued) C. The contracted ulnar sagittal fibers are released and the radial sagittal fibers are reefed (red arrows) to rebalance and support the extensor tendon in the midline. The radial collateral ligament is advanced (green arrow) and the ulnar intrinsic muscle is transferred to the radial collateral ligament (blue arrow) of the adjacent digit. D. The radial collateral ligament is advanced, as in this case, or reefed. E. The capsule is closed in a pants-over-vest manner so that the metacarpophalangeal joint is supported in extension. F. The extensor tendon is sutured directly to the dorsal base of the proximal phalanx using absorbable suture. G. Postoperative radiograph of a patient showing suture anchors in place after extensor tendon centralization.

PEARLS AND PITFALLS

- Patient selection and control of the disease process are probably the most important factors.
- Joints with fixed deformities and cartilage loss are best treated with replacement arthroplasty.
- Proximal joint and distal joint correction must be performed before MCP joint surgery.
- Intrinsic transfers do not improve the long-term outcome of this procedure.
- Intrinsic lengthening is used only in patients with SLE.
POSTOPERATIVE CARE
- The postoperative dressing is removed at about 10 to 14 days and the sutures are removed.
- An Orthoplast splint with the MCP joints extended and slightly overcorrected, usually in slight radial deviation, is applied until 4 weeks postoperatively.
- At 4 weeks postoperatively, if Kirschner wires were inserted they are removed. Splinting is then continued for 2 additional weeks.
- At 6 weeks postoperatively, hand therapy is started, concentrating on active MCP joint extension. Active MCP flexion is also started. Protective splinting is continued for another 2 weeks in between exercises and at night.
- The fingers are splinted together as a unit to maintain alignment and concentrate flexion at the MCP level.
- To increase the postoperative flexion, the PIP joint is occasionally splinted in extension, concentrating the flexion force at the MCP joint.
- Dynamic splinting can be used to support extension and maintain digital alignment during the early healing stage but is usually not necessary.
- At 8 weeks postoperatively daytime splinting is decreased and gradual return to functional activities is encouraged.
- Nighttime extension splinting is continued for 3 months.

OUTCOMES
- MCP joint extension and ulnar drift are improved postoperatively.
- MCP flexion is usually slightly less than it was preoperatively.
- Strength is not significantly improved.
- Maintenance of correction is usually good with slight increase in ulnar drift, usually without recurrent subluxation.
- When the deformity is seen early and is still passively correctable with preserved joints, extensor tendon centralization and MCP joint synovectomy (as needed) is often beneficial, improving patient function.
- As with all joint procedures for deformities resulting from inflammatory arthritis, the procedure itself does not stop the progression of the disease. However, the new generation of disease-modifying medications combined with surgery may result in long-lasting correction of joint deformity.

COMPLICATIONS
- Infection
- Wound healing problems
- Loss of motion
- Recurrent ulnar drift with tendon subluxation
- Radial subluxation of the extensor tendon (seen in SLE)
- Progressive joint destruction from the arthritis and need for joint replacement

REFERENCES
DEFINITION

- Arthritis of the metacarpophalangeal (MCP) or proximal interphalangeal (PIP) joints may cause pain, deformity, and decreased motion. Rheumatoid arthritis (RA), osteoarthritis, and posttraumatic arthritis are common causes.
- Silicone implant arthroplasty may be considered as a surgical option after failure of nonoperative treatment in the patient with pain, functional disability, or both secondary to arthritis at the MCP or PIP joint.
- The primary function of the silicone implant is to serve as a dynamic spacer until the joint is encapsulated; thereafter, the joint can be expected to maintain alignment and provide a satisfactory range of motion.

ANATOMY

Metacarpophalangeal Joint

- The MCP joint is condyloid with motion in three planes: flexion–extension, abduction–adduction, and rotation.
- The head of the metacarpal is wider on its volar aspect, providing greater stability in flexion. The radial condyle is larger as well, contributing to the ulnar deviation posture most commonly seen in RA patients.
- Collateral ligaments arise dorsal to the center of rotation; this, together with the shape of the metacarpal head, contributes to the cam effect that is manifest by collateral ligament laxity in extension and tightness in flexion.
- Hyperextension of the MCP joints is common; however, the volar plate limits excessive motion.

Proximal Interphalangeal Joint

- The PIP joint is a hinge joint with an average arc of motion of 0 to 100 degrees of flexion.
- The bony anatomy is crucial to PIP joint stability in all positions; the base of the middle phalanx is wider volarly, thus helping to prevent dorsal dislocation. The PIP joint is more stable in all positions compared to the MCP joint.
- The proper collateral ligaments originate from the center of rotation of the proximal phalanx head and insert onto the volar base of the middle phalanx; they provide stability in all positions. The accessory collateral ligaments insert onto the volar plate and provide more stability in extension. There is no significant cam effect with the PIP joint.
- The volar plate resists hyperextension and is a key supporting structure of the joint.

PATHOGENESIS

- Arthritis of the MCP or PIP joints may be idiopathic, posttraumatic, or inflammatory (RA).
- Idiopathic osteoarthritis involves the distal interphalangeal joint most commonly, but the PIP joint is also affected; the MCP joint is less commonly involved.
- The PIP joint is the most frequently traumatized finger joint and, thus, has the highest incidence of posttraumatic arthritis.

Given the shortcomings of the salvage procedures for PIP joint arthritis, an anatomic joint reduction and aggressive restoration of the normal anatomy after trauma is critical as a means of prevention of arthritis.

- The bony congruity of the PIP joint makes it poorly tolerant of any loss of cartilage; deformity and loss of motion may progress quickly.
- Inflammatory arthritis (RA) most commonly affects the MCP joint but may also involve the PIP joint. In RA, a proliferative synovitis compromises the soft tissue support of the affected joint and may lead to the characteristic deformities at the MCP joint, including volar subluxation (and a flexed posture) and ulnar deviation. In the PIP joint, an attenuation of the volar supporting structures may lead to joint hyperextension, while compromise of the central slip insertion will lead to a joint flexion deformity.
- The efficacy of the disease-modifying antirheumatic drugs has dramatically decreased the need for joint arthroplasty in these patients.

NATURAL HISTORY

- The natural history of osteoarthritis or posttraumatic arthritis of the PIP joint is progression with loss of motion, pain, and in some patients deformity. The MCP joint is less commonly affected and is also more tolerant of arthritis, given its increased mobility in all planes.
- In the patient with severe RA not controllable by disease-modifying antirheumatic drugs, joint inflammation will lead to progression of the arthritis.
- The functional affect of the arthritis depends on both the degree of involvement of the specific joint and the involvement of the adjacent joints.

PATIENT HISTORY AND PHYSICAL FINDINGS

- It is vital that the surgeon understand how the arthritis specifically affects the function of a particular patient. This depends on many factors, including adjacent joint involvement, specific patient activities, and the degree of pain experienced.
- Physical examination methods include the following:
  - Palpation of the joint at the joint line: Confirms origin of the pain and allows evaluation for synovitis
  - Active and passive range of motion of the joint are measured with a goniometer. Joint motion is lost with arthritis. Pain with motion is noted.
  - Deformity of joint alignment is measured with a goniometer. Progressive arthritis leads to deformity.
  - Radial–ulnar stress testing: Evaluation of collateral ligaments. The MCP should be tested in flexion; the PIP joint may be tested in any position but is most commonly tested in extension. Attenuation of collateral ligaments may occur in RA or after trauma.
Integrity of tendon function: Most commonly abnormal in RA or after prior trauma.

Intrinsic tightness (Bunnell) test: If the intrinsics are tight, therapy or surgical intervention may be needed.

Elsen test: Integrity of the central slip is important when contemplating PIP joint arthroplasty.

The alignment and function of the adjacent joints (including the wrist) should be assessed, given the intimate relationship between the joints.

A complete examination of the hand includes an examination of adjacent joints. The ligamentous stability of all joints of the hand and the functioning of the extrinsic and intrinsic flexor and extensor musculature are evaluated.

In inflammatory conditions, the proximal joints, most importantly the wrist, must be examined. If wrist deformity is not corrected before surgical correction of distal disease, surgical correction (such as MCP arthroplasty) will have a higher incidence of failure due to the uncorrected deforming forces.

In patients with posttraumatic arthritis (especially affecting the PIP joints), the functioning of the flexor and extensor tendons must be understood. The presence of tendon shortening or lengthening (for example, after repair of an open injury) and the presence of tendon adhesions should be sought.

Intrinsic or extrinsic contractures after hand trauma are assessed before surgical intervention.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Plain radiographs provide sufficient diagnostic information. AP and lateral radiographs are usually sufficient, although oblique radiographs may be helpful (FIG 1).

MRI and CT are of limited utility in the evaluation of the MCP and PIP joints.

**DIFFERENTIAL DIAGNOSIS**

- Acute fracture with or without joint subluxation
- Collateral ligament injury
- Joint infection
- Flexor or extensor mechanism injury

**NONOPERATIVE MANAGEMENT**

- Anti-inflammatory medications
- Steroid injections
- Splinting

**SURGICAL MANAGEMENT**

Surgery is considered if nonoperative management fails. Given the limitations of silicone implant arthroplasty as noted below, the decision for surgical intervention should be patient-driven.

The best outcome is expected in patients with a preserved arc of motion, minimal deformity, and pain. Patients without pain and presenting with deformity or a lack of motion are not ideal candidates for arthroplasty, especially if the adjacent joints are functioning well. Joint arthroplasty does not reliably increase motion at long-term follow-up.

In RA, an ulnar drift and volar subluxation of the MCP joints with a flexion posture of the joints may lead to weakness and a loss of the ability to grasp larger objects. These deformities are also unsightly. Surgical intervention in these patients can be expected to improve the aesthetic appearance and function of the hand.

**Preoperative Planning**

- All imaging studies should be reviewed.
- Involvement of adjacent joints should be assessed.
- Multiple MCP or PIP joints can be treated with silicone arthroplasty at the same surgical setting, but we do not typically recommend MCP and PIP joint silicone arthroplasty in the same finger.
- In patients with symptomatic disease at both the MCP joint and the PIP joint, the MCP is typically treated with silicone implant arthroplasty and the PIP joint is fused.
- An assessment of the ligamentous stability of the MCP and PIP joints should be performed under anesthesia.

**FIG 1** • A. Rheumatoid arthritis affecting hand, with most notable disease affecting metacarpophalangeal (MCP) joints. The wrist is also affected. B. Isolated osteoarthritis of the MCP joint of the long finger. C. Posttraumatic arthritis affecting the small finger proximal interphalangeal joint.
■ MCP and PIP arthroplasty is performed cautiously in the index (or long) finger as pinch forces may be problematic for joint stability.
■ Templating should be performed to ensure that appropriately-sized implants are available.

**Positioning**
■ The patient is placed supine with the extremity on an arm table.
■ A nonsterile arm tourniquet is used.
■ General or axillary block anesthesia is used.

**Approach**
■ The MCP joint is approached from dorsally with a midline incision.
■ The PIP joint may be approached from either the dorsal or volar approach.

---

**METACARPOPHALANGEAL JOINT SILICONE ARTHROPLASTY**

**Incision and Dissection**
■ If a single joint is being addressed (osteoarthritis or posttraumatic arthritis), make a longitudinal incision over the MCP joint. If multiple joints are being addressed, make a transverse incision over the metacarpal necks (TECH FIG 1A).
■ Protect the superficial veins (most importantly in RA patients).
■ Identify and protect the extensor tendons.
■ In RA, the tendons may be translocated in an ulnar direction. If so, divide the sagittal bands on the ulnar side to allow later centralization of the tendons.
■ If the tendons are centralized, the interval between tendons (index and small finger between extensor indicis proprius or extensor digit minimi and extensor digitorum communis) can be used to approach the joint (TECH FIG 1B).
■ In RA, the ulnar intrinsic tendon is often a deforming force. In fingers with marked ulnar deviation, bring the tendon into the surgical field with a blunt hook and divide it.
■ Divide the joint capsule longitudinally for later repair.
■ Débride the joint (TECH FIG 1C).
■ It may be necessary to recess the collateral ligaments off their origin from the metacarpal head. Carefully protect their insertion onto the base of the proximal phalanx.
■ In osteoarthritis or posttraumatic arthritis, the collateral ligaments need not be released if adequate exposure can be obtained.
■ If the joint is volarly subluxated, it may exhibit a flexion contracture that must be released.
■ Perform a soft tissue release using a Freer to elevate the volar plate off the volar distal metacarpal; this, together with bony resection, will allow joint reduction.
■ Once the proximal phalanx can be mobilized dorsal to the metacarpal head, a sufficient release has been obtained.

**Bone Preparation**
■ Using an oscillating saw, remove the metacarpal head just distal to the collateral ligament origin, staying perpendicular to the axis of the bone in the posteroanterior and lateral planes.
■ The amount of bone removed depends on the degree of deformity and contracture (TECH FIG 2A).
■ In severe cases it is necessary to elevate the collateral ligaments from their origins to resect more metacarpal. In these cases, radial collateral (and ulnar) ligaments are repaired during closure.
■ Prepare the base of the proximal phalanx by removing the articular cartilage using osteotomes or a rongeur. Carefully protect the collateral ligament insertions.
■ Use an awl to identify the metacarpal medullary canal first.
■ The awl typically enters the canal dorsal to the apparent center of the cut end of the metacarpal given the dorsal–volar bone curvature.
■ Use hand reamers to prepare the bone.
■ Use progressive broaches, taking care to ensure correct broach alignment and integrity of the cortex (TECH FIG 2B).
■ The ring finger metacarpal is frequently much narrower and may require more reaming, use of a burr, and potentially a smaller implant.
■ Once the metacarpal is prepared, initiate the same procedure for the proximal phalanx.
■ The base of the proximal phalanx can be reamed in slight supination for the index finger to improve pinch (TECH FIG 2C).

Implant Placement and Closure
■ Place a trial prosthesis, choosing the largest “comfortable” fit that allows full joint motion. Ensure proper clinical alignment (TECH FIG 3A).
■ If the prosthesis buckles, choose a smaller prosthesis or create more space through soft tissue release or additional bone resection.
■ If the prosthetic stem is too long and is contributing to buckling of the prosthesis, the stem may be trimmed using scissors.
■ If the origins of the collateral ligaments were disturbed, drill holes in the dorsal radial and the dorsal ulnar (in the case of osteoarthritis or posttraumatic arthritis) metacarpal and place 2-0 nonabsorbable suture for later repair of the collateral ligaments.
■ The radial collateral ligaments are typically attenuated in RA, especially if the joints have been ulnarly deviated. The ligaments are tightened when repaired through imbrication (TECH FIG 3B).
■ A distally based radial slip of the volar plate may be mobilized and integrated into the repair in the case of severely attenuated radial collateral ligaments.
■ Place the final implants using a “no touch” technique.
■ To minimize the risk of a reaction between the silicone implant and the sterile gloves, do not directly handle the implants; instead, insert them using forceps.
■ Grommets are not routinely used.
■ Insert the proximal stem first; then bend the implant and place the distal stem.
■ Once the implant has been placed in a stable position, the collateral ligaments are repaired.
■ The collateral ligaments are repaired, imbricated, or reconstructed as may be required to restore stability (especially against ulnar deviation).
■ If the capsule is sufficiently robust, repair it with interrupted 3-0 absorbable suture.
- Repair the extensor mechanism in a centralized position with nonabsorbable 2-0 suture. Use passive joint range of motion to ensure there is no tendon subluxation after repair.
- If the radial sagittal band is attenuated, imbricate or incise it and advance it deep to the extensor digitorum communis tendon in a pants-over-vest manner.
- Additional release of the ulnar sagittal band may also be required to centralize the extensor mechanism.
- Obtain C-arm or standard radiographs to confirm clinical alignment.
- Close the skin with 4-0 nylon suture. Once the wound is closed, deflate the tourniquet.
- A Penrose drain may be used if excessive bleeding is noted (uncommon). The drain is removed the next day.

PROXIMAL INTERPHALANGEAL JOINT SILICONE ARTHROPLASTY

Volar Approach for Proximal Interphalangeal Joint Arthroplasty

Incision and Dissection
- Use a volar, Brunner incision centered at the PIP joint (TECH FIG 4A).
- Raise full-thickness flaps with careful protection of the neurovascular bundles.
- Divide the C1, A3, and C3 pulleys at their insertion on one side and elevate them to expose the flexor tendons (TECH FIG 4B,C).
- Protect the A2 and A4 pulleys.
- Retract the flexor tendons to either side using a Penrose drain.
- Detach the volar plate proximally and divide the accessory collateral ligaments from their insertion onto the volar plate. Leave the volar plate attached distally (TECH FIG 4D).
- Detachment of the collateral ligaments at their insertion is required for optimal exposure and visualization (may be repaired back to volar plate at closure).
- Dislocate the joint in a “shotgun” manner to expose the articular surfaces.

Bone Preparation
- Using an oscillating saw, remove the condyles of the proximal phalanx head, staying perpendicular to the long axis of the bone in both the posteroanterior and lateral planes.
- Carefully prepare the base of the middle phalanx, taking great care not to injure the central slip insertion or proper collateral ligament insertion. Remove remaining cartilage with a rongeur or osteotome. Create a flat surface to accommodate the implant.
- Use awls, hand reamers, and broaches to prepare the medullary canals of the proximal and middle phalanges.
- The proximal phalanx is typically prepared before the middle phalanx.
- Use the rectangular shape of the broach base to ensure correct rotation of the final implant.

Implant Placement and Closure
- The trial should allow satisfactory joint range of motion without buckling or displacement.
- The trial and final implant should remain flush against the cut ends of the bones.
- The implant can be shortened or additional reaming can be performed as needed for the trial that buckles.

**TECH FIG 4 • A.** A volar skin incision is centered at the proximal interphalangeal joint in a Brunner fashion. **B, C.** The flexor tendon sheath is incised between the A2 and A4 pulleys to allow retraction of the tendons. **D.** The volar plate is released proximally for exposure.
Chapter 78  PIP AND MCP JOINT SILICONE IMPLANT ARTHROPLASTY

TECHNIQUES

■ The volar plate can be divided longitudinally and used to reconstruct the collateral ligaments if needed.
■ Obtain C-arm or standard radiographs to confirm clinical alignment (TECH FIG 5).
■ The flexor sheath need not be repaired.
■ Use 4-0 nylon sutures to close the skin.

Dorsal Approach for Proximal Interphalangeal Joint Arthroplasty

■ Make a straight or gently curved longitudinal incision centered over the dorsal PIP joint.
■ Raise full-thickness flaps at the level of the extensor mechanism.
■ Split the central slip longitudinally and elevate it radially and ulnarly, taking care not to injure the central slip insertion and create an iatrogenic boutonnière deformity. Other alternatives are as follows:
  ■ The longitudinal split of the extensor mechanism may be carried to one or both sides of the central slip insertion for its protection (TECH FIG 6A).
  ■ The Chamay approach may be used. A distally based triangular flap of the extensor mechanism is created; this provides excellent joint exposure and the extensor mechanism is later repaired (TECH FIG 6B).1
  ■ Recess the collateral ligaments off their origin from the proximal phalanx head for later repair. Before final implant placement, drill holes adjacent to the collateral ligament origin to allow suture passage for ligament repair (TECH FIG 6C).
■ The volar plate is protected with the dorsal approach.
■ The remaining portion of the procedure is similar to that described as part of the volar approach.

TECH FIG 5 • Postoperative radiograph of patient with diffuse osteoarthritis. Note the silicone implant arthroplasties for the proximal interphalangeal joints of the index and long fingers as well as the fusions of the distal interphalangeal joints of the long and ring fingers.

■ Create small drill holes at the radial and ulnar bases of the proximal phalanx before final prosthesis fitting to allow volar plate repair.
■ Create dorsal drill holes at the origin of the proper collateral ligaments to be used for repair.

TECH FIG 6 • A. Preservation of the central slip is crucial for successful postoperative rehabilitation. B. The Chamay approach may be utilized for PIP joint exposure. C. The collateral ligaments are recessed off the head of the proximal phalanx.
PEARLS AND PITFALLS

Indications
- Painless loss of motion is not an ideal indication; the operation does not reliably increase motion at long-term assessment.
- Osteoarthritis and posttraumatic arthritis are more common in the PIP joint than in the MCP joint. MCP arthroplasty has traditionally been performed for RA but has declined in frequency due to better control of disease in RA patients.
- PIP joint arthroplasty is helpful in maintaining motion in the ring and small fingers (for grip); PIP fusion is more acceptable in the index and long fingers (especially in workers).
- Avoid arthroplasty at both the MCP and PIP joints in one finger.

Technique
- Broaching should be carefully performed to avoid penetration of the cortex and rotation of the implant.
- The central slip insertion must be carefully protected at the PIP joint.
- The implant fit must be carefully assessed; buckling of the implant requires bony or soft tissue adjustments before final implant placement.

Rehabilitation
- Motion must be carefully allowed until joint encapsulation.
- Rotation or deformity after arthroplasty may be corrected with dynamic splinting.

POSTOPERATIVE CARE
- The patient is placed in a plaster splint after surgery for 3 to 5 days. The MCP and PIP joints are immobilized in extension.
  - Some surgeons advocate 3 to 4 weeks of immobilization after MCP joint implant arthroplasty before the initiation of hand therapy.
- Early joint motion is important for appropriate joint encapsulation.
- An engaged hand therapist is crucial in obtaining a satisfactory surgical outcome.
  - Early therapy emphasizes edema control and patient comfort through splinting.
  - Subsequent therapy focuses on range of motion.
- MCP joint arthroplasty, especially in the rheumatoid patient, requires meticulous postoperative hand therapy.
  - Dynamic extension (daytime) splints, static extension (nighttime) splints, or both are fabricated.
  - The alignment and motion of the fingers are carefully monitored. Adjustments to the splints are commonly required as the encapsulation process and the healing process progress.
  - Active and gentle passive motion are progressively allowed.
  - After PIP joint implant arthroplasty through a volar approach, the flexor and extensor mechanism need not be protected. Active and gentle passive motion may be initiated quickly, although the collateral ligament repairs should be protected for at least 6 weeks.
    - Dynamic extension splinting may be used during the first 6 weeks.
  - If the central slip was spared during a dorsal PIP joint approach and implant placement, early active motion is initiated with progression to gentle passive motion.
  - If the approach for PIP implant arthroplasty required central slip takedown and repair, the extensor mechanism should be carefully protected during the rehabilitation period.

OUTCOMES
- Pain is reliably improved in patients with MCP or PIP joint arthroplasty.2–7
- Most patients are improved functionally after silicone MCP arthroplasty. Patients with RA and a marked flexion and ulnar deviation posture of the MCP joints stand to benefit most.2,3 While the arc of motion may be improved in the early postoperative period, at long-term follow-up the arc of motion is not dramatically increased; however, the arc is moved to a more extended and functional position.2,3
- The ulnar drift of the MCP joints most commonly seen in RA is improved (although some recurrence in drift over time may also occur).2,3
- MCP arthroplasty for osteoarthritis can be expected to maintain or somewhat improve MCP range of motion and strength while decreasing pain. In contrast to RA patients, MCP joint flexion may be increased in patients treated for osteoarthritis.2,5
- PIP arthroplasty can be expected to place the PIP joint in a more extended and functional posture but should not be expected to increase range of motion at long-term follow-up. Total joint motion depends on the preoperative motion but typically averages about 45 degrees. Pain relief is reliable for most patients no matter what the diagnosis.4,6,7
- PIP arthroplasty for RA may have a lesser outcome compared for PIP arthroplasty performed for posttraumatic arthritis or osteoarthritis. Patients with a boutonnière or swan-neck deformity are most likely to be unchanged or worse in regard to their deformity.7
- PIP silicone implant survivorship decreases from 98% at 2 years to 80% at 10 years to 49% at 16 years (in a mixed population analysis).7

COMPLICATIONS
- Infection
- Implant fracture (which may or may not necessitate revision arthroplasty; if the encapsulated joint is stable, a fractured implant may not need to be addressed)
- Rotational malalignment
- Joint subluxation
- Silicone synovitis
- In RA patients, recurrent ulnar drift may occur.

REFERENCES

DEFINITION

- Rheumatoid arthritis is a disorder that can affect the hands and can cause fatigue, muscle pain, loss of appetite, depression, weight loss, anemia, and immunocompromise. The effect on the hands is a combination of tenosynovitis and inflammation of the metacarpophalangeal (MCP) synovial lining of the joints (synovitis).\textsuperscript{10,12}

- Rheumatoid arthritis less frequently involves the proximal interphalangeal (PIP) joints of the hand; more commonly, the PIP joints are affected by degenerative arthritis. Degenerative arthritis may occur after trauma or infection or may arise as an idiopathic process.\textsuperscript{1}

ANATOMY

- Anatomy of the extensor tendon mechanism is shown in FIG 1.

FIG 1 • Anatomy of the extensor tendon mechanism of the finger.

PATHOGENESIS

- Rheumatoid arthritis is a multifactorial entity and is poorly understood.
  - The disease is autoimmune mediated and may occur after a bacterial or viral infection.
  - There is a hereditary influence.
  - The B lymphocytes, T lymphocytes, and macrophages lead to proliferation and hypertrophy of synovial cells. The enzymes released by these cells can cause bony erosions, ligamentous laxity, and tendon ruptures.\textsuperscript{10}
  - MCP joint deformities in rheumatoid patients include ulnar deviation and volar subluxation or dislocation of the proximal phalanx on the metacarpal head (FIG 2).\textsuperscript{4,11}
  - These deformities occur after synovial proliferation in the recesses between the collateral ligaments and the metacarpal head, attenuating the collateral ligaments.
  - Radial inclinations of the metacarpals and wrist joint destruction often leads to an ulnar translation of the entire carpus. This translation can cause ulnar and volar extensor tendon subluxation between the metacarpal heads. Ulnar forces generated by the extensor apparatus and volar forces produced by the flexors lead to ulnar drift of the fingers and fixed MCP flexion deformities or volar dislocations of the MCP joints.
  - Degenerative arthritis affecting the PIP joints of the hand is a process whereby the articular cartilage develops irreversible wear changes, caused by an incompletely understood mechanism. Subchondral bone stiffens and periarticular new bone formation occurs, which leads to restricted joint motion and pain.\textsuperscript{9}
  - Less commonly, degenerative arthritis can affect the MCP joints of the hand. This can occur after trauma, infection, or osteonecrosis.\textsuperscript{9}

FIG 2 • Ulnar drift of the digits.
NATURAL HISTORY

- Rheumatoid arthritis has a variable prognosis based on the severity of the disease and the structures involved. Mild presentations may go undiagnosed for years, while severe presentations may progress to rapid joint destruction in the third or fourth decade of life.
- Three clinical stages of rheumatoid arthritis exist.
  - First, swelling of the synovial lining, which causes pain, warmth, stiffness, redness, and fullness around the joint
  - Second, synoviocyte hypertrophy and proliferation leading to synovial thickening
  - Third, enzymatic release causing bone and cartilage destruction, ligamentous laxity, and tendon ruptures
- Medical management as well as surgical synovectomy can halt or minimize progression of rheumatoid arthritis in the destructive stage.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough patient history and physical examination are important before implant arthroplasty of the fingers.
  - The surgeon should note the patient’s occupation, hobbies, and expectations.
  - The history of the patient’s condition is helpful in gauging the progression of the disease.
  - The primary indication for surface replacement arthroplasty of the MCP or PIP joints is pain relief. Correction of deformity and improvement in function are secondary considerations. Mild deformity may be painful for some, while profound deformity may be painless and functional for others.
  - Examination of the entire upper extremity should be performed. Although the order of reconstruction is controversial, deficits of the shoulder, wrist, and elbow should be addressed before addressing hand conditions.
- Particular attention should be paid to elements of radiocarpal instability or ulnar translation of the carpus. In some situations a wrist arthrodesis may be necessary before performing MCP arthroplasties.
  - Failure to correct carpal collapse and radial deviation of the metacarpals can result in recurrence of ulnar drift deformity after MCP arthroplasty.
  - Careful examination of flexor and extensor tendons of the hand and wrist should be performed. The extensor digiti quinti minimi, extensor pollicis longus, and flexor pollicis longus often rupture in more active forms of rheumatoid arthritis.
  - Extensor tendon or flexor tendon ruptures should be treated before considering implant arthroplasty of the hand.
- Examination of the PIP joint should include range-of-motion assessment of the joint, assessment of volar plate integrity, central slip integrity, and collateral ligament stability.
  - Normal range of motion of the PIP joint is 0 to 110 degrees.
  - Varus and valgus stability should be compared to the contralateral side.
  - Failure of volar plate integrity in rheumatoid arthritis can lead to swan-neck deformity, which is characterized by PIP joint hyperextension, dorsal subluxation of the lateral bands, and flexion of the distal phalangeal joint. The swan-neck deformity is considered a relative contraindication for surface replacement arthroplasty of the PIP joint (FIG 3A).
  - A boutonnière deformity is caused by failure of the central slip mechanism. This can occur in rheumatoid arthritis or after trauma (FIG 3B). It is characterized by flexion of the PIP joint due to central slip incompetence, volar subluxation of the lateral bands, and hyperextension of the DIP joint.
  - Normal MCP range of motion is between 0 and 90 degrees.
  - Instability testing: The individual MCP or PIP joints are tested by the examiner grasping the patient’s finger and then applying a valgus and then a varus stress. The resultant motion is compared to the contralateral side. Differences in laxity indicate ligamentous instability. Attempts at hyperextension of the digit at the PIP or the MCP joint can identify volar plate instability and the propensity of the digit to subluxate or dislocate. Surface replacement arthroplasty of either the MCP or the PIP joint is contraindicated in patients with ligamentous instability as these are minimally constrained devices.
  - Grade 1: No difference in joint line opening compared to the contralateral joint
  - Grade 2: Notable opening of the joint line compared to the contralateral joint, but a solid “endpoint” is reached
  - Grade 3: Complete opening of the radial or lateral joint line with valgus or varus stress. This can be demonstrated at either the MCP or the PIP joints. No endpoint can be discerned.
  - Bunnell test of intrinsic tightness of the PIP joints: The resistance encountered with the MCP joint in this position is compared with the resistance encountered with the MCP joint.
in the flexed position. An increase of resistance with the MCP joint in the extended position indicates intrinsic tightness of that digit.
- It is important to distinguish intrinsic tightness from extrinsic tightness. Extrinsic tightness is encountered when the long extensors of the digits are adherent to either the surrounding soft tissues or the metacarpals. The result is increased resistance to flexion of the PIP joint with the MCP in flexion. In either instance, the limitation of motion is important to clarify as it can affect the outcome of implant arthroplasty of the MCP or the PIP joint.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Posteroanterior, lateral, and oblique views of the hands will adequately image the MCP joints. Brewerton views may add additional information.
- Posteroanterior and lateral views are sufficient to image the PIP joints.

**DIFFERENTIAL DIAGNOSIS**
- Psoriatic arthritis
- Chronic septic arthritis
- Osteomyelitis
- Gout
- Calcium pyrophosphate dihydrate arthropathy
- Articular malunions of the MCP and PIP joints
- Scleroderma
- Lupus

**NONOPERATIVE MANAGEMENT**
- Nonoperative management in rapidly progressing rheumatoid arthritis is largely ineffective.
- In the quiescent forms of rheumatoid arthritis, nighttime wrist and hand splinting in conjunction with medical management may provide pain relief. Various combinations of methotrexate, prednisone, remitting agents, and nonsteroidal anti-inflammatory agents may prove effective for extended periods in certain cases.
- During periods of active rheumatoid arthritis of the MCP joints, corticosteroid injections into the joint may provide acute pain relief and improve function in the short term.
- The symptoms of MCP and PIP joint degenerative arthritis may come and go, successfully responding to nighttime wrist and hand splinting and nonsteroidal anti-inflammatory agents.
- Corticosteroid injection into the MCP and PIP joints for advanced degenerative arthritis seldom provides long-term benefits.

**SURGICAL MANAGEMENT**
- The indications for surface replacement or pyrocarbon MCP arthroplasty are similar to those for flexible MCP implants. These include pain in the face of deformity and worsening function.
- Surface replacement implants are designed to recreate the anatomy of a native joint, potentially resulting in greater stability than with flexible MCP implants.
- The enhanced stability of these implants is best demonstrated in the index and long fingers, where flexible MCP implants are prone to failure.
- Contraindications to surface replacement implant arthroplasty of the MCP joint include infection, lack of adequate bone stock, insufficient radial or ulnar collateral ligament support, lack of adequate soft tissue coverage, and excessively small metacarpal or proximal phalanx medullary canals.
- These implants rely on intact soft tissue elements. This includes functioning flexors and extensors as well as intact radial and ulnar collateral ligaments.
- Indications for PIP joint surface replacement arthroplasty are pain and diminishing function in the context of advanced radiographic articular degeneration. \(^1,7\)
- Contraindications to PIP joint surface replacement arthroplasty include inadequate bone stock of either the proximal or the middle phalanx, ulnar or radial collateral ligament insufficiency, acute or chronic infection, inadequate soft tissue coverage, insufficient digital flexor function, or disruption of the extensor central slip insertion on the middle phalanx.
- Relative contraindications include the presence of a static swan-neck\(^5\) or boutonnière deformity.
- In general PIP joint surface replacement arthroplasty is not indicated in patients with rheumatoid arthritis.
- The importance of postoperative therapy should be emphasized. To ensure that the implants heal with a stable and a functional range of motion the patient must wear a combination of static and dynamic splints for several weeks to months after. Patients must also be aware that heavy lifting or gripping must be avoided indefinitely.

**Preoperative Planning**
- Sizing templates with a 3% parallax enlargement are available for MCP and PIP joint systems and should be used preoperatively to give the surgeon an idea of the size implant required.

**Positioning**
- The patient is positioned supine with the arm placed on an armboard for either MCP or PIP joint surface replacement arthroplasty.
- A nonsterile tourniquet is placed proximal to the drapes on the arm.
- The hand is pronated to allow access to the dorsum.

**Approach**
- For MCP surface replacement arthroplasty, two different incisions can be used.
- A transverse incision across the dorsum of the hand, centered over the MCP joints, will facilitate access to multiple joints.
- Alternatively, multiple longitudinal incisions can be used to address all four MCP joints.
- If a single joint is being addressed, a longitudinal incision should be used.
- For PIP joint surface replacement arthroplasty, a midline longitudinal incision is preferred.
- Alternative approaches include the lateral approach and the volar approach.
Chapter 79  PIP AND MCP JOINT SURFACE REPLACEMENT ARTHROPLASTY

METACARPOPHALANGEAL JOINT SURFACE REPLACEMENT ARTHROPLASTY

Exposure
- Incise the extensor hood just ulnar to the extensor mechanism.
- Carry dissection down through the subcutaneous tissue to expose the extensor tendons.
  - Preserve the dorsal veins.
- Retract the extensor hood and extensor mechanism radiallyward.
- In the rheumatoid patient, the extensor tendon ulnarly translates with destruction of the radial sagittal band. If possible, dissect the sagittal bands from the capsule and preserve them so that the extensor tendon can be relocated and the sagittal bands imbricated at the end of the procedure in order to maintain a centralized extensor tendon position.
- Incise the remnants of the MCP joint capsule and use small Hohmann retractors to deliver the head of the metacarpal into the wound.
- After the joint is exposed, perform a synovectomy, carefully preserving the collateral ligaments.
- If the joint is irreducible, it may be necessary to release one or both collateral ligaments from their origins.
  - Tag the ends of the collateral ligaments for later repair to their tuberosity origins.

Joint Preparation and Trial Implant Insertion
- Use a metacarpal sizing template to identify the appropriate amount of metacarpal head to be resected.
- Remove the metacarpal head by first making a vertical saw cut distal to the collateral ligaments. A second cut oriented 45 degrees proximally and volarly removes the remainder of the metacarpal head, retaining the collateral ligament origins.
- Remove the articular surface along with a small portion of the base of the proximal phalanx, preserving the collateral ligaments (TECH FIG 1A).
- Contracture of the ulnar capsule may require detaching the ulnar collateral ligament to achieve alignment of the finger in some circumstances.
- Insert an awl into the dorsal aspect of the intramedullary canal of the metacarpal (TECH FIG 1B).
- Perform sequential broaching for the metacarpal until a proper fit has been attained.
  - For the index and long finger, the broaching is slightly ulnarly displaced. This provides a better moment arm for the radial intrinsic and extrinsic tendons to compensate for ulnar drift.
- Repeat the broaching in a similar fashion for the proximal phalanx.
- A plastic impactor with a concave surface aids insertion of the metacarpal proximal trial component.
  - The tip of the prosthesis should pass the midpoint of the metacarpal.
- Avoid forceful impaction in order to avoid fracture.
- A convex impactor aids insertion and seating of the distal component.
- Once the trial components are inserted and the joint is reduced, check component fit and position using an image intensifier. Then assess range of motion, component tracking, and stability.
  - Revisions of bone cuts may be necessary for soft tissue balancing and to ensure adequate range of motion.
  - If release of the collateral ligaments was required, drill two holes through the tuberosity at the dorsal radial and dorsal ulnar aspect of the remaining metacarpal head for reattachment of the ligaments.

TECH FIG 1 • A. Exposure of the metacarpophalangeal (MCP) joint demonstrating the bone cuts for preparation of MCP surface replacement arthroplasty. B. Broaching of the metacarpal preparing for MCP surface replacement arthroplasty. (Courtesy of Small Bone Innovations, Morrisville, PA.)
Insert sutures for repair of the collateral ligament (4-0 Ticron/Mersilene).

**Final Implant Insertion**
- Irrigate the intramedullary canal with saline and 0.5% neomycin solution, then dry it.
- Inject polymethylmethacrylate (PMMA) in a liquid state into the metacarpal and the proximal phalanx using a size no. 14 plastic angiocath catheter attached to a 10-cc syringe.
  - Under some circumstances “finger packing” may be necessary.
- Insert the distal component first. Convex and concave plastic impactors are provided to assist in implant insertion (TECH FIG 2).
  - Avoid impacting with metallic instruments, which can accelerate prosthetic wear.
- The joint is extended and viewed under the image intensifier before allowing the cement to harden so that last-minute corrections in alignment can be made.
- Cement fixation of one finger at a time is advisable if positioning is difficult.
  - If multiple MCP joints are to be implanted, it may be easier to do the distal components as a group, followed by the proximal components.
- After the cement has cured, check passive range of motion to ensure adequate range without impingement or prosthetic binding.

**Closure and Soft Tissue Balancing**
- After hardening of the cement, tighten the collateral ligaments or reattach them to the tuberosity of the metacarpal head with nonabsorbable suture.
- Ensure proper radial and ulnar stability as well as rotational alignment before securing the sutures.
- Close any remaining capsule with absorbable suture before extensor apparatus closure.
- Centralize the extensor tendon and imbricate the radial sagittal bands in rheumatoid hands using nonabsorbable suture.
  - A pants-over-vest centralization of the sagittal bands may be required in moderate to severe ulnar drift along with intrinsic releases or crossed-intrinsic transfers (TECH FIG 3).
  - With the finger held in slight overcorrection, imbricate the radial sagittal band over the extensor tendon.
- The skin is closed in a routine manner and a splint is applied with the MCP joints in slight flexion.

---

**PROXIMAL INTERPHALANGEAL JOINT SURFACE REPLACEMENT ARTHROPLASTY**

**Exposure**
- Through a midline longitudinal incision, reflect the extensor tendon distally by creating a distally based flap, as described by Chamay (TECH FIG 4A).
  - Identify and incise remnants of the dorsal PIP joint capsule.
  - Protect the radial and ulnar collateral ligaments using small Hohmann retractors while bringing the articular surface of the middle phalanx into view.
Chapter 79  PIP AND MCP JOINT SURFACE REPLACEMENT ARTHROPLASTY

TECHNIQUES

Joint Preparation and Trial Implant Insertion

- Resect the proximal phalanx head by an osteotomy performed 90 degrees to the long axis of the proximal phalanx, just proximal to the most proximal extent of the articular surface (TECH FIG 4A).
- During the osteotomy, protect the origins of the radial and ulnar collateral ligaments by using small retractors or by hyperflexing the joint.
- It may be necessary to release a small portion of the proximal phalangeal origin of the collateral ligaments to facilitate the proximal phalangeal osteotomy and prosthesis insertion.
- Minamikawa et al have shown that the PIP joint remains stable after removal of 50% of the collateral ligament substance.
- While protecting the volar plate with a small retractor, use a 2-mm burr to assist in making a small back cut (or chamfer cut) to accept the posterior aspect of the prosthetic condyles of the proximal phalangeal component.
- This can also be accomplished with the oscillating saw, but that can place the volar plate at risk.
- Make a perpendicular osteotomy at the base of the middle phalanx with a small rongeur and remove no more than 1 to 2 mm of bone.
- Protect the collateral ligament insertions with small retractors or by hyperflexing the digit.

- Broach the proximal and middle phalanges with specific and sequential instruments.
- Broach the proximal and middle phalanges to the largest size possible (TECH FIG 4B).
- Undersized components can result in limited motion due to bony impingement during flexion.
- Insert the trial components using proximal and middle phalanx-specific impactors.
- The components are not modular and are generally not interchanged. Under certain circumstances, such as revision surgery, it is permissible to implant unmatched sizes, but no more than one size up or one size down should be used.
- After trial component insertion, examine the digit for implant position, range of motion, and stability as detailed for the MCP joint. Make appropriate adjustments.

Final Implant Insertion and Closure

- Implant the permanent components by “press-fit” using the “no-touch” technique.
- Cementing is discouraged except perhaps in cases with capacious canals or in patients with substantial bone loss or articular erosion. In these circumstances, the prosthetic stems and flanges are simply coated with cement. Excessive cement packing into the medullary canal is not necessary.
- Another technique is to pack the canal with morselized allograft bone. This is analogous to
the Ling technique described for revision total hip arthroplasty.\textsuperscript{5}

- Using specific impactors, seat the permanent components (TECH FIG 5).
- Repair the extensor mechanism with 3-0 Surgilon suture.
- Release the tourniquet before skin closure.
- The patient leaves the operating room with a sterile dressing, splinted in extension.

</table>

**POSTOPERATIVE CARE**

- Postoperatively the MCP joints should be placed in slight flexion and the PIP joints in about 45 degrees of flexion. If there was ulnar deviation before surgery, the fingers should be placed in 10 degrees of radial deviation.
- The dressing is removed 2 to 4 days after surgery and a dynamic splint is applied for daytime exercises. A static rest or nocturnal splint capable of holding the fingers in the corrected position is used for 4 to 6 weeks.
- The rehabilitation program is enhanced by the close supervision of a hand therapist. The first week of therapy is best carried out with daily supervision.
- Follow-up examinations should include range-of-motion assessment for all the joints of the hand and wrist. Static deformities, grip strength, and pinch strength should also be assessed and recorded.
- Follow-up radiographic examination includes posteroanterior, lateral, and oblique views of the hand. Any residual deformity should also be assessed and recorded.
- For the PIP joint surface replacement arthroplasty, a controlled rehabilitation protocol is needed to prevent central slip failure.
- Initiation of formal postoperative rehabilitation is encouraged by postoperative day 5. A dynamic extension splint permitting active flexion is applied at this time and used for about 6 weeks. A static forearm-based digital extension splint is used at bedtime.
- During the first 2 weeks after surgery, PIP flexion is limited to 30 degrees.
- Flexion to 60 degrees is allowed beginning at 4 weeks.
- By 6 weeks, the extension outrigger splint is discontinued and unrestricted flexion and extension is permitted.
- The static bedtime splint is used for an additional 6 weeks. Heavy lifting or gripping is not permitted.

**OUTCOMES**

- Initial results after 76 PIP joint surface replacement arthroplasties were published.\textsuperscript{6}
- At a mean follow-up of 4.5 years, 32 joints had good results, 19 fair, and 25 poor.
- Better results were obtained with arthroplasties performed through a dorsal approach rather than the volar approach.
- Range of motion at follow-up averaged $-14$ degrees of extension and 61 degrees of flexion. There was a 12-degree
improvement in the flexion–extension arc compared to the preoperative examination.

- The MCP joint surface replacement arthroplasty (Small Bone Innovations, Morrisville, PA) has been available in Europe for 8 years and is under clinical trial in the United States. No series has been published reporting results of this implant. Although from a theoretical perspective there are advantages to the use of the MCPJ surface replacement arthroplasty, it currently cannot be considered a replacement for the Swanson Silastic MCP joint spacer.

- Previous primate studies have shown no evidence of debris or inflammatory reaction after implantation of the pyrolytic carbon MCP joint arthroplasty. Good bone incorporation of the prosthesis was also observed.

- In contrast to the Small Bone Innovations MCP joint surface replacement arthroplasty, a series of 151 pyrolytic carbon MCP prostheses (Ascension Orthopaedics, Austin, TX) implanted over an 8-year period, mostly in patients with rheumatoid arthritis, have been followed for an average of 11.7 years. The arc of MCP joint motion improved an average of 130 degrees.
- The 10-year survivorship was 81.4%.
- At follow-up, the degree of digital ulnar drift was the same as preoperative.
- Complications led to 18 implant revisions (12%).

**COMPLICATIONS**

- PIP
  - Failure of the central slip can occur, resulting in extensor lag or, more commonly, a flexion contracture or boutonnière deformity.
  - With the volar approach, failure of the volar plate may occur, leading to swan-neck deformity.
  - Tenodesis as well as joint instability and joint subluxation can occur.

- MCP
  - Postoperative infection or prosthesis loosening is seldom seen.
  - Stiffness
  - Loosening
  - Subluxation
  - Proliferative synovitis

**REFERENCES**

DEFINITION
- Conditions resulting in the need for arthrodesis in the hand include arthritis, unreconstructable soft tissue problems, and certain neurologic conditions.

ANATOMY
- The proximal (PIP) and distal (DIP) interphalangeal joint configurations are quite similar.
  - The condylar heads are biconvex but slightly asymmetric, being about twice as wide volarly as dorsally.
  - The reciprocal bases of the distal segment are biconcave, having a central ridge.
  - The volar plate extends from the neck of the phalanx to the volar base of the more distal phalanx, preventing joint hyperextension.
  - Radial and ulnar collateral ligaments provide additional joint stability. The “true” collateral ligaments have bony attachments at both ends, whereas the accessory collateral ligaments extend from the condylar head to the volar plate.
  - The axis of rotation and radius of curvature for a given interphalangeal joint are fairly constant. Consequently, the true collateral ligaments are effectively isometric, while the accessory collateral ligaments resist lateral translation when the joint is extended.
  - As a result of the ligamentous and bony architecture, the PIP and DIP joints normally function as highly constrained hinge joints.
  - The extensor tendon crosses the DIP joint dorsally as the terminal tendon, inserting slightly distal to the dorsal base of the distal phalanx.
  - The germinal matrix of the nailbed is close to the terminal tendon insertion (average of 1.3 mm distal).
  - The flexor digitorum profundus (FDP) tendon inserts broadly on the volar aspect of the distal phalanx, extending from the base to the midshaft.
  - Over the PIP joint, the extensor apparatus splits into thirds. Contributions from the extensor tendon, the interosseous tendons, and lumbricals form the central slip, which inserts onto the dorsal base of the middle phalanx. The lateral bands travel past the PIP joint along the lateral margins, and then combine to form the terminal tendon distally.
  - The flexor digitorum superficialis (FDS) tendon splits to insert on the volar lateral margins of the proximal shaft of the middle phalanx.
  - Unlike the interphalangeal joints, the metacarpophalangeal joints (MCP) are multiaxial, permitting motion in multiple planes.
  - The metacarpal head has a complex, convex shape. Viewed end-on, the metacarpal head is pear-shaped, being wider volarly. In the sagittal plane, the radius of curvature increases progressively from dorsal to volar.
  - The metacarpal attachment of the collateral ligaments is dorsal to the axis of rotation. The phalangeal and volar plate attachments are similar to the interphalangeal joint.
  - As a consequence of the metacarpal head shape and ligament attachments, the MCP joints are typically more lax in extension and tight in flexion.
  - Significant variability exists in the shape of the thumb metacarpal head. Some heads are more square than round, potentially limiting lateral translation and MCP flexion.
  - In the thumb, the extensor pollicis brevis (EPB) tendon inserts onto the dorsal base of the proximal phalanx. The size of the EPB tendon is variable.
  - For some patients, the extensor pollicis longus (EPL) tendon assumes the major role in MCP joint extension.
  - In the other digits, no direct extensor attachment exists. MCP joint extension occurs through a sling effect of the sagittal hood fibers lifting the proximal phalanx through the pull of the extensor tendon.
  - MCP joint flexion is produced through a combination of direct intrinsic tendon attachments to the volar-lateral phalangeal base and indirect actions of the intrinsics on the more distal transverse fibers of the extensor hood.

PATHOGENESIS
- Arthritis is the principal indication for small joint arthrodesis.
- Osteoarthritis (OA) most commonly affects the DIP joints. It is estimated that at least 60% of individuals over age 60 have DIP joint arthritis, which may not necessarily be symptomatic.
- In the early stages, the joints may be painful and swollen in spite of normal radiographs. As the arthritis progresses, osteophytes and mucous cysts may develop. Bony prominences (Heberden nodes) and angular deformities in both the coronal and sagittal planes (mallet appearance) may develop. In the final stages, DIP joint motion may be severely restricted.
- OA may also involve the PIP joints and the MCP joints, especially in the index and middle fingers.
- Inflammatory arthritis may also affect the small joints of the hand. About 70% of rheumatoid patients have hand involvement. Synovitis may result in deformity due to attenuation of supporting structures (collateral ligaments, extensor tendons) long before arthritic changes are evident.
- At the DIP joint, terminal tendon incompetence may result in a secondary swan-neck deformity.
- At the PIP joint, central slip attenuation results in a boutonnière deformity.
- At the MCP joint, collateral ligament involvement may contribute to ulnar drift. Persistent synovitis produces cartilage loss.
Hand involvement in systemic lupus erythematosus (SLE) may mimic rheumatoid arthritis. Supporting structures are affected principally in SLE, which may result in joint subluxation or dislocation with relatively normal-appearing articular cartilage. The capsuloligamentous problems may compromise attempts at joint salvage.

In contrast, psoriatic arthritis may produce a remarkable degree of bone loss as the arthritis progresses. Pencil-in-cup deformity is a characteristic feature of psoriatic arthritis of the interphalangeal joints. Severe bone resorption is the characteristic feature of arthritis mutilans, most commonly seen in patients with psoriatic arthritis. Arthrodesis is the most reliable method for halting this destructive process.

Scleroderma typically produces PIP flexion and MCP extension contractures. Impaired vascularity of the digits may result in dorsal PIP ulcer formation and central slip attenuation, compounding the PIP flexion deformity.

Presentations of crystalline arthropathy in the small joints of the hand may be varied. The process may be indolent, presenting as gouty tophi over the DIP joint, or acute, presenting as an exquisitely painful, swollen, tender joint. Untreated, gout results in a resorptive arthritis.

Infection is another cause of small joint arthritis.

A “fight bite” directly inoculates the MCP joint and, if undertreated, can result in rapid joint destruction.

Contiguous spread, for example, from a felon or a wound over the DIP or PIP joint, may destroy the adjacent joint.

Hematogenous spread is an uncommon cause of septic arthritis in the hand.

Trauma is another cause of unreconstructable problems in the small joints of the hand.

Intra-articular fractures and fracture-dislocations may result in arthritis, particularly in cases of residual joint incongruity. The PIP joint does not tolerate injury well.

Severe periarticular soft tissue injuries may cause severe joint stiffness, even if the underlying joint surface is not initially involved. Certain soft tissue injuries, such as central slip disruptions, may confound attempts at reconstruction.

Central or peripheral nerve injury may produce imbalances in the hand. Arthrodesis can potentially simplify reconstructions in an effort to improve function.

PATIENT HISTORY AND PHYSICAL FINDINGS

Pain is the most common complaint of patients who are candidates for arthrodesis. Ideally, the location of the pain should correlate with the joint in question.

In OA, multiple DIP joints may appear abnormal, although they may not necessarily be painful.

Polyarticular involvement is common in rheumatoid arthritis. A priority list should be elicited from the patient.

Handedness, occupation, and avocational activities should be documented.

The functional impact of the problem should be clearly defined.

When a single joint is involved, a history of trauma should be sought.

In cases of acute, painful swelling, a history of penetrating injury, gout, or recent infection should be considered.

The physical examination should include the appearance of joints and overlying skin, active and passive range of motion of the affected joints, stability, grip and pinch strength, and sensibility.

The status of adjacent joints should be evaluated.

For example, chronic DIP OA resulting in a DIP flexion deformity may produce a secondary hyperextension deformity of the PIP (swan-neck) that may be more disabling than the primary (DIP) problem.

Multiple DIP joint bumps (Heberden nodes) are a characteristic feature of OA.

Mucous cysts are suggestive of underlying DIP OA.

Onycholysis and eczema are suggestive of psoriatic arthritis.

Discrepancies between active and passive motion are indicative of an associated tendon problem.

Stress examination may demonstrate collateral ligament incompetence.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Plain radiographs (posteroanterior [PA], lateral, oblique) of the affected digit are usually sufficient to make the diagnosis.

In cases of suspected inflammatory arthritis, a collagen vascular screen is ordered. This blood panel includes a rheumatoid factor, ANA, complete blood count with differential, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP).

A uric acid level may be drawn in cases of suspected gout.

Blood tests are not generally helpful in the setting of an acute finger infection.

MRI or ultrasound may rarely be ordered to evaluate tendon pathology if stiffness is associated with tendon abnormality.

DIFFERENTIAL DIAGNOSIS

OA

Inflammatory arthritis (rheumatoid, SLE, psoriatic arthritis)

Crystal arthritis

Posttraumatic arthritis

Infection

NONOPERATIVE MANAGEMENT

The mainstays of nonoperative treatment for unreconstructable small joint problems in the hand include oral medications, splints, and intra-articular corticosteroid injections.

For OA and posttraumatic arthritis, oral anti-inflammatory agents may reduce pain and stiffness.

Glucosamine and chondroitin sulfate appear to be of limited value for hand arthritis.

Rheumatoid patients can consider modifications in their medication regimen, supervised by a rheumatologist.

Resting splints may reduce pain and inflammation.

At the DIP and PIP joints, a simple padded aluminum splint may suffice.

Corrective splints, such as the safety pin static progressive or LMB dynamic splint (DeRoyal), will not be tolerated when the joint is inflamed.

For the thumb MCP joint, a hand-based thermoplast splint may lessen discomfort and improve function.

Buddy taping to the adjacent digit may be appropriate for some MCP joint problems. Dynamic MCP joint splints are usually reserved for postoperative protection.

Corticosteroid injections may provide temporary relief of pain and synovitis. The joint may be difficult to access and the joint capacity is quite small.
The surgeon should use a 27-gauge needle and inject 0.5 mL of Celestone Soluspan and 0.5 mL of 1% Xylocaine through a dorsal approach.

SURGICAL MANAGEMENT
Arthrodesis Versus Arthroplasty
- Arthrodesis is a reliable procedure for managing arthritis and instability of the DIP joint. The functional impairment from loss of motion at the DIP joint is minimal.
- At the PIP joint level, the surgeon and patient must weigh the potential benefits of stability and pain relief against the functional impairment resulting from the loss of PIP joint motion. For the index finger, PIP joint stability is critical for pinch. On the other hand, in the small finger, PIP joint mobility is necessary for grip.
- As a general rule, for isolated unreconstructable PIP problems, the index finger gets arthrodesis, the middle finger gets arthrodesis or arthroplasty, and the ring and small fingers get arthroplasty.
- Exceptions to the rule include associated unsalvageable tendon problems and soft tissue coverage issues, in which arthrodesis may be preferred.
- The status of the adjacent joints is an important factor in deciding whether to perform arthrodesis or arthroplasty. In the rheumatoid patient with both MCP and PIP involvement, the temptation is to perform arthroplasties of all involved joints. So-called double-row arthroplasties tend to compromise the results at both the MCP and PIP joints. In such instances, the goal is stability at the PIP joint (arthrodesis) and motion at the MCP joint (arthroplasty).
- Arthrodesis of the thumb MCP joint is a reliable procedure for managing arthritis and unreconstructable ligament problems. Arthrodesis is a far superior procedure to arthroplasty for the thumb. However, before undertaking this, it is important to ensure adequate motion and function of the adjacent joints (interphalangeal, carpometacarpal).
- The chronic radial collateral ligament tear with static volar-ulnar subluxation is a good indication for thumb MCP fusion.
- Arthrodesis of the digital MCP joints is not commonly performed. Indications include multiply failed arthroplasty or inadequate bone stock for arthroplasty, unremitting infection, refractory instability of the index MCP, and an unreconstructable extensor mechanism.
- Candidates for arthrodesis must understand that all motion in the affected joint will be eliminated, and that the principal goals are pain relief and stability.\textsuperscript{19}

Arthrodesis Position
- The fusion position varies with the digit and joint involved. Invariably, the decision is a compromise between appearance and function. The ideal posture should replicate the normal digital cascade (FIG 1).
- In general, the DIP joints and thumb interphalangeal joint should be fused in 0 to 10 degrees of flexion.\textsuperscript{14}
- For the PIP joint, some authors recommend a uniform 40-degree flexion position for all digits,\textsuperscript{9} while others recommend 40 degrees for the index finger, progressing ulnarward in 5-degree increments to 55 degrees in the small finger.\textsuperscript{17}
- Many prefer a slightly more extended position for the index PIP that will still allow functional tip-to-tip pinch.
- The recommended fusion angle of the MP joints is a cascade from 25 degrees of flexion in the index digit, progressing ulnarward in 5-degree increments to 40 degrees in the small finger.\textsuperscript{14}
- The recommended fusion angle of the MP joint of the thumb is 10 to 15 degrees of flexion.\textsuperscript{14}

Fixation Options
- The choice of surgical technique depends on a number of factors, including the affected joint to be fused, the availability and cost of implants, the adequacy of bone stock, and the comfort of the surgeon. The goal is to achieve a solid fusion of the affected joint in a timely manner. Bone preparation is essential.
- The specific method of fixation may be less important in obtaining union than specific patient factors such as bone quality. Certain constructs, such as the tension band, are more rigid but may be associated with more hardware-related problems.
- The biomechanical issues must be weighed against potential soft tissue problems when deciding on a form of fixation. Maintenance of motion in the adjacent joints is critical.
- Kirschner wire fixation has been associated with fusion rates of up to 99%.

Advantages
- Simplicity of the technique
- Ready availability of low-cost implants

Disadvantages
- Infection risk, including superficial pin site and deep wound infections, osteomyelitis; pin migration; minimal compression across the fusion site
- Less rigid fixation,\textsuperscript{9} requiring additional external immobilization to enhance stability, possibly leading to stiffness of surrounding joints\textsuperscript{8,15}
- Interosseous wiring has been found to be biomechanically stronger than Kirschner wire fixation.\textsuperscript{18} It is especially useful for PIP fusion and thumb interphalangeal fusion.

Advantages
- Biomechanically stronger than Kirschner wire fixation\textsuperscript{18}
- Readily available low-cost implants

Disadvantages
- Large amount of soft tissue stripping for appropriate placement of drill holes
- Higher rate of nonunion, up to 9%\textsuperscript{11}
Tension band fixation is a biomechanically stable method of fixation\textsuperscript{16} combining parallel Kirschner wires for rotational control and interosseous wiring for compression. This technique is especially useful for MCP, PIP, and thumb interphalangeal arthrodesis.

- The tension band construct converts the strong distracting force created by the finger flexors to a compressive force across the arthrodesis interface.
- This technique is relatively simple, with a high fusion rate and reliable outcomes,\textsuperscript{1,16} especially when used for arthrodesis of the MCP and PIP joints.
- Postoperative immobilization is necessary only in the immediate postoperative period to allow for healing of the incision.\textsuperscript{1,8}

**Advantages**
- Simplicity of the procedure
- Low rate of infection\textsuperscript{16}
- High fusion rates, reportedly 97\% to 100\%\textsuperscript{1,16}
- Readily available, low-cost implants
- Enhanced biomechanical stability and strength of the construct, allowing for early active range of motion\textsuperscript{16} The tension band construct for small joint arthrodesis has been shown to be biomechanically superior compared to crossed Kirschner wire fixation and intraosseous wiring, especially in anteroposterior bending and in axial torsion.\textsuperscript{9}

**Disadvantages**
- Increased soft tissue dissection to place the drill holes, with resultant increased risk of soft tissue and tendon scarring
- Difficult to remove fully internalized hardware if necessary

Plate fixation provides biomechanically strong fixation, especially useful for PIP and MCP joint arthrodesis.\textsuperscript{4,19}

**Advantages**
- Excellent fusion rate by 6 weeks, 96\% to 100\%\textsuperscript{1,16}
- Ability to correct deformity
- Useful in cases with segmental bone loss\textsuperscript{4}

**Disadvantages**
- Technically demanding
- Time-consuming
- Extensor tendon adhesions, possibly necessitating hardware removal and tenolysis\textsuperscript{16}; stiffness in adjacent joints
- Hardware prominence

Compression screw fixation is a biomechanically strong fixation technique\textsuperscript{20} that is especially useful for arthrodesis of the finger DIP and PIP joints, as well as the thumb interphalangeal joint.

**Advantages**
- Using a headless screw keeps the fixation hardware low profile and prevents the problems associated with prominent hardware.
- PIP joint fusion uses the same principles but has a slightly different surgical technique.\textsuperscript{2}

**Disadvantages**
- Fusion rates 85\% to 98\%\textsuperscript{2,3}
- Hardware is buried and low profile.
- Risk of penetration and fracture of the dorsal cortex,\textsuperscript{3} especially with screw fixation of the PIP joint, results in poor fixation
- Risk of nail irregularities from disturbance of germinal matrix\textsuperscript{3} in DIP fusion

**Complications**
- Risk of infection, hardware complications, nail irregularities secondary to penetration of the dorsal cortex of the distal phalanx by the screw, and fractures of the dorsal cortex from screw breakthrough\textsuperscript{3}
- Easily avoided by maintaining adequate space between the dorsal proximal entry site and the arthrodesis site
- For DIP arthrodesis, the nail-associated complications usually occurred in the small finger because of the large diameter of the screw used relative to the size of the small finger distal phalanx medullary canal.\textsuperscript{20} This is less of a problem in the distal phalanges of the other fingers or thumb.\textsuperscript{2,3}

**Preoperative Planning**
- Radiographs of the affected joint must be reviewed before operative management. Assessment of the bone stock, quality, and size is useful in helping to determine the optimal type of surgical fixation.
- Should a fusion screw be considered, templates may be used to determine the appropriate screw length and diameter.

**Positioning**
- The patient is placed in the supine position, with the affected limb resting on a hand table. Sterile preparation and draping is performed.
- For arthrodesis of the PIP and DIP joints, local anesthesia with or without sedation is adequate.
- Two percent mepivacaine provides a rapid rate of onset and lasts about 1 hour.
- For the PIP joint, a web space block is performed, including the dorsal cutaneous branches.
- For the DIP joint, the flexor tendon sheath is injected.
- For the MCP joint, either regional or general anesthesia is necessary.

---

**DIP JOINT ARTHRODESIS**

**Exposure**
- A digital tourniquet is used.
- Center a dorsal H-shaped incision over the DIP joint (TECH FIG 1A).
- Transect the terminal tendon (TECH FIG 1B).
- Release the collateral ligaments from the middle phalanx, using a no. 15 blade directed dorsally, parallel to the sides of the phalanx (TECH FIG 1C).

**Preparation of the DIP Joint**
- Hyperflex the DIP joint and remove peripheral osteophytes with a small rongeur.
- Remove the volar condyles of the head of the middle phalanx with the rongeur.
- Identify the periphery of the base of the distal phalanx with a no. 15 blade, protecting the germinal matrix and the neurovascular bundles.
- Remove bone necessary to correct any joint malalignment, but minimize loss of digital length.
- Dechondrify and decorticate the opposing surfaces until healthy-appearing bone is present.
- Contour the head of the middle phalanx into a transversely oriented cylindrical shape (TECH FIG 2A), and fashion the base of the distal phalanx into a reciprocal shape.
  - Alternatively, create flat opposing surfaces perpendicular to the shafts.
- On occasion, the base of the distal phalanx is eburnated. Multiple 0.035-inch drill holes may be placed (“pepperpot” technique), which may then be connected with a small rongeur to unveil subchondral bone (TECH FIG 2B,C).

### Reduction and Fixation

- The type of fixation depends on the size of the bone. An Acutrak fusion screw (Acumed, Hillsboro, OR) is preferred when the diameter of the middle and distal phalanges is sufficient to accommodate the screw.
- Insert a 0.062-inch Kirschner wire antegrade beginning at the base of the distal phalanx and exiting the tip of the distal phalanx, just volar to the nail plate (TECH FIG 3A).
  - If the Kirschner wire penetrates the nail plate, discard it and use another to minimize the likelihood of contamination.
- Drive a smooth 0.062-inch Kirschner wire retrograde into the center of the middle phalanx to create a pilot hole, and then remove it (TECH FIG 3B).
- Reduce and compress the joint and then advance the wire retrograde across the DIP joint into the middle phalanx (TECH FIG 3C).
- Assess the reduction and Kirschner wire position clinically and fluoroscopically (TECH FIG 3D).
- While manually maintaining the joint position, remove the Kirschner wire and replace it with the appropriate drill bit.
  - Proper drill bit size is based on preoperative templating as well as an estimate of the available space based on the lateral fluoroscopic image with the 0.062-inch Kirschner wire in place.
- While maintaining compression across the joint, advance the drill retrograde by hand along the path created by the removed Kirschner wire (TECH FIG 3E).
- Determine the proper depth by fluoroscopy, using the external drill bit markings as a reference.
- Remove the drill bit and insert the appropriate-sized fusion screw (TECH FIG 3F) while maintaining manual compression across the joint.
- Final seating of the screw is based on the external reference used for the drill bit.
Chapter 80  DIP, PIP, AND MCP JOINT ARTHRODESIS

TECHNIQUES

A B C D E

I

J

TECH FIG 3 • A. A 0.062-inch Kirschner wire is driven antegrade through the center of the distal phalanx. B. A second 0.062-inch Kirschner wire is driven retrograde down the center of the middle phalanx to prepare a path for the screw. C. The distal interphalangeal joint is reduced and the distal Kirschner wire is driven retrograde into the middle phalanx. D. Proper alignment is confirmed fluoroscopically. The diameter of the intramedullary Kirschner wire is used as a reference for determining the screw diameter, based on the lateral radiograph. E. The Kirschner wire is removed. While maintaining manual compression across the joint, the appropriate drill bit is advanced by hand retrograde through the Kirschner wire path under fluoroscopic control. External markings on the drill bit serve as a reference for depth. F. The appropriate-sized screw is selected and secured to the driver. External markings on the driver correlate with the drill bit. G,H. PA and lateral radiographs during screw insertion. I. An alternative method of fixation involves the use of two or three Kirschner wires. J. Clinical appearance after fixation and closure.

Avoid inadvertent malrotation of the distal segment as the screw is tightened.

Obtain final radiographs and evaluate the stability (TECH FIG 3G,H).

Insert a supplemental 0.035-inch oblique Kirschner wire if necessary for stability.

If Kirschner wires are used as the sole form of fixation, drive an appropriate-diameter pin antegrade into the distal phalanx, reduce the joint, and advance the pin retrograde, preferably into the subchondral plate at the base of the middle phalanx.

One or two additional Kirschner wires are inserted obliquely in a retrograde fashion.

Final radiographs are obtained, and the pins are cut beneath the skin (TECH FIG 3I).

Completion

Remove the digital tourniquet and achieve hemostasis using bipolar electrocautery.

Irrigate the wound copiously.

Approximate the skin with 5-0 nylon interrupted sutures (TECH FIG 3J).

Repair of the terminal tendon is unnecessary.

Apply a sterile dressing and dorsal aluminum DIP splint, leaving the PIP joint free.

Instruct the patient on PIP exercises.
PIP JOINT ARTHRODESIS

Exposure
- Make a longitudinal dorsal incision.
- The surgical approach is similar to the thumb MCP arthrodesis (discussed later).
- In the multiply operated finger, a pre-existing midaxial scar may be used.
- The central slip and capsule are split longitudinally and elevated subperiosteally.
- The collateral ligaments are released from the middle phalanx, using a no. 15 blade directed dorsally, parallel to the sides of the phalanx.

Preparation of the PIP Joint
- Hyperflex (shotgun) the PIP joint and prepare the joint in the manner detailed for the DIP joint.
- Correct joint malalignment but minimize loss of digital length.
- As for the DIP joint, contour the head of the proximal phalanx into a transversely oriented cylindrical shape, and fashion the base of the distal phalanx into a reciprocal shape.
- Alternatively, use a water-cooled sagittal saw to cut flat surfaces perpendicular to the phalangeal shafts in the coronal plane, and with an appropriate degree of flexion in the sagittal plane.
- The flexion angle is built into the proximal phalanx saw cut. The middle phalanx cut is perpendicular to the axis of the phalanx in the sagittal plane.
- There is little room for error with the bone cuts. Commitment to the final position of the arthrodesis is made when the bone cuts are made. Any change may result in excessive shortening of the bone.7
- On occasion, as with the DIP joint, the base of the middle phalanx is eburnated. Multiple 0.035-inch drill holes may be placed (“pepperpot” technique), which may then be connected with a small rongeur to unveil subchondral bone.

Kirschner Wire Fixation
- In patients with inflammatory arthritis, the overlying skin is quite thin and may not tolerate prominent hardware. In those instances, crossed 0.035- to 0.045-inch Kirschner wires are used.
- Preset the appropriately sized Kirschner wires into the sides of the middle phalanx.
- Reduce and compress the joint manually, then advance the Kirschner wires in a retrograde manner into the proximal phalanx.
- If the skin is very thin, it may be impossible to cut the Kirschner wires beneath the skin. In those instances, the Kirschner wires are simply bent and left exposed.

Tension Band Fixation
- A tension band technique is used for posttraumatic and OA cases, particularly those involving the index PIP joint (TECH FIG 4A).
- Use a 0.035-inch Kirschner wire to make a transverse hole in the middle phalanx, dorsal to the mid-axis, about 8 mm distal to the joint.
- Pass a 26-gauge surgical steel wire through the hole.
- With the joint manually reduced, drive parallel 0.035- to 0.045-inch Kirschner wires antegrade across the PIP joint into the subchondral head of the middle phalanx.
- Begin the Kirschner wires on the dorsoradial and dorsoulnar margins of the proximal phalanx, about 10 mm proximal to the fusion site.
- The Kirschner wires should remain intramedullary in the middle phalanx.
- Loop the 26-gauge wire into a figure 8 configuration around the Kirschner wires proximally and tighten carefully with a needle driver.
- A gentle distraction force on the needle holder as the device is used to turn the wire and compress the fusion site helps avoid wire breakage.
- Remove the excess knot and impact the knot into bone.
- Withdraw the Kirschner wires slightly, bend them as close to the bone as possible so they can capture the 26-gauge wire, cut the Kirschner wires just distal to the bend, and advance them using the needle holder.
- Obtain final radiographs (TECH FIG 4B) and assess stability.
- Remove the tourniquet, achieve hemostasis, and irrigate the wound.
- Reapproximate the extensor tendon using interrupted inverted 4-0 nonabsorbable sutures. Close the skin with 5-0 nylon interrupted sutures.
- Place a sterile dressing and dorsal aluminum splint, leaving the DIP joint free. Instruct the patient on DIP joint exercises.

TECH FIG 4 • A. Preoperative PA radiograph demonstrating advanced osteoarthritis of the index proximal interphalangeal joint. Note the angular deformity, joint space loss, and large subchondral cyst. B. Postoperative PA radiograph demonstrating proximal interphalangeal arthrodesis with tension band fixation.
THUMB MCP JOINT ARTHRODESIS

Exposure
- Make a longitudinal dorsal incision over the MCP joint (TECH FIG 5A).
- Incise the extensor apparatus longitudinally between the EPB and EPL tendons (TECH FIG 5B). This will reveal the joint capsule (TECH FIG 5C).
- Perform a longitudinal capsulotomy and subperiosteally dissect around the dorsal base of the middle phalanx (TECH FIG 5D).
- Release the collateral ligaments from the metacarpal head (TECH FIG 5E), and hyperflex the MCP joint (TECH FIG 5F).

Joint Preparation
- Dechondrify the articular surfaces and remove peripheral osteophytes as well as the volar condyles of the metacarpal head with a rongeur (TECH FIG 6A).
- Decorticate and prepare the fusion surfaces in a “cup-and-cone” configuration\(^5,12\) using Coughlin reamers (Howmedica, Rutherford, NJ) (TECH FIG 6B,C).
  - This method allows for maintenance of thumb length and subtle adjustments in joint position while still maintaining optimal bone contact.
  - The 14- and 16-mm sizes are most often appropriate. Size selection is usually based on the size of the metacarpal head in order to avoid notching.
  - The same dimensions must be used for both metacarpal and phalangeal reaming or the surfaces will be incongruent.

Fixation and Reduction
- Tension band fixation is performed to stabilize the thumb MCP joint fusion in much the same manner as detailed for arthrodesis of the PIP joint.
- Alternative methods of fixation include Kirschner wires alone, headed or headless screw fixation, and plate fixation.

---

TECH FIG 5 • A. A longitudinal incision is centered over the metacarpophalangeal joint. B. The extensor hood is incised between the extensor pollicis longus and brevis tendons (dotted line). C. The hood has been split, revealing the dorsal joint capsule. D. The capsule has been incised longitudinally and reflected subperiosteally from the dorsal base of the proximal phalanx. Note the full-thickness cartilage loss along the ulnar aspect of the metacarpal head and dorsal base of the proximal phalanx secondary to volar-ulnar subluxation. E. The collateral ligaments are released from the metacarpal head. F. The metacarpophalangeal joint is now hyperflexed.
The remaining articular cartilage is removed. Peripheral osteophytes and the volar condyles are trimmed with a rongeur. **B.** Coughlin cup and cone reamers. Care must be taken to ensure that the same-sized reamer is used for both sides to maximize bone contact. **C.** The metacarpal head is used as a reference in determining reamer size. The smallest reamer that will not notch the cortex is selected. **D,E.** A 0.062-inch Kirschner wire is advanced antegrade in the proximal phalanx to be used as a guidewire. The pin is positioned in the center of the bone in the coronal plane (dot in the center of the interphalangeal joint) and in slight flexion in the sagittal plane. **F.** The “cup” reamer is placed over the Kirschner wire under power with frequent irrigation until bleeding subchondral bone is revealed. The asymmetry of the base of the proximal phalanx due to chronic subluxation is corrected. **G,H.** A 0.062-inch Kirschner wire is then inserted retrograde into the metacarpal head. The pin is positioned in slight flexion and slight ulnar deviation. **I.** The matching “cone” reamer is placed over the Kirschner wire under power with frequent irrigation until bleeding subchondral bone is apparent. **J.** Appearance of the surfaces after joint preparation.

- The tension band construct is strong enough to allow for early motion with a hand-based splint.
- Plate fixation is reserved for cases of bone loss requiring supplemental grafting.
- Use a 0.045-inch smooth Kirschner wire to create a transverse hole in the proximal phalanx, about 1 cm distal to the joint and dorsal to the midline.
- Pass a 24- or 26-gauge surgical steel wire though the tunnel (**TECH FIG 7A**).
- Anticipating the ultimate position of the thumb fusion, advance parallel 0.054- or 0.062-inch Kirschner wires retrograde, exiting dorsally along the metacarpal shaft (**TECH FIG 7B**).
- Reduce the MCP joint in slight (less than 25 degrees) flexion, abduction (5 degrees), and pronation (5 degrees), and drive the preset Kirschner wires antegrade.
- Take care to avoid perforating the volar cortex into the flexor tendon sheath.
Loop the wire in a figure 8 configuration around the Kirschner wires, and tighten using a needle driver.

Trim excess wire and impact the knot into the bone.

Pull back, bend, cut, and advance the Kirschner wires (as detailed earlier) to secure the tension band wire (TECH FIG 7C).

Completion

- Remove the tourniquet, achieve hemostasis, and irrigate the wound.
- Close the capsule over the hardware using absorbable 4-0 suture and then close the extensor mechanism using 4-0 nonabsorbable interrupted inverted stitches (TECH FIG 8A).
- Approximate the skin using 5-0 nylon interrupted suture, and apply a sterile dressing and radial gutter splint.
  - The interphalangeal joint is left free, and the patient is instructed on interphalangeal motion exercises.
- Obtain final radiographs (TECH FIG 8B,C).

TECH FIG 7 • A. A 24-gauge wire is passed through a drill hole in the proximal shaft of the proximal phalanx, dorsal to the midline and parallel to the joint. B. A 0.062-inch Kirschner wire is then driven retrograde in the metacarpal head, exiting dorsally, anticipating the ultimate position of the metacarpophalangeal joint. C. The 24-gauge wire is looped around the base of the Kirschner wires in figure 8 fashion and tensioned. The Kirschner wires are cut short and the wire knot is tamped against the cortex.

Loop the wire in a figure 8 configuration around the Kirschner wires, and tighten using a needle driver.

Trim excess wire and impact the knot into the bone.

Pull back, bend, cut, and advance the Kirschner wires (as detailed earlier) to secure the tension band wire (TECH FIG 7C).

Completion

- Remove the tourniquet, achieve hemostasis, and irrigate the wound.
- Close the capsule over the hardware using absorbable 4-0 suture and then close the extensor mechanism using 4-0 nonabsorbable interrupted inverted stitches (TECH FIG 8A).
- Approximate the skin using 5-0 nylon interrupted suture, and apply a sterile dressing and radial gutter splint.
  - The interphalangeal joint is left free, and the patient is instructed on interphalangeal motion exercises.
- Obtain final radiographs (TECH FIG 8B,C).

TECH FIG 8 • A. The capsule and extensor hood are repaired in layers. B,C. Postoperative PA and lateral radiographs demonstrate good joint apposition and alignment.

INDEX THROUGH SMALL FINGER MCP JOINT ARTHRODESIS

- The approach and bone preparation mirror those described for the thumb.
- Fixation may be achieved with Kirschner wires alone, a tension band construct, screws, or plates (TECH FIG 9).
  - Keep in mind the anticipated deforming forces, which may be out of plane with the fixation.
- Immobilization should protect the fused joint from stress, while simultaneously permitting motion of the PIP and DIP joints. We prefer to apply a short-arm cast extending out to the PIP joints, allowing PIP and DIP motion.

TECH FIG 9 • A, B. PA and lateral radiographs showing chronic right index metacarpophalangeal volar-ulnar subluxation in patient who had undergone two previous attempts at radial collateral ligament reconstruction. (continued)
The surgical approach, bone preparation, and closure are performed as detailed earlier.

Most frequently, flat bone cuts are used with these fixation techniques.

### Interosseous Wiring
- Drill two parallel holes from dorsal to volar, each 3 to 4 mm away from the arthrodesis site, using a 0.035-inch Kirschner wire.
- Drill two additional holes, this time in the radioulnar plane, again about 3 to 4 mm on either side of the arthrodesis site.
- Thread two 26-gauge surgical steel wires through the drill holes.
  - A 20-gauge hypodermic needle may be used to facilitate wire placement.
- Pass one wire from dorsal to volar through one drill hole, and then volar to dorsal in the parallel drill hole, forming a loop.
- Pass the second 26-gauge steel wire through the drill holes in the coronal plane, forming a second loop.
- After the wires are placed, tighten the ends of the wires sequentially and shorten and bend them to decrease their profile.
- This configuration results in two perpendicular loops providing compression and fixation across the arthrodesis interface.

### Plate Fixation
- Fill bone defects with intercalary grafts as needed (TECH FIG 10A,B).
- Select the largest compression plate that will not be prominent.
  - These range in size from 1.5 to 2.7 mm.
- The plate is precontoured to match the angle of the fusion.
  - A slight increase in concavity is created to allow compression of the volar cortex when the plate is applied (TECH FIG 10C).
- Insert a bicortical screw through the plate into the distal fragment.
  - Be certain that this and other screws do not penetrate the volar cortex and impair the function of the flexor tendons.
- Using AO compression technique, place a screw through the plate into the proximal fragment.
  - Drill as proximally and eccentrically as possible within the plate’s screw hole so that when the screw is tightened, compression is obtained.
- Place the remaining screws (TECH FIG 10D).
  - Four to six cortices on either side of the fusion site provides adequate fixation.14

### Compression Screw Fixation
- In much the same manner as described for placement of Kirschner wires for tension band fusion of the
A B C

TECH FIG 10 • A,B. After silicone implant arthroplasty, rigid swan-neck deformities developed. Conversion to arthrodesis in a more functional position was complicated by large bone defects resulting from removal of the implants. C. A prebent 2-mm dynamic compression plate is applied to the dorsal surface for the proximal and middle phalanges. D. A B

Chapter 80 DIP, PIP, AND MCP JOINT ARTHRODESIS

thumb MCP joint, the guidewire is introduced into the proximal fragment in a retrograde manner, exiting the dorsal cortex at least 5 mm proximal to the arthrodesis site.
- This protects against inadvertent fracture of the dorsal cortex.
- Manually reduce and compress the prepared joint.
- It may be helpful to place a small (0.028- to 0.035-inch) provisional Kirschner wire away from the anticipated screw site to provide rotational stability.
- Advance the guidewire antegrade from proximal to distal, perpendicular to the fusion interface, and into the medullary canal of the distal segment.
- Advance the wire just beyond the mid-diaphyseal region of the distal fragment.
- Evaluate clinically and fluoroscopically to ensure proper position (TECH FIG 11).
- Measure the guidewire and choose the appropriate-length screw to ensure that after compression, the distal screw threads will engage the endosteal cortex and the proximal aspect of the screw will be buried.
- Remove the derotation Kirschner wire.

A B
PEARLS AND PITFALLS

Bone end preparation
- If flat bone cuts are to be used, predetermine and create accurate flexion angles for the joint fusion. There is little room for error with this technique. Inaccurate cuts will result in excessive bone shortening.
- The cup-and-cone preparation technique is more forgiving, allowing for angular and rotational adjustments while maintaining bone contact.
- Ensure that there is no malrotation of fusion interface.

Surgical approach
- Preserve joint capsule for later repair to minimize extensor tendon adherence.

Tension band fixation
- To minimize hardware problems, position the Kirschner wires within the intramedullary canal and advance them into the subchondral plate.

Compression screw fixation
- In the PIP and MCP joints, ensure that the starting point is 5 mm from the bony end of the proximal fragment to prevent fracture of the dorsal cortex.

POSTOPERATIVE CARE
- Postoperative management depends on the involved joint and method of fixation. Early motion of the adjacent joints is critical to minimize stiffness.
- For DIP joint arthrodesis, protection with a simple aluminum splint is sufficient. PIP motion is encouraged. Splinting may be unnecessary if a fusion screw is used. Radiographs are taken at 6 weeks postoperatively. Buried pins may be removed once the fusion is radiographically solid (at least 8 weeks postoperatively).
- For PIP joint arthrodesis, tension band, screw, and plate constructs are usually strong enough to obviate the need for supplemental splinting. Early MCP and DIP motion is encouraged; however, the patient is advised against lateral stress or forceful grip with the affected digit. With simple pin fixation, a supplemental dorsal aluminum or thermoplast PIP splint is used until radiographs demonstrate union.
- For the thumb MCP joint treated with tension band fixation, a protective custom-molded thermoplast hand-based MCP splint is used for about 6 weeks. Early IP joint motion is encouraged.
- In general, arthrodesis of the other MCP joints must be protected with a hand- or forearm-based splint, regardless of the type of fixation. Significant flexion and lateral stresses must be neutralized while simultaneously allowing for PIP and DIP motion. It may be necessary to splint the PIP joint in extension part-time to prevent an extensor lag from developing.

OUTCOMES
- Multiple studies have evaluated the biomechanical advantages of one type of surgical technique versus another in order to establish the most rigid type of fixation that will allow a rapid and complete arthrodesis.
- A comparison between the failure load of a Herbert screw and the failure load of a tension band construct showed no significant difference between the two; the authors concluded that these two methods of fixation have similar biomechanical strength.
- A comparison of multiple fixation techniques showed that arthrodesis by screw fixation had a better fusion rate than Kirschner wires, tension band construct, and plate fixation.10
- A comparison of tension band constructs versus Kirschner wire fixation for PIP joint arthrodesis concluded that tension bands provide more rigid fixation.9
- Biomechanical testing comparing the Herbert screw and tension band construct for DIP arthrodesis showed that the Herbert screw has significantly higher bending strength as well as more rigidity against axial torsion, although no difference was noted in the bending stiffness between these two methods of fixation.20

COMPlications
- Pin tract infection
- Nonunion
- Malunion
- Vascular insufficiency
- Skin necrosis
- Cold intolerance
- Stiffness of adjacent digits
- Painful hardware

REFERENCES

DEFINITION
- When ligamentous restraint at the thumb carpometacarpal (CMC) joint is compromised, functional grip and pinch may result in painful synovitis and hypermobility long before the development of cartilage wear and arthritis.
- So-called Eaton stage 1 disease can be treated with an extension osteotomy at the base of the thumb metacarpal as an alternative to either ligament reconstruction or arthroscopic synovectomy and pinning.\(^7,8\)

ANATOMY
- The thumb metacarpal (TM) joint is a biconcave-convex saddle joint with minimal bony constraints, so ligamentous support is extremely important, especially considering the compressive forces transmitted across the joint during functional pinch. Eaton and Littler identified the anterior oblique “beak” ligament, so called for its attachment on the palmar beak of the thumb metacarpal, as the primary stabilizer of the TM joint.
- With the assistance of TM joint arthroscopy, Bettinger et al\(^1\) have further defined the anterior oblique ligament (AOL) into a superficial (sAOL) and deep ligament (dAOL). The dAOL, which is intracapsular, is, in fact, the beak ligament. The dAOL plays an important role in the kinematics of thumb opposition. It acts as a pivot point and becomes tight during pronation, opposition, and palmar abduction. The dAOL limits pronation in flexion and both pronation and supination in extension.
- In their comprehensive assessment of the ligamentous anatomy of the TM joint, Bettinger et al\(^1\) described a total of 16 ligaments that stabilize the trapezium and TM. Seven of these ligaments, including the sAOL, dAOL “beak” ligament, dorsoradial (DRL), posterior oblique, ulnar collateral, intermetacarpal, and dorsal intermetacarpal, are responsible for directly stabilizing the TM joint.
- The DRL’s role in joint stability has been debated, but Bettinger et al\(^1\) showed that the DRL is an important joint stabilizer. The DRL, which covers a large percentage of the posterior aspect of the joint, is a wide thick ligament that attaches to the trapezium and inserts on the dorsum of the metacarpal base. This ligament tightens with dorsoradial and dorsal translational forces in all positions except full extension. It also tightens in supination and in pronation with joint flexion.

PATHOGENESIS
- Functional incompetence of the basal joint’s AOL results in pathologic laxity, abnormal translation of the metacarpal on the trapezium, and generation of excessive shear forces between the joint surfaces, particularly within the palmar portion of the joint during grip and pinch activity. Histologic study has shown that attritional changes in the AOL at its attachment to the palmar lip of the metacarpal precede degeneration of cartilage.\(^2\)

NATURAL HISTORY
- Because the AOL appears to be the primary stabilizer of the TM joint, and since its detachment results in dorsal translation of the metacarpal, its reconstruction has been recommended to restore thumb stability not only in cases of end-stage osteoarthritis but also for early-stage disease.
- Pellegrini et al\(^5\) were the first to evaluate the biomechanical efficacy of extension osteotomy. Palmar contact area was unloaded with a concomitant shift in contact more dorsally so long as arthrosis did not extend more dorsal than the midpoint of the trapezium.
- Shrivastava et al\(^6\) studied the effect of a simulated osteotomy on TM joint laxity by flexing the metacarpal base 30 degrees, thus placing the joint in the relationship it would assume if an extension osteotomy was performed.
  - The simulated extension osteotomy reduced laxity in all directions tested: dorsal-volar (40% reduction), radial-ulnar (23% reduction), distraction (15% reduction), and pronation-supination (29% reduction).
  - They hypothesized that the beneficial clinical effects of a TM extension osteotomy may be partially due to tightening of the DRL, which might reduce dorsal translation.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Basal joint arthritis may present with mild symptoms beneath the thenar eminence at the level of the TM joint, particularly during pinch and grip. Ultimately, the greatest functional impairment occurs with advanced disease—limiting breadth of grasp and forceful lateral pinch activities such as brushing teeth, turning a key, opening a jar, or picking up a book.
- Complaints are directed toward the base of the thumb, and pain is frequently associated with a sensation of movement or “slipping” within the joint. An enlarging prominence, or “shoulder sign,” inevitably develops at the base as the clinical manifestation of dorsal metacarpal subluxation on the trapezium and metacarpal adduction.
- Early presentation may result in only pain with TM stress and palpation beneath the thenar cone, without deformity, instability, subluxation, or crepitance.
- Methods for examining the thumb CMC joint for hypermobility (stage 1 disease) include the following:
  - Trapeziiometacarpal stress test, which may cause pain or a slight shift or subluxation
  - Thenar CMC joint palpation test, which may cause pain...
IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographic evaluation includes a posteroanterior (PA) 30-degree oblique stress view, lateral view, and a Robert (pronated anteroposterior [AP]) view (FIG 1).
- Osteoarthritis may be confined to the TM joint, or it may involve the pan-trapezial joint complex. Indeed, the staging system described by Eaton and Littler describes four stages:
  - Stage 1: a normal joint with the exception of possible widening from synovitis
  - Stage 2: joint space narrowing with debris and osteophytes smaller than 2 mm
  - Stage 3: joint space narrowing with debris and osteophytes larger than 2 mm
  - Stage 4: scaphotrapezial joint space involvement in addition to narrowing of the TM joint

DIFFERENTIAL DIAGNOSIS
- CMC arthritis (stages 2 to 4)
- De Quervain tendonitis
- Flexor carpi radialis tendinitis

NONOPERATIVE MANAGEMENT
- Nonoperative treatment includes anti-inflammatory medication, intra-articular steroid injection, hand- or forearm-based thumb spica splint immobilization, and thenar muscle isometric conditioning.
- Although none of these measures may provide permanent or even long-lasting relief from symptoms, they may indeed provide temporary relief. This allows the patient to contemplate surgery, to gain acceptance, and to participate in the surgical decision-making process.

SURGICAL MANAGEMENT
- Until recently, surgical treatment has centered around reconstruction of the palmar beak ligament with a slip of flexor carpi radialis tendon, as described by Eaton and Littler.3
- The rationale for TM extension osteotomy involves dorsal load transfer and a shift in force vectors during pinch. Pellegrini et al5 showed that a 30-degree closing wedge extension osteotomy effectively unloaded the palmar compartment when eburnation involved less than half, and optimally only one third, of the palmar joint surfaces. Osteotomy in this setting shifted the contact areas to the intact dorsal articular cartilage.
- The most recent biomechanical assessment of metacarpal osteotomy suggested that joint laxity is reduced in lateral pinch because of obligatory metacarpal flexion and resulting increased tightening of the dorsal radial ligament.6

Preoperative Planning
- Radiographs should show a normal joint or slight widening from synovitis. A trapeziometacarpal stress test should elicit pain along with palpation of the joint beneath the thenars. Obviously, other causes of discomfort in the region should be excluded.

Positioning
- The extremity is placed on a standard hand table.

Approach
- A dorsal approach is used and subperiosteal exposure of the base of the metacarpal is provided.
- The osteotomy is made 1 cm distal to the base and is 5 mm wide, so the incision should extend 4 cm distal to the base.
- The base of the wedge is therefore 5 mm wide and is dorsal. Its apex is palmar.
EXTENSION OSTEOTOMY WITH STAPLE FIXATION

- Regional, axillary block anesthesia is performed and a nonsterile tourniquet is placed.
- After exsanguination with an Esmarch bandage and inflation of the tourniquet to 250 mm Hg, make a dorsal incision from the base of the TM distally for about 3 cm.
- In the subcutaneous tissue, identify and protect the sensory branches of the radial and lateral antebrachial cutaneous nerves. Obtain subperiosteal exposure without injuring the extensor pollicis longus, and identify the TM joint with a 25-gauge needle.
  - One centimeter distal to the TM joint, obtain near-circumferential access around the metacarpal in anticipation of the osteotomy.
- Visualize the volar extent of the metacarpal at this location to facilitate accurate resection of a dorsally based 30-degree wedge of bone (TECH FIG 1A).
- Use a microsagittal saw to score the metacarpal 1 cm distal to its base transversely, but do not make a complete cut through the volar cortex.
- Leave a new saw blade in that partial osteotomy site and use a second blade about 5 mm distal to the first cut at an angle of 30 degrees so that the two blades intersect at the volar cortex.
- Remove the wedge of bone, extend the distal metacarpal and compress it against the proximal fragment, and place one 11/10038 staple (OSStaple™ BioMedical Enterprises, Inc., San Antonio, TX).
- Typically, I maintain the reduced position of the metacarpal while my assistant predrills and then places the staple (TECH FIG 1B,C).
- Perform a layered closure of the periosteum and skin and place an overlying thumb spica splint.

TECH FIG 1 • A. Radiograph showing planned osteotomy. B,C. AP and lateral postoperative thumb radiographs.

EXTENSION OSTEOTOMY WITH KIRSCHNER WIRE AND TENSION BAND FIXATION

- The technique is as described for staple fixation except for the use of Kirschner wires.
- Use a microsagittal saw to score the metacarpal 1 cm distal to its base transversely, but do not make a complete cut through the volar cortex.
  - Leave a new saw blade in that partial osteotomy site and use a second blade about 5 mm distal to the first cut at an angle of 30 degrees so that the two blades intersect at the volar cortex.
- Remove the wedge of bone and use a 0.045-inch Kirschner wire to place a transverse hole on either side of the osteotomy.
- Pass a 22-gauge wire radial to ulnar and ulnar to radial.
- Place a 0.045-inch Kirschner wire retrograde through the distal osteotomy site, exiting out the ulnar aspect of the thumb, and compress the osteotomy by extending the distal metacarpal.
- With an assistant maintaining compression, tighten the wire, cut it, and bend it beneath the thenar musculature. Then advance the Kirschner wire anterograde.
- Cut the Kirschner wire external to the skin to facilitate removal, and repair the periosteal origin of the thenar musculature with absorbable suture.

POSTOPERATIVE CARE

- A thumb spica splint is placed for 10 days.
- At that time sutures are removed, and a thumb spica cast with the interphalangeal joint of the thumb left free is placed for an additional 4 weeks.
- About 6 weeks after surgery a forearm-based thumb spica Orthoplast splint is placed, and the patient is instructed to begin gentle TM motion.
- Grip and pinch exercises are started at about 8 weeks after surgery unless union is delayed.

OUTCOMES

- In light of Pellegrini et al’s biomechanical data and my own relative dissatisfaction with Eaton ligament reconstruction for stage 1 disease, primarily related to a prolonged recovery period (8 to 10 months) and a stiff TM joint, I prospectively evaluated the efficacy of a 30-degree extension osteotomy in 12 patients (12 thumbs) between 1995 and 1998.8
  - TM arthroscopy allowed accurate intra-articular assessment and verified AOL detachment from the metacarpal rim in each case.
  - Follow-up averaged 2.1 years (range 6 to 46 months).
  - All osteotomies healed at an average of 7 weeks. Eleven patients were satisfied with outcome. Grip and pinch strength increased an average of 8.5 and 3 kg, respectively.
  - Since that study’s publication, I have become even more impressed by the efficacy of the procedure and believe, as Koff et al suggested, that osteotomy decreases laxity and shifts contact area more dorsally. It seems logical that the DRL participates in this effect, and this substantiates the contention that the DRL is an important stabilizer.

COMPLICATIONS

- Nonunion
- Persistent pain necessitating resection arthroplasty with trapezium excision
- Radial sensory nerve injury or dysethesia

REFERENCES

DEFINITION

- Osteoarthritis, or more appropriately termed osteoarthrosis, is a common problem in the hand.
- The trapeziometacarpal joint is frequently affected, second in frequency only to the distal interphalangeal joint, but much more disabling due to pain and weakness of grip and pinch strength.
- The surgical management of symptomatic basilar joint arthritis depends on anatomy, radiographic staging, and patient requirements, followed by intraoperative confirmation of the stage of disease.
- Arthrodesis of the thumb carpometacarpal (CMC) joint was initially described by Muller over 50 years ago. With refinements in arthroplasty procedures, arthrodesis of the basal joint of the thumb has become less popular, but the procedure still can provide an excellent result in the right circumstances; it is a valid treatment option for stage II or stage III disease only.

ANATOMY

- The thumb CMC joint is a biconcave joint, allowing for motion in three planes: flexion-extension, abduction-adduction, and pronation-supination.
- There are minimal osseous constraints, making the ligamentous structures extremely important stabilizers of the thumb base.
- A total of 16 ligaments have been described around the thumb CMC joint:
  - Seven are primary stabilizers of the thumb metacarpal:
    - Superficial and deep anterior oblique (sAOL and dAOL)
    - Dorsal radial
    - Posterior oblique
    - Ulnar collateral
    - Intermetacarpal
    - Dorsal intermetacarpal
  - The remainder stabilize the trapezium, providing a stable foundation for the thumb.

PATHOGENESIS

- The pathogenesis of CMC joint arthrosis is multifactorial, involving biochemical and biomechanical influences. The synovial fluid within the joints contains cytokines, which invariably play a role in cartilage degradation and decreased ability to withstand the loads generated at the joint during daily activities.
  - Although not clearly delineated, there probably is some protective role played by estrogen or estrogen-related compounds, which may explain the increased incidence of osteoarthritis in postmenopausal women (10 to 15:1).
  - The anterior (palmar) oblique ligament, or so-called beak ligament, has been shown to be the most important stabilizing ligament of the thumb, and its degeneration or functional incompetence leads to laxity, followed by abnormal translation of the metacarpal on the trapezium, resulting in increased shear forces and abnormal wear patterns. This eventually leads to eburnation of the articular cartilage, initially along the palmar aspect of the joint. With progression of disease, osteophytes develop and eburnation progresses throughout the entire joint surface.

- Osteoarthritis can also develop from disruption of the articular cartilage. Any fracture involving the articular surfaces (most commonly the base of the thumb metacarpal) will predispose to or accelerate the development of arthrosis.
  - Anatomic restoration of the joint surface can minimize this progression but not eliminate it completely.
  - Paradoxically, a Bennett fracture may protect the joint from the development of osteoarthritis (assuming subluxation is not present) by virtue of consequential unloading of the volar aspect of the joint.

NATURAL HISTORY

- Arthrosis of the thumb CMC joint begins along the palmar aspect of the metacarpal secondary to laxity of the AOL.
- The entire base of the metacarpal and the distal trapezium experience eburnation of the cartilage, which progresses to develop osteophytes.
- The thumb metacarpal assumes an adducted position and the metacarpophalangeal (MCP) joint may compensate by becoming hyperextensible, resulting in hyperextension.
- Finally, the entire surface of the trapezium becomes involved, resulting in degeneration between the proximal trapezium and the distal scaphoid.
- Disease can involve all the trapezial articulations as well as the scaphotrapezial joint.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Thumb CMC joint arthrosis will often present with pain at the base of the metacarpal.
  - The pain will be exacerbated with activities involving loading the thumb metacarpal base, such as turning a doorknob, twisting a lid off a jar, or turning a key.
  - Pain at rest may or may not be present.
  - Symptoms do not always correlate with the clinical or radiographic appearance. A patient may have advanced clinical and radiographic disease but be minimally symptomatic. Conversely, a patient may have significant symptoms with minimal radiographic changes and no clinical deformity at rest.
  - Physical examination of the patient with advanced disease reveals deformity.
    - The thumb subluxates in a dorsal direction and becomes fixed in adduction, manifesting as a prominence at the base of the thumb and decreased ability to abduct the thumb away from the palm.
    - In an effort to compensate for this limitation, the MCP joint will often hyperextend, creating a zig-zag deformity.
Asking the patient to place one finger on the point that is most symptomatic helps localize the point of maximal tenderness to the CMC joint or another area.

CMC grind test: Reproduction of symptoms confirms the CMC joint as a site of disease.

CMC distraction test: Reproduction of symptoms confirms the CMC joint as a site of disease.

Finkelstein maneuver: Maximal tenderness indicates that DeQuervain disease may be a greater source of symptoms.

Phalen test: Reproduction of symptoms indicates carpal tunnel syndrome as a more likely etiology.

Carpal tunnel compression test: Reproduction of symptoms indicates carpal tunnel syndrome as a more likely etiology.

Trigger evaluation: Reproduction of pain, triggering, or locking of the thumb indicates trigger thumb as an etiology.

Allen test: The radial and ulnar arteries are compressed and the hand is exsanguinated. The ulnar artery is released and the circulation of the hand is assessed. The process is repeated, releasing the radial artery while the ulnar artery is occluded. Surgical procedures often involve mobilization of the radial artery in the snuffbox. Damage to this artery will require reconstruction if the ulnar artery cannot compensate.

Other conditions causing pain at the base of the thumb must be eliminated, such as DeQuervain disease, trigger thumb, and carpal tunnel syndrome. Although more than one condition may exist, the physical examination can usually determine the most problematic area.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Plain radiographs are the imaging modality of choice for evaluation of thumb CMC joint arthrosis (FIG 1).

These include a pronated AP (Robert view), lateral, and a 30-degree posteroanterior stress view.

Eaton and Littler3 have described a radiographic staging system that is commonly used, but Tomaino et al11 have emphasized routine assessment of the scaphotrapezial joint, both radiographically and intraoperatively, to rule out scaphotrapezial arthritis, or what they termed “stage V disease.”

Stage I: normal-appearing or widened joint space secondary to synovitis

Stage II: joint space narrowing and osteophyte formation smaller than 2 mm

Stage III: joint space narrowing with osteophytes larger than 2 mm

Stage IV: stage III appearance with the addition of narrowing or osteophytes in the scaphotrapezial joint

The scaphotrapezial joint is not specifically addressed in this system and may be difficult to assess radiographically, but this joint should always be assessed at the time of surgery because it may be a source of continued pain.

DIFFERENTIAL DIAGNOSIS

- Thumb CMC arthrosis
- DeQuervain disease
- Trigger thumb or stenosing tenosynovitis
- Carpal tunnel syndrome
- Intramuscular (thenar) processes, such as vascular or tumor etiologies

NONOPERATIVE MANAGEMENT

- Most patients with symptomatic thumb CMC joint arthrosis benefit from a trial of conservative therapy, which may include corticosteroid injection, thenar isometric strengthening exercises, and splinting.3

- Although this will not eliminate the problem or alter the underlying disease process, it often reduces symptoms, at least transiently, allowing the patient the opportunity to plan for surgical treatment at the most opportune time.

- Steroid injections can also be helpful in determining how much of a patient’s symptoms are coming from the thumb CMC joint versus other areas (carpal tunnel or De Quervain disease).

SURGICAL MANAGEMENT

- The indications for surgical intervention for symptomatic thumb basilar joint arthrosis include pain and weakness not responsive to conservative treatments.

- There are multiple procedures used to treat symptomatic CMC thumb arthritis, many of which have merit depending on several factors. Consideration should be given to the age of the patient and the demands placed on the thumb (specifically looking at the patient’s occupation) as well as the radiographic stage and the condition of surrounding joints.

- The best candidates for thumb CMC arthrodesis are young, active patients who need to maintain power grip and pinch, and regularly place high demand on their thumb. These are typically young, male manual laborers with stage II or III disease.

- Special consideration should be given to the thumb MCP joint. If hyperextension and laxity are present, arthrodesis of the CMC joint is not an appropriate option, because fusion of both the thumb CMC and MCP joints will result in significant functional impairment.

- Pan-trapezial involvement represents a contraindication for CMC arthrodesis because of the risk of incomplete pain relief.

Preoperative Planning

- The patient should be made aware of the decreased mobility, inability to flatten the palm on the table, potential difficulty in placing the hand in tight confined spaces, and possible difficulty placing the hand in a glove.
Patients also should understand the risks of nonunion, potential for hardware complications, and potential for developing degenerative changes at adjacent joints.

Positioning
- The procedure is performed under regional or general anesthesia with the use of a pneumatic tourniquet.
- The patient is in supine position with the arm extended on an armboard.

Approach
- The procedure can be performed through a Wagner-type incision, along the junction of the glabrous and dorsal skin, or through a dorsal incision.
- The dorsal incision can be oriented in a longitudinal fashion, along the radial aspect of the first dorsal compartment tendons, or in a transverse direction, with the incision oriented in the resting skin tension lines centered over the trapeziometacarpal joint.

**THUMB CMC (TRAPEZIOMETACARPAL) ARTHRODESIS**

**Incision and Dissection**
- Make a dorsal longitudinal incision along the radial aspect of the first dorsal compartment tendons (TECH FIG 1A).
- Identify and protect sensory branches of the radial nerve and the lateral antebrachial cutaneous nerve (TECH FIG 1B).
- Identify the first dorsal compartment tendons and release the compartment along the ulnar aspect to allow for better exposure (TECH FIG 1C).
- Identify the dorsal branch of the radial artery deep to the abductor pollicis longus and extensor pollicis brevis tendons running in a dorsal and ulnar direction (TECH FIG 1D). Carefully mobilize and protect it.
- Identify the base of the metacarpal, and complete a longitudinal capsulotomy to expose the base of the metacarpal, the entire trapezium, and the distal aspect of the scaphoid.
- Fluoroscopy is used to confirm the location of the CMC joint if necessary.

**Preparation of the Joint**
- Inspect the scaphotrapeziotrapezoid joints (TECH FIG 2A).
  - If there is evidence of arthrosis, consideration is given to alternative procedures.
- Then inspect the CMC joint (TECH FIG 2B).
  - By freeing the surrounding capsular attachments, the base of the metacarpal can be flexed to allow better access to the joint.
- Use a rongeur to remove osteophytes (TECH FIG 2C), any remaining articular cartilage, and subchondral bone. Shape the metacarpal base in a cone fashion to provide a larger surface area and greater freedom for obtaining the ideal position for arthrodesis (TECH FIG 2D).
- Decorticate the distal aspect of the trapezium in a similar fashion, creating a cup for placement of the prepared metacarpal base.

**Positioning and Fixation**
- The position for arthrodesis should allow the tip of the thumb to rest against the radial aspect of the index middle phalanx when the hand is placed in the fisted position.
- The exact angles to accomplish this position are debated, but in general there should be about 45 degrees of palmar abduction and adequate pronation to allow positioning.
- Place three 0.045-inch smooth Kirschner wires through the decorticated metacarpal base in an antegrade manner,
exiting the dorsal aspect of the metacarpal until the tip of the wires are just beneath the prepared proximal metacarpal (TECH FIG 3A).

- The metacarpal is then aligned with the trapezium, properly positioned, and compressed with axially directed force (TECH FIG 3B).
- Advance the Kirschner wires retrograde across the joint into the trapezium, anchoring in the subchondral bone. The wires can be advanced into the carpus (TECH FIG 3C).
- Fluoroscopy is used to confirm reduction and Kirschner wire placement (TECH FIG 3D). If there is inadequate bony apposition, distal radius bone graft can be harvested and used to fill any voids.
- Close the capsule with a nonabsorbable suture and close the skin with buried absorbable sutures.
- Bend the Kirschner wires and cut them external to the skin.
- If mild thumb MCP joint hyperextension is noted at this juncture, pin the MCP joint in 20 degrees of flexion. If dynamic collapse accompanies pinch, then perform volar capsulodesis.
- Apply a well-padded short-arm thumb spica splint.

TECH FIG 2 • A. Inspection of the scaphotrapeziotrapezoid (STT) joint for arthrosis (probe is in the scaphotrapezial joint). B. Exposure of the carpometacarpal (CMC) joint (forceps are around trapezium and probe is in CMC joint). C. Close-up view of small dorsal osteophyte along base of thumb metacarpal. D. View of the CMC joint after removal of articular cartilage in preparation for arthrodesis.

TECH FIG 3 • A. Preliminary placement of Kirschner wire to check alignment before compression of the arthrodesis site. B. Final inspection of the prepared surfaces before compression and advancement of the Kirschner wires across site of arthrodesis. (continued)
Bony Preparation
- Rather than the “cup and cone” technique, an oscillating saw can be used to create two flat surfaces that can be apposed, allowing a large contact area.
- Make the cuts in the exact plane desired, or the position of the thumb will be compromised.
- This is a much less forgiving technique than the cup and cone method, which allows for correction by rotation of the metacarpal while positioning it on the trapezium.

Fixation Devices
- Single or multiple smooth Kirschner wires, tension band wiring, cerclage wiring, staples, compression screws, and plates and screws have all been used with documented success.
- Union rates are comparable for Kirschner wires and more rigid fixation devices, but plates and screws result in a higher rate of additional procedures, typically due to hardware prominence or tendon irritation.
- Kirschner wires are associated with the fewest complications and are the simplest method of fixation.

PEARLS AND PITFALLS

**Surgical approach**
- Take care to protect the cutaneous branches of the radial sensory nerve and the lateral antebrachial cutaneous nerve throughout the entire procedure.
- Protect the radial artery located under the abductor pollicis longus and extensor pollicis brevis tendons.

**Intraoperative joint inspection**
- Carefully inspect the scaphotrapeziotrapezoid joints, as arthritic involvement at these joints will preclude success with CMC arthrodesis.

**Judicious use of bone graft**
- Make sure there is good apposition of the bony surfaces before closure. Use bone graft to fill any voids, which may lead to nonunion.

**Treatment of MCP joint laxity**
- Consider pinning the MCP joint in 20 degrees of flexion if mild hyperextension exists.

**Radial sensory nerve injury**
- If there is inadvertent injury to the radial sensory nerve and this is recognized, it should be repaired with fine epineurial suture.

**Radial artery injury**
- If there is inadvertent injury to the radial artery, it should be temporarily clipped with temporary vascular clamps. After the arthrodesis is completed and the capsule is closed, the tourniquet is deflated. If there is good perfusion to all the digits, the artery can be ligated. If the perfusion is inadequate, microvascular repair must be accomplished.

**Nonunion or malunion**
- Inadequate preparation of joint surfaces may lead to nonunion.
- Improper positioning of thumb metacarpal on the trapezium may lead to malunion.
POSTOPERATIVE CARE

- The patient is seen in the office at 10 to 14 days to check the wound and the Kirschner wires and to obtain radiographs.
- If fixation is secure and the Kirschner wires are not advanced through the trapezium, a well-molded short-arm thumb spica splint is applied and removed for hygiene purposes only. If the Kirschner wires are advanced into the carpus, the patient is placed in a thumb spica cast.
- If there is any concern about fixation, a short-arm thumb spica cast is applied and the patient is seen at 2- to 3-week intervals until clinical tenderness subsides and there is radiographic evidence of fusion (FIG 2). This typically occurs by 6 to 8 weeks after surgery.
- Once healing is documented, the pins are removed and range-of-motion exercises are begun under the direction of a hand therapist. The splint is continued for protection.
- At 3 months, strengthening exercises are begun, the splint is discontinued, and the patient is allowed to return to unrestricted activities.

OUTCOMES

- The outcomes of trapeziometacarpal arthrodesis are generally good, with predictable pain relief and patient satisfaction.
- Hartigan et al\(^5\) retrospectively reviewed patients who had arthrodesis and compared them to those having trapezial excision and ligament reconstruction. At 6 to 9 months there were no significant differences in pain, function, patient satisfaction, or grip strength. The arthrodesis group had greater key pinch and three-point pinch but more difficulty with opposition and the ability to flatten the hand, all of which were statistically significant. The arthrodesis group also had a higher complication rate, most of which was attributable to nonunion. Interestingly, all patients with nonunion had improvement in their pain and were satisfied with their outcomes.
- Forseth and Stern\(^4\) compared the complication rate with Kirschner wire fixation to that with plates and screws and found similar nonunion rates (less than 10% in their small series), but there were higher rates of secondary procedures and lower patient satisfaction in the plate and screw group.
- Despite Hartigan et al’s report, which found that the ligament reconstruction and tendon interposition (LRTI) arthroplasty and arthrodesis resulted in high levels of patient satisfaction, Mureau et al\(^7\) found less subjective improvement with arthrodesis in comparison to arthroplasty and no significant differences in pinch strength. They also found a higher incidence of complications in the arthrodesis group.

COMPLICATIONS

- Complications from thumb CMC arthrodesis are generally related to nonunion or hardware problems, including malposition (screws in the trapeziotrapezoid joint), prominence and tendon irritation, and rupture.
- The patient should be made aware of the possible need for secondary procedures.

REFERENCES

DEFINITION
- Osteoarthritis, or more appropriately osteoarthrosis, is a common problem in the hand. The trapeziometacarpal joint is commonly affected, second in frequency only to the distal interphalangeal joint. Trapeziometacarpal joint osteoarthritis, however, can be much more disabling secondary to pain and weakness of grip and pinch strength.
- The surgical management of symptomatic basilar joint arthrosis varies according to the anatomy, radiographic staging, intraoperative confirmation of disease stage, and patient requirements.

ANATOMY
- The thumb carpometacarpal (CMC) joint is a biconcave joint, allowing for motion in three planes: flexion-extension, abduction-adduction, and pronation-supination.
- There are minimal constraints from an osseous standpoint, making the ligamentous structures extremely important in providing stability to the base of the thumb. A total of 16 ligaments have been described around the thumb CMC joint, 7 of which are primary stabilizers of the thumb metacarpal (TM).
- The superficial and deep anterior oblique, dorsal radial, posterior oblique, ulnar collateral, intermetacarpal, and dorsal intermetacarpal ligaments directly stabilize the TM, while the remainder serve to stabilize the trapezium, allowing for a stable foundation for the thumb to rest on (FIG 1).

PATHOGENESIS
- The pathogenesis of CMC joint arthrosis is multifactorial, involving biochemical and biomechanical influences. The synovial fluid within the joints contains cytokines that invariably play a role in cartilage degradation and decreased ability to withstand the loads generated at the joint during daily activities. Although not clearly delineated, estrogen or estrogen-related compounds probably play some protective role, which may explain the increased incidence of osteoarthritis in postmenopausal women (10 to 15:1).
- The palmar or anterior oblique ligament (AOL), or so-called beak ligament, has been shown to be the most important stabilizing ligament of the thumb. Degeneration or functional incompetence of this ligament leads to laxity, abnormal translation of the metacarpal on the trapezium, increased shear forces, and resultant abnormal wear patterns. This eburnation of the articular cartilage initially occurs along the palmar aspect of the joint. With progression of disease, osteophytes develop and eburnation progresses throughout the entire joint surface.
- Osteoarthrosis can also develop from damage and disruption of the articular cartilage. Any fracture through the metacarpal or trapezium joint surfaces yield arthrosis. Anatomic restoration of the joint surface can minimize this sequela but cannot eliminate the risk entirely. Paradoxically, however, a Bennett fracture may protect the joint from the development of osteoarthritis, assuming subluxation has been treated, by virtue of consequential unloading of the volar aspect of the joint.

FIG 1 • Carpometacarpal thumb joint.
NATURAL HISTORY

- Arthrosis of the thumb CMC joint begins along the palmar aspect of the metacarpal secondary to laxity of the AOL. As the process progresses, the entire base of the metacarpal and distal trapezium becomes involved.
- There is initial eburnation of the cartilage, which progresses to osteophyte formation. As the disease continues, the TM assumes an adducted position and the metacarpophalangeal (MCP) joint may compensate by becoming hyperextensible, resulting in varying degrees of MCP joint hyperextension.
- The disease can involve all the trapezial articulations as well as the scaphotrapezial joint.¹⁴

PATIENT HISTORY AND PHYSICAL FINDINGS

- Thumb CMC joint arthrosis often presents with pain at the base of the metacarpal. The pain may or may not be present at rest. It will be exacerbated with activities involving loading the TM base, such as turning a doorknob, twisting a lid off a jar, or turning a key.
- With advanced disease, the thumb subluxes in a dorsal direction and becomes fixed in adduction. This manifests as a prominence at the base of the thumb and decreased ability to abduct the thumb away from the palm. In an effort to compensate for this, the MCP joint will often hyperextend, creating a zig-zag deformity.
- Symptoms do not always correlate with the clinical or radiographic appearance, meaning that a patient may have advanced clinical and radiographic disease but be minimally symptomatic. Conversely, a patient may have substantial symptoms with minimal radiographic changes and no clinical deformity at rest.
- Other conditions causing pain at the base of the thumb must be eliminated, such as De Quervain disease, trigger thumb, and carpal tunnel syndrome. Although more than one condition may exist, the physical examination can usually determine the most troubled area.
- Physical examination includes the following:
  - Point tenderness assessment: With the TM adducted, the CMC joint is palpated beneath the thenars. Tenderness confirms the clinical significance of changes seen on radiographs.
  - Reproduction of symptoms on the CMC grind test confirms the CMC joint as a site disease.
  - Key pinch assessment: If dynamic collapse accompanies pinch, MCP joint fusion or capsulodesis is recommended (FIG 2).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs are the imaging modality of choice for evaluation of thumb CMC joint arthrosis. These include a pronated AP (Robert view), lateral, and a 30-degree posteroanterior stress view (FIG 3).
- Eaton and Littler have described a radiographic staging system, which is commonly used, but Tomaino et al¹⁴ have emphasized routine assessment of the scaphotrapezial joint, both radiographically and intraoperatively, to rule out scaphotrapezial arthritis—what they termed stage V disease.
  - Stage I: normal-appearing or widened joint space secondary to synovitis
  - Stage II: joint space narrowing and osteophyte formation smaller than 2 mm
  - Stage III: joint space narrowing with osteophytes larger than 2 mm
  - Stage IV: scaphotrapezial joint space involvement in addition to narrowing of the TM joint

FIG 2 • Dynamic collapse of the thumb on key pinch testing.

FIG 3 • Preoperative PA stress and lateral radiographs of the right thumb.
- Stage V: stage IV appearance with the addition of narrowing or osteophytes in the scaphotrapezoid joint
- The scaphotrapezoid joint is not specifically addressed in this system and may be difficult to assess radiographically, but it should always be assessed clinically during operative intervention because it may be a source of continued pain.

**DIFFERENTIAL DIAGNOSIS**
- De Quervain disease
- Trigger thumb or stenosing tenosynovitis
- Carpal tunnel syndrome

**NONOPERATIVE MANAGEMENT**
- Most patients with symptomatic thumb CMC joint arthrosis benefit from a trial of conservative therapy, which may include corticosteroid injection, thenar isometric strengthening exercises, and splinting.
- Although this will not eliminate the problem or alter the underlying disease process, conservative treatment often reduces symptoms, at least transiently, allowing the patient the opportunity to plan for surgical treatment at the most opportune time.
- Differential injection of steroids can also be helpful to assess how much of a patient’s symptoms are coming from the thumb CMC joint versus other areas (carpal tunnel or De Quervain disease).

**SURGICAL MANAGEMENT**
- The indications for surgical intervention for symptomatic thumb basilar joint arthrosis include pain and weakness.
- There are multiple procedures used to treat symptomatic CMC thumb arthritis, many of which have merit depending on the extent of arthritic involvement.
- Pan-trapezial involvement contraindicates the use of arthrodesis or implant arthroplasty, in particular, because of the risk of incomplete pain relief.
- Arthrodesis may be preferable in younger, high-demand patients such as laborers.
- Resection arthroplasty can be performed with ligament reconstruction or without (hematoma distraction arthroplasty).4,6
- The flexor carpi radialis (FCR) and abductor pollicis longus (APL) are most commonly used when performing “suspensionplasty.”

**Preoperative Planning**
- Consideration should be given to the age of the patient and the demands placed on the thumb.
- Dynamic collapse of the MCP joint during key pinch necessitates MCP fusion or capsulodesis.
- Intraoperative evaluation of the scaphotrapezotrapezial (STT) joint is critical to ensure adequate pain relief after surgery. Thus, hemitrapeziectomy is rarely performed once the decision to proceed with conventional resection arthroplasty is made. If retention of the proximal trapezium is elected because of the absence of STT disease, Artelon resurfacing or joint arthroplasty may be elected.
- Intraoperative assessment of the scaphotrapezial joint is recommended, and if changes exist, a 2- to 3-mm resection of the proximal trapezium is performed.4 Care is taken not to injure the capitate.
- Suspensionplasty ensures stability of the TM during pinch and grip, resisting the cantilever bending forces that will potentially lead to subluxation and proximal migration compared to trapeziectomy alone.
- Intermediate-term outcome of the hematoma distraction arthroplasty suggests that this procedure may have a role in providing excellent pain relief in well-selected patients for whom grip strength is a less important issue.4

**Positioning**
- The patient is supine and the involved hand and arm are supported by a hand table.

**Approach**
- Trapeziectomy and ligament reconstruction and suspensionplasty can be performed using the Wagner (volar) approach or a dorsal approach. I prefer the dorsal approach except when performing an Eaton ligament reconstruction, in which case a volar approach is used. I have modified my technique since performing the ligament reconstruction and tendon interposition (LRTI) arthroplasty exclusively during the first 10 years of practice.11,12
- Over the past 5 years I have performed a suspensionplasty using a distally based slip of the APL tendon, which obviates the need for a bony channel. This is a variation of other suspensionplasty techniques.7,10,12 In addition, I no longer pin the joint or interpose tissue into the space remaining after trapezial resection. The procedure is performed more expeditiously and seems to be associated with equivalent outcomes.13

**LRTI ARTHROPLASTY USING THE FCR TENDON**

**Incision and Superficial Dissection**
- A triradiate is drawn before the tourniquet is inflated to allow palpation of the radial pulse in the vicinity of the anatomic snuffbox; this typically identifies the scaphotrapezial joint.
- When a substantial shoulder sign (prominence associated with dorsal subluxation of the proximal phalanx trapezium) exists, it can be difficult to identify the TM joint. In these cases, palpation of the scaphoid tuberosity is helpful to ensure that the incision is neither too distal nor too proximal.
- The triradiate incision facilitates dissection of the radial artery off the dorsal capsule; when first extensor compartment release is planned, however, a longitudinal incision may be preferred.
- At the outset, the radial sensory nerve must be identified and small branches must not be skeletonized or divided. This may cause postoperative sensory neuritis and even transient reflex sympathetic dystrophy.
- Place blunt retractors beneath the extensor pollicis longus (EPL) in a dorsal and ulnar position and the APL radially and volarly.
The radial artery courses within this interval, and deep perforators to the dorsal capsule must be coagulated and divided so the artery can be retracted dorsally and ulnarly.

**Capsular Incision and Trapezial Excision**

- With gentle traction on the thumb, perform a longitudinal capsulotomy and obtain subperiosteal exposure of the trapezium and the base of the metacarpal (TECH FIG 1A). Extend the capsulotomy proximally so the scaphotrapezial joint is identified.
- Either retractors or tag sutures of 3-0 Vicryl can be used to retract the capsule.
- Before the trapezium is excised, use a microsagittal saw to remove a thin sliver of bone at the base of the metacarpal. This facilitates exposure of the distal extent of the trapezium and, with further traction on the thumb, provides a safer window for sectioning of the trapezium.
- Cut the trapezium into quadrants, beginning with the limb that parallels the expected course of the FCR tendon. Injury to the tendon during this portion of the procedure is unlikely if the saw is not brought completely through the trapezium.
- After making perpendicular cuts in the trapezium, place an osteotome and twist it to break apart its four quadrants. Removal of the trapezium in pieces with a rongeur is facilitated by sharp dissection of the remaining capsule, particularly volarly and around loose bodies. Avoid inordinate ripping and pulling with the rongeurs because damage to the underlying capsule can increase postoperative discomfort, particularly where it abuts the carpal tunnel.
- Remove osteophytic bone between the base of the thumb and index metacarpal so that pain does not accompany key pinch after the procedure. Identify the FCR tendon at the base of the arthroplasty space so it is not injured; remember that the trapezium may encircle the flexor carpi radialis tendon at its volar extent.
- At this portion of the procedure, I routinely have an assistant place traction on the index and long finger to allow inspection of the scaphotrapezial joint. If there is cartilage fraying or eburnation, a motorized burr or rongeur is used to remove 2 to 3 mm of proximal trapezoid so that, with axial compression applied to the index and long finger metacarpals, there is no contact between the remaining trapezoid and scaphoid (TECH FIG 1B). I do not interpose soft tissue or FCR tendon into the space. Take care not to remove bone from the capitate.

**Creation of the Bony Channel Through the Metacarpal Base**

- One centimeter distal to the squared-off base of the metacarpal, in the plane of the nail, create a bone tunnel with a motorized 3-mm burr that exits at the volar base of the metacarpal (TECH FIG 2).
- This position is selected rather than central exit point in the metacarpal base because passage of the FCR tendon volarly more closely simulates the original attachment of the beak ligament.
- Enlarge the bony channel with two curettes of increasing size, but do not make it large enough for the entire width of the leading edge of the FCR tendon. Rather, trim the full width of the FCR tendon to its tip to facilitate passage with a Carroll tendon passer. In that light, the bony channel needs to be large enough only for the Carroll tendon passer to be used.

**FCR Harvest**

- Palpate the FCR tendon at wrist level during passive flexion and extension of the wrist, where it is clearly tendinous. More proximally in the forearm the tendon becomes less discrete. This generally correlates with the proximal one third to half of the forearm. At that location make a 1.5-cm transverse incision.
- Open the fascia, maximally flex the wrist, and identify the interval between the FCR tendon and muscle. Lift it into the wound via a curved clamp and divide it. Close this wound with 5-0 nylon sutures.
- Retract the capsular flaps to protect the overlying radial artery dorsally and ulnarly. Place a curved clamp beneath the FCR tendon and pull it. This typically delivers the entire tendon into the arthroplasty space.
- Grasp the tendon at its tip and mobilize it to its insertion at the base of the index metacarpal without violating the small blood vessels that perfuse the tendon insertion itself.
- If adhesions between the FCR and the volar capsule are not released, the vector of the ligament reconstruction is based more proximally and will not closely
simulate the original vector of the beak ligament. This, in my opinion, is a potential cause of early subsidence after ligament reconstruction.

- Taper the tendon for about 2 to 3 cm so the diameter of the tip of the tendon will easily fit through the bone tunnel via the Carroll tendon passer.
- Use a 4-0 Vicryl suture on a small needle to purchase the volar capsule for subsequent stabilization of the tendon interposition.
- If there are rents in the volar capsule, this same suture can be used to repair them, but I no longer am inordinately preoccupied with repairing small tears in the volar capsule because there is little risk of the tendon interposition extruding into the carpal canal or into the base of the metacarpal.

**Stabilization of the Thumb Metacarpal (Optional) and FCR Tendon Tensioning**

- Kirschner wire placement, when elected, is one of the more tedious parts of the procedure and must be performed skillfully so that the bony channel is not violated. If the Kirschner wire inadvertently purchases the FCR tendon within the bony channel in the metacarpal, it will impair the ability to pull it tight and properly tension the new ligament.
- Usually a 0.045- or 0.054-inch wire is used. It begins obliquely at the dorsoradial aspect of the metacarpal and purchases the ulnar carpus.
- I place the thumb in the “fisted” position as if engaged in key pinch. The TM is suspended at the level of the index metacarpal. Its base should be colinear with the scaphoid articular surface and the thumb tip should rest on the index finger, neither too extended nor flexed at its base.
- Ideally, this positions the thumb intrinsic muscles optimally on the Blix curve and ensures optimal restoration of pinch strength.
- Bend the wire external to the skin and cut it.
- A hand probe or the like is used to take the FCR tendon at the base of the metacarpal and pull it proximally (TECH FIG 3).
- When pinning has been performed, it should not prevent free excursion of the FCR through the bone channel. Pull the tendon tightly as it exits the dorsum of the TM and suture it to adjacent periosteum and soft tissue with 3-0 Vicryl suture.
- If pinning is not performed, at this point, ensure that you have suspended the metacarpal at the level of the index CMC joint.
- The extensor pollicis brevis (EPB) tendon is sutured more radially and divided distally. This completes the EPB tenodesis, rendering it an abductor of the metacarpal as opposed to a potential hyperextender of the MP joint.
- Place a second suture slightly more proximal to the tenodesis suture so that the ligament reconstruction is stabilized adequately, and perform tissue interposition.

**Tissue Interposition (Optional)**

- Although Burton’s original technique continues to “resurface” the metacarpal base to minimize the chance that interposition material may extrude through the channel, this is unlikely. Studies have suggested that interposition is not a critical element of the procedure if suspension of the metacarpal has been effectively executed. Furthermore, proximal migration, short of causing scaphometacarpal impingement, appears not to affect the functional outcome.
- In a higher-demand patient, however, residual length of the FCR is available for interposition as follows. The tendon is folded into the volar aspect of the arthroplasty space to ensure that it will sink into its depth. From that point distally, the tendon is folded back and forth about four times on a single Keith needle, like ribbon candy.
- A 4-0 Vicryl suture is used to stabilize each corner of the tendon anchovy, and then a second Keith needle is placed through it, parallel to the first. Apertures in each needle should be volar, the tip of each needle dorsal, and, with the previously placed volar capsular suture, each limb is threaded and the anchovy is slid down and delivered into the arthroplasty space. The two Vicryl limbs are tied, securing the tissue interposition (TECH FIG 4).

**Capsular Repair and Wound Closure**

- Tightly repair the capsule using 3-0 Vicryl sutures. If redundant capsule is present, a pants-over-vest closure can be performed.

![TECH FIG 3](image_url) **A.** The flexor carpi radialis (FCR) is passed through bony tunnel. **B.** A hand probe indicates FCR suspensionplasty.
Chapter 83  THUMB CARPOMETACARPAL JOINT RESECTION ARTHROPLASTY

TECHNIQUES

TECH FIG 4 • The tendon anchovy held in place with Vicryl sutures.

APL SUSPENSIONPLASTY

Incision and Deep Dissection

- Make a 6-cm curvilinear incision from two finger-breadths proximal to the radial styloid process to 1 cm distal to the base of the metacarpal (TECH FIG 5A). Expose and retract the radial artery and branches of the radial sensory nerve.
- Release the first extensor compartment retinaculum as would be performed for De Quervain disease, leaving the volar attachment intact.
- At the myotendinous junction of the APL, release the ulnarnest slip of APL and free it to the level of its insertion at the metacarpal base (TECH FIG 5B).
- Expose the EPL and APL tendons—in between is the capsule of the TM joint.
- Perform a capsulotomy to expose the trapezium (TECH FIG 5C), which is resected after being cut partially into four fragments with a saw and osteotome.
  - The base of the thumb metacarpal is not squared off; not resecting a small sliver from the metacarpal base may help to preserve the intermetacarpal ligament.
  - The FCR tendon is visualized in the base of the arthroplasty space. With traction on the index and long fingers, inspect the scaphotrapezoidal joint; if it is arthritic, resect the proximal trapezoid.

Creation of the APL Suspensionplasty

- Poke the APL slip through the capsule to within the arthroplasty space. Using a right-angle clamp, pass it through a slit in the FCR tendon or around the FCR, while grabbing some local capsule as well (TECH FIG 6).
- Position the thumb so that it rests on the index finger in the fisted position—distracted so that the metacarpal base is at the level of the index CMC joint. A Kirschner wire is not placed.
